and 0.4 ml. of aminonaphtholsulfonic acid reagent, dilute to 10 ml. with water, and mix. Allow to stand 5 minutes and determine the density in the photometer whose zero is set with a blank as described above.

**CALCULATION.** *For colorimetric measurement:* Since the 5 ml. of filtrate taken represent 1 ml. of original sample, and the standard containing 0.4 mg. of P is in ten times the volume of the unknown, the calculation becomes:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{0.4}{10} \times 100$$

= mg. inorganic P per 100 ml. whole blood, plasma, or serum

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times 100$$

= mg. inorganic P per 100 ml. whole blood, plasma, or serum

The density of the standard at 660  $m\mu$  in a 1-cm. cuvette is approximately 0.500 (see Fig. 166); at 720  $m\mu$ , the peak position of the curve, the density is about 10 per cent

FIG. 166. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN FISKE-SUBBAROW PHOSPHATE METHOD.

For standards containing (a) 0.02 mg., and (b) 0.04 mg. phosphorus. Solution depth, 1 cm.

greater. Under these conditions the limit of accurate measurement corresponds to an inorganic phosphate content of approximately 7 to 8 mg. per cent, and this range is proportionately reduced with photometric measurement at greater depth of solution. To permit the covering of a greater range of phosphate concentration, the amount of sample taken for protein precipitation may be decreased, e.g., 1 ml. (or 0.5 ml.) of whole blood, serum, or plasma is treated with 10 per cent trichloroacetic acid at a final volume of 10 ml., and 5 ml. of filtrate taken for analysis as described. If this is done, the calculation is the same except that the final result is multiplied by 2 (or 4, if 0.5 ml. of sample was taken). The color obtained in this procedure shows little change between 5 and 20 minutes after adding the aminonaphtholsulfonic acid reagent, and the agreement with Beer's law is excellent, permitting calculation of results in terms of the density of a simultaneously prepared standard and eliminating the necessity for a calibration curve.

**Interpretation.** The normal inorganic phosphorus content of the blood plasma or serum is about 5 mg. per 100 ml. in infants and children and 3.7 mg. in the adult. In severe nephritis inorganic phosphorus may

rise 15 to 20 mg. and may bear a relation to the acidosis found in such cases. Clinically, the most important changes are those in rickets. In the rickets of children or in experimental rickets produced in animals by low-phosphorus diets the inorganic phosphorus of the blood may fall to 2 mg. or lower. Treatment with antirachitic vitamin or ultraviolet radiation increases the phosphorus of the blood and leads to recalcification of the rachitic lesions. Occasionally rickets may be accompanied by high inorganic phosphorus of the blood, and the tendency of irradiated ergosterol to restore normal phosphorus values may be independent of its calcifying activity. During the healing period following fracture of a bone, an increase in plasma phosphates is sometimes observed. The phosphate level of the plasma of children rises during the summer and falls during the winter. Rickets has its greatest incidence during the late winter, reaching its peak in March. These findings may be correlated with the degree of exposure to solar ultraviolet rays. Injections of insulin decrease the phosphate of the plasma.

**2. Determination of Total Acid-soluble Phosphorus: Principle.** The organic matter in an aliquot of a trichloroacetic acid filtrate is destroyed by digestion with sulfuric acid and subsequent oxidation with 30 per cent hydrogen peroxide. The phosphate-containing solution is then analyzed for phosphate by the method of Fiske and SubbaRow.

**Procedure.**<sup>219</sup> Prepare a trichloroacetic acid filtrate of whole blood, plasma, or serum as described for the determination of inorganic phosphate. Transfer 2 ml. of this filtrate to a test tube, 200 by 25 mm., and add 2.5 ml. of 5 N sulfuric acid and a quartz chip to minimize bumping. Place in a slanting position over a microburner, with the burner tip about 2 cm. below the bottom of the tube, or suspend in a wire basket about 1.5 inches above an electric hot plate. After evaporation is complete and the mixture turns brown or black with no further change, remove the tube, cool slightly, and add 1 drop of 30 per cent hydrogen peroxide, allowing the drop to fall directly into the digestion mixture. Replace the tube and continue heating. The contents of the tube should become colorless; if not, repeat the addition of hydrogen peroxide and heating. When colorless, cool the tube, add a few ml. of water, and heat to boiling momentarily. Cool again and transfer the contents of the tube to a 25-ml. volumetric flask, with washings until the flask is about half full. Add 2.5 ml. of 2.5 per cent ammonium molybdate solution, followed by 1 ml. of aminonaphtholsulfonic acid reagent. Dilute with water to the 25-ml. mark and mix. Allow to stand 5 minutes, then read in the colorimeter or photometer.

---

<sup>219</sup> Reagents Required: 10 Per Cent Trichloroacetic Acid Solution, Molybdate I Solution, Aminonaphtholsulfonic Acid Reagent, and Standard Phosphate Solution as described for the determination of Inorganic Phosphate (p. 631), and in addition:

**5 N Sulfuric Acid.** Fill a 250-ml. volumetric flask to the mark with 10 N sulfuric acid solution (see p. 631). Pour the contents of the flask into a 500-ml. volumetric flask, with rinsings, and dilute to the mark with water. Mix. Stable indefinitely.

**2.5 Per Cent Ammonium Molybdate Solution.** Dissolve 2.5 g. of reagent-grade ammonium molybdate in water, transfer to a 100-ml. volumetric flask, fill to the mark, and mix. As soon as any appreciable amount of sediment forms in this solution, it should be discarded.

**30 Per Cent Hydrogen Peroxide.** Only the highest purity, essentially phosphate-free material may be used. The products of Merck and of J. T. Baker are known to be satisfactory. *This reagent is extremely corrosive to the skin and must be handled carefully. Keep in the cold, and use a medicine dropper for dispensing.*

For colorimetric measurement, compare against a standard prepared as described above for the determination of blood inorganic phosphate. For photometric measurement, the most accurate procedure is to run a digested blank and a digested standard along with each series of unknowns. This corrects for any phosphate or other factors in the reagents which may affect the final results. Digested blank: 2 ml. of 10 per cent trichloroacetic acid, treated with sulfuric acid, evaporated, oxidized with hydrogen peroxide, and color reagents added, exactly as described for the unknown. Digested standard: 1 ml. of standard phosphate solution, containing 0.08 mg. of phosphorus, plus 2 ml. of 10 per cent trichloroacetic acid, treated with sulfuric acid, evaporated, oxidized with hydrogen peroxide, and color developed, exactly as described for the unknown. The color of the digested blank and standard is developed at a final volume of 25 ml., as with the unknown. Set the photometer to zero density with the blank, and determine the densities of the standard and the unknown, using the same wavelength as specified for the determination of inorganic phosphate on p. 632.

CALCULATION. *For colorimetric measurement:* Since the standard contains 0.4 mg. of P in a final volume of colored solution four times that of the unknown, and the 2 ml. of unknown filtrate represent 0.4 ml. of original sample, the calculation is as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{0.4}{4} \times \frac{1}{0.4} \times 100 = \text{mg. total acid-soluble phosphorus per 100 ml. blood, plasma, or serum}$$

If the reagents, particularly the trichloroacetic acid and the hydrogen peroxide, contain significant amounts of phosphorus, the quantity present must be established by a blank digestion and analysis and suitable corrections made.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.08 \times \frac{1}{0.4} \times 100 = \text{mg. total acid-soluble phosphorus per 100 ml. blood, plasma, or serum}$$

The conditions for photometric measurement have been presented in connection with the determination of inorganic phosphate.

**Interpretation.** The acid-soluble phosphorus content of normal blood is approximately 25 to 30 mg. per 100 ml. of whole blood. The total acid-soluble phosphorus includes the inorganic phosphate as well as those organic phosphate esters which are not present as lipide or nucleoprotein material. Such esters include hexosephosphate, diphosphoglyceric acid,<sup>220</sup> certain free nucleotides, and other compounds which have not been characterized. In the plasma, the total acid-soluble phosphorus is represented largely by inorganic phosphate. In the cells, the reverse is true, ester phosphate being relatively much more abundant; thus interpretation of total acid-soluble phosphorus values for whole blood must include a consideration of the relative volume of cells to plasma. There is some evidence that the acid-soluble phosphorus of blood is of significance in acid-base balance in the body, since it is found to be considerably depleted during experimental acidosis.

### 3. Determination of Lipide Phosphorus. See p. 589.

<sup>220</sup> Greenwald: *J. Biol. Chem.*, **63**, 339 (1925).

4. **Determination of Total Phosphorus.** Dilute 1 ml. of blood, plasma, or serum to 10 ml. with 0.9 per cent sodium chloride solution and mix. Transfer 2 ml. of this diluted solution to a 200 × 25 mm. test tube, add 2.5 ml. of 5 N sulfuric acid and a quartz chip, and heat over a microburner or electric hot plate as described for the determination of acid-soluble phosphorus on p. 633. Foaming may be minimized by blowing clean compressed air into the digestion tube through a fine-tipped glass tube. When the water has been driven off and the contents of the tube turn black, continue with the digestion, oxidation, color development, and measurement as described for the determination of acid-soluble phosphorus. Calculation of results is the same except that since the 2 ml. of sample taken for analysis represent 0.2 ml. of original sample instead of 0.4 ml. as in the determination of acid-soluble phosphorus, results are multiplied by 2 to give the total phosphorus, in mg. per 100 ml.

**Determination of Phosphorus in Tissues and Other Biological Material.** The colorimetric method described above may be used for tissues and other biological material. Dry-ashing may sometimes be necessary. If little organic matter is present, ignition with a small amount of sodium carbonate will suffice. In other cases magnesium nitrate (1 ml. of 10 per cent) is satisfactory. For tissues, carbonate-nitrate fusion mixtures are perhaps best. Porcelain dishes may generally be used, but blanks should be run on them. Some silica will not interfere. If platinum is used, dissolve most of the ash with water before adding acid to remove the last of the material, since nitrous acid attacks platinum. Evaporate the total solution to dryness in a beaker or porcelain dish (covered with a watch glass as long as carbon dioxide is evolved). Dissolve the residue in water, make to volume, and determine as usual.

## DETERMINATION OF SERUM PHOSPHATASE ACTIVITY

**Introduction.** Normal blood serum contains several enzymes or groups of enzymes which catalyze the liberation of inorganic phosphate from phosphate esters such as glycerophosphate, phenylphosphate, etc. The most active phosphatase, and the one longest recognized, has an optimum pH of approximately 9, and is now known as "alkaline" phosphatase to distinguish it from a second or "acid" phosphatase which is of limited activity in normal serum but whose activity is of significance in certain pathological conditions and which has an optimum pH of approximately 5. Neither type of enzyme has any significant activity at the optimum pH of the other, although both are active at the pH of normal blood. The enzymatic activity of serum or plasma with respect to either or both enzymes is established in terms of the rate of hydrolysis of suitable phosphate ester substrates buffered to the proper pH.

Various methods have been proposed for the determination of phosphatase activity of serum. For "alkaline" phosphatase, the method of Bodansky<sup>221</sup> has perhaps found the widest application. In this method, the phosphate liberated on incubation of serum with buffered glycerophosphate at pH 8.6 is used as an index of phosphatase activity, one Bodansky

<sup>221</sup> Bodansky: *J. Biol. Chem.*, **99**, 197 (1932); **101**, 93 (1933). This method is described in the eleventh edition of this book.

unit corresponding to the liberation of 1 mg. of inorganic phosphate per 100 ml. of serum during a one-hour period of incubation under these conditions. In the Bodansky method, the liberated phosphate is determined with stannous chloride as reducing agent, and various corrections for the influence of protein precipitant and substrate on the phosphate determination are necessary; these have been established by the author. Shinowara, Jones, and Reinhart<sup>222</sup> claim that these correction factors become unnecessary under the proper conditions and likewise feel that "alkaline" phosphatase activity should be determined at pH 9.3, the optimum pH for this enzyme. They have described procedures for the determination of inorganic phosphate, "alkaline" phosphatase, and "acid" phosphatase on as little as 0.06 ml. of serum. King and Armstrong<sup>223</sup> proposed the determination of "alkaline" phosphatase activity in terms of the phenol liberated on incubation with buffered phenylphosphate, and Gutman and Gutman<sup>224</sup> have applied this procedure to the determination of "acid" phosphatase. A disadvantage of the King and Armstrong procedure is that the serum inorganic phosphate content, which is usually of importance along with phosphatase activity, must be determined separately with an entirely different set of reagents. In the procedures described here, the incubation procedure of the Bodansky method is used for "alkaline" phosphatase determination, with modification to permit the use of the method of Fiske and SubbaRow (see p. 630) for the determination of phosphate liberated; for "acid" phosphatase, the conditions prescribed by Shinowara, Jones, and Reinhart are followed, likewise modified to permit the use of the Fiske and SubbaRow phosphate method.

### 1. Determination of "Alkaline" Phosphatase.<sup>225</sup>

**Procedure.** Collect about 5 ml. of whole blood in a centrifuge tube, allow to clot at room temperature, remove clot, then centrifuge (twice if necessary). The separated serum may be kept for several hours in the refrigerator, or for several days if frozen.

<sup>222</sup> Shinowara, Jones, and Reinhart: *J. Biol. Chem.*, **142**, 921 (1942).

<sup>223</sup> King and Armstrong: *Can. Med. Assoc. J.*, **31**, 376 (1934).

<sup>224</sup> Gutman and Gutman: *J. Biol. Chem.*, **136**, 201 (1940).

<sup>225</sup> Reagents Required: "Alkaline Phosphate" Substrate. Into a 100-ml. volumetric flask introduce successively 3 ml. of petroleum ether (B.P. 20° to 40° C., J. T. Baker Analyzed Special), about 80 ml. of distilled water, 0.5 g. of sodium  $\beta$ -glycerophosphate (Eastman), 0.424 g. of sodium diethyl barbiturate (Merck), and water to volume (read at interface between petroleum ether and aqueous solution). Empty (out of doors) into a 100-ml. glass stoppered pyrex bottle containing an inch layer of petroleum ether. Keep in the refrigerator. When multiples of 100 ml. are prepared, it is advisable to distribute the substrate into small bottles.

**30 Per Cent Trichloroacetic Acid.** Dissolve 30 g. of reagent-grade trichloroacetic acid in water and dilute to 100 ml. Stable indefinitely. To prepare a 10 per cent solution from this, dilute 1 volume with 2 volumes of water. To prepare a 5 per cent solution, dilute 1 volume with 5 volumes of water.

**Standard Phosphate Solution.** Place 6.25 ml. of the standard phosphate solution used for the determination of inorganic phosphate (see p. 631), containing 0.5 mg. of phosphorus, in a 100-ml. volumetric flask. Add 16.7 ml. of 30 per cent trichloroacetic acid solution, dilute to 100 ml. with water, and mix. This solution contains 0.04 mg. of phosphorus in 8 ml., in 5 per cent trichloroacetic acid. It should be stable indefinitely if stored in the cold.

**Molybdate II, Aminonaphtholsulfonic Acid Reagent.** See p. 631.

(a) **INCUBATED SAMPLE.** Measure 9 ml. of "alkaline phosphate" substrate into a glass-stoppered cylinder<sup>226</sup> and place in an incubator or water bath at 37° C. until the fluid reaches incubator temperature. Add 1 ml. of serum, mix, note the time, and incubate for exactly 1 hour. Remove, cool in ice water for several minutes, and add 2 ml. of 30 per cent trichloroacetic acid. Mix, let stand a few minutes, and filter through a low-ash filter paper.

(b) **CONTROL SAMPLE.** At or near the end of the incubation period, prepare a control sample as follows: Measure 9 ml. of substrate into a glass-stoppered cylinder and add 2 ml. of 30 per cent trichloroacetic acid. With mixing add 1 ml. of serum, stopper, shake, and filter as above.

When both filtrates are ready, transfer 8 ml. of each to cylinders or test tubes graduated at 10 ml. In a third similar container place 8 ml. of standard phosphate solution, containing 0.04 mg. of phosphorus. For photometric measurement, a fourth or blank tube is necessary. This contains 8 ml. of 5 per cent trichloroacetic acid alone. When all the tubes are ready, add to each 1 ml. of Molybdate II reagent, and mix. Add 0.4 ml. of aminonaphthol-sulfonic acid reagent to each, dilute immediately to 10 ml. with water, and mix. Allow to stand 5 minutes for color development.

**CALCULATION.** For colorimetric measurement, compare both control and incubated unknowns against the standard. Since the 8 ml. of filtrate represent two-thirds of the total sample, the calculation is as follows:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.04 \times \frac{3}{2} \times 100 = \text{mg. inorganic phosphate per 100 ml. serum (control or incubated)}$$

For photometric measurement, read the unknowns and standard in a photometer which is set to zero density with the blank, using the same conditions as for the determination of inorganic phosphate described on p. 631. The calculation is as follows:

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.04 \times \frac{3}{2} \times 100 = \text{mg. inorganic phosphate per 100 ml. serum (control or incubated)}$$

The *phosphatase activity* is the difference between the inorganic phosphate content of the incubated and control samples, expressed in mg. of phosphorus per 100 ml. Thus, if the control result is 4.0 mg. per cent, and the incubated result is 8.5 mg. per cent, the phosphatase activity is  $8.5 - 4.0 = 4.5$  Bodansky units per 100 ml. serum.

In colorimetric measurement, with the standard set at 20 mm., the control tube usually reads approximately 30 mm., and a phosphatase activity up to about 8 units may be accurately determined. In photometric measurement in a 1-cm. cuvette, the limit is about 12 units. For activities greater than this, the phosphate analysis is repeated on a smaller portion of filtrate from the incubated serum, making up to 8 ml. volume with 5 per cent trichloroacetic acid, and correcting the calculations accordingly. If the liberated phosphate is 60 mg. per cent or higher, inhibition of hydrolysis occurs and the incubation is repeated with the time shortened to 30 or 15 minutes, in which case results are multiplied by 1.8 or 3.3 respectively. The result on the control sample is essentially an analysis for serum inorganic phosphate, but includes any effect of glycerophosphate on color development. This effect is frequently very low or negligible, in which case the results on the control serum may be accepted as the measure of the serum inorganic phosphate, and reported as such along with the phosphatase values.

**Interpretation.** The serum "alkaline" phosphatase activity in normal adults ranges from 1.5 to 4.0 units per 100 ml. (average 2.7) and in normal

<sup>226</sup> Ordinary test tubes and clean rubber stoppers may be used.

children 5 to 12 units (average 8.0). These values are greatly exceeded in polyostotic Paget's disease (up to 50 times), rickets (up to 20 times), hyperparathyroidism (10 times). Smaller increases are observed in a number of other diseases of osseous origin. High serum phosphatase is a manifestation of processes that cause rapid growth of bone in the normal young, of new bone (repair), and of calcified and uncalcified pathological bone. Among nonosseous conditions in which increased phosphatase activity is observed are acute catarrhal jaundice and other cases of liver involvement. Under certain conditions the serum phosphatase activity may be used in the differential diagnosis of liver disease.

**2. Determination of "Acid" Phosphatase.**<sup>227</sup> The procedure is exactly the same as for "alkaline" phosphatase, except that the buffered "acid phosphate" substrate of Shinowara, Jones, and Reinhart is used for the incubation and for the control sample. Calculation of results is the same as for "alkaline" phosphatase, the unit of "acid" phosphatase activity being defined as equivalent to the liberation of 1 mg. per cent of inorganic phosphate during 1 hour incubation at pH 5.0.

**Interpretation.** In terms of the unit above defined, normal serum contains from 0.0 to 1.1 units of acid phosphatase activity, with no significant elevation observed except in cases of carcinoma of the prostate with metastases, when values as high as 30 units or more have been observed. It should be pointed out here that the King and Armstrong unit as used by Gutman and Gutman<sup>224</sup> is defined in terms of the liberation of 1 mg. per cent of phenol, and is approximately double the value of the phosphate unit here described. Results by the method described here will therefore tend to be about half as high as those obtained by the use of phenylphosphate as substrate.

## DETERMINATION OF CHOLINESTERASE ACTIVITY

**Introduction.** Enzymes which catalyze the hydrolysis of acetylcholine are known as cholinesterases and are found in both the red cells and the plasma of the blood, as well as in most other body tissues. They are particularly active in nervous tissue, as discussed on p. 297. Available evidence indicates that cholinesterase is not a single enzyme but rather a name for a group of enzymes which can be further characterized as *true cholinesterase* and *pseudocholinesterase* in terms of tissue location, physiological function, and substrate specificity. The red blood cell enzyme is considered to be a true cholinesterase, as is the brain enzyme, since it is found that these enzymes act more rapidly on acetylcholine than on other choline esters such as butyrylcholine and benzoylcholine. The

---

<sup>227</sup> Reagents Required: "Acid Phosphate" Substrate. This is identical with the "alkaline phosphate" substrate already described except that sufficient acetic acid is incorporated to bring the pH to 5.0. Into a 100-ml. volumetric flask introduce successively 3 ml. of petroleum ether, about 80 ml. of water, 0.5 g. of sodium  $\beta$ -glycerophosphate, 0.424 g. of sodium diethylbarbiturate, and 5 ml. of 1 N acetic acid. Dissolve by mixing, and add water to bring the aqueous meniscus to the 100-ml. mark. Keep in the refrigerator. The pH of the final solution should be checked and, if it is not 5.0, adjusted to that value by the addition of dilute acid or alkali as necessary.

Other reagents required are those described for the determination of "alkaline" phosphatase, with the exception of the substrate.

plasma enzyme is a pseudocholinesterase in the sense that it will act rapidly not only on acetylcholine but also on a variety of other esters. Since the red cell and plasma enzymes differ in physiological function (see discussion below) as well as in substrate specificity, determination of whole-blood cholinesterase activity is relatively meaningless, the analysis being carried out on the separated red cells or plasma as required.

Estimation of cholinesterase activity is based on measurement of the rate of hydrolysis of the substrate (usually acetylcholine) under specified conditions. When acetylcholine is hydrolyzed, acetic acid is formed, and measurement of rate of enzyme action is conveniently made in terms of rate of acid production. The standard method for measuring cholinesterase activity is that of Ammon,<sup>228</sup> based upon the use of the Warburg apparatus (see p. 334), for the manometric measurement of CO<sub>2</sub> liberated from bicarbonate by the enzymatic production of acid. A variety of simpler methods based upon acid production have been described, of which the method of Michel,<sup>229</sup> described here, is believed to be one of the most satisfactory. A colorimetric procedure based upon the determination of acetylcholine present before and after treatment with the enzyme has been described by Hestrin.<sup>230</sup> It is not always possible to compare cholinesterase activities obtained by various methods because of the sensitivity of the enzyme to temperature, pH, and particularly substrate concentration, and these conditions are rarely the same from one method to another.

**Method of Michel:**<sup>229</sup> **Principle.** The enzyme in an aliquot of diluted plasma or red cell hemolyzate is allowed to act on acetylcholine in a standard buffer solution for a measured time (usually 1–2 hours). The pH of the mixture is measured at the beginning and at the end of this time. The action of the enzyme on the substrate produces acid which lowers the pH of the mixture; the rate of change in pH is therefore a measure of enzymatic activity.

**Procedure.**<sup>231</sup> (a) SEPARATION OF RED CELLS AND PLASMA. Place approximately 5 ml. of freshly drawn blood, heparinized to prevent clotting, in a graduated centrifuge tube and centrifuge at 2,000 r.p.m. for 15 minutes. Remove the

<sup>228</sup> Ammon: *Arch. f. d. ges. Physiol.*, **233**, 57 (1933).

<sup>229</sup> Michel: *J. Lab. Clin. Med.*, **34**, 1564 (1949).

<sup>230</sup> Hestrin: *J. Biol. Chem.*, **180**, 249 (1949).

<sup>231</sup> Reagents Required: *Buffer Solution I (for Red Cells)*. Dissolve 4.12 g. sodium barbital, 0.54 g. KH<sub>2</sub>PO<sub>4</sub>, and 44.7 g. KCl in about 900 ml. of distilled water. Add 28.0 ml. 0.1 N hydrochloric acid solution with mixing, dilute to 1 liter, and mix. Check the pH, which should be 8.10 at 25° C.; if necessary, adjust to the proper pH by the careful further addition of 0.1 N acid or alkali as required. Add a few drops of toluene and keep in the refrigerator.

*Buffer Solution II (for Plasma)*. Dissolve 1.24 g. sodium barbital, 0.17 g. KH<sub>2</sub>PO<sub>4</sub> and 17.54 g. NaCl in about 900 ml. distilled water. Add 11.6 ml. 0.1 N hydrochloric acid with mixing, dilute to 1 liter, and mix. The pH should be 8.00 at 25° C.; if not, adjust as described above. Preserve with toluene and keep in the refrigerator.

*Acetylcholine Substrate (0.11 M) for Red Cells*. Dissolve 2.00 g. of high-grade acetylcholine chloride in 100 ml. of distilled water. Add toluene as preservative and keep in the refrigerator.

*Acetylcholine Substrate (0.165 M) for Plasma*. Dissolve 3.00 g. acetylcholine chloride in 100 ml. of distilled water. Preserve with toluene and store in the cold.

*Saponin Solution*. 0.01 per cent saponin in distilled water.

Both Buffer Solution I and Buffer Solution II show a slow decrease in pH and buffer capacity after standing for several weeks, and should be checked with a pH meter before use. If the pH<sub>1</sub> reading in a determination is more than 0.03 pH units below 8.00, a fresh

supernatant plasma with a capillary pipet and set it aside if desired for analysis as described under (c) below. Add 2 to 3 volumes of 0.9 per cent NaCl solution to the red cells, mix well, and again centrifuge for 15 minutes. Discard the supernatant saline and repeat the washing procedure, this time centrifuging for 20 minutes. Note the volume of packed red cells, and remove the supernatant saline to a point where the volume of cells and saline is twice the volume of cells alone. Mix the cells well in the remaining saline, thus obtaining a 1:1 dilution of the washed cell suspension in saline. Transfer 0.4 ml. of this cell suspension to a test tube containing 9.6 ml. of 0.01 per cent saponin solution. This hemolyzed red cell solution, of which 1 ml. represents 0.02 ml. of red cells, is used for the procedure described under (b).

(b) MEASUREMENT OF RED CELL ACTIVITY. Transfer 1 ml. of hemolyzed red cell solution, prepared as described above, to a small beaker<sup>232</sup> containing 1 ml. of Buffer Solution I. Mix and place the beaker in a water bath at 25° C. for 10 minutes, for temperature equilibration. Measure the pH of the mixture, using a pH meter and reading to the nearest 0.01 unit. Return the beaker to the thermostat. Note the time, and add 0.2 ml. of 0.11 M acetylcholine solution with rapid mixing. Allow the beaker to stand in the thermostat for 1 to 1½ hours. Again measure the pH and note the time. Calculate results as described below.

(c) MEASUREMENT OF PLASMA ACTIVITY. Dilute 0.2 ml. of plasma to 10 ml. with water, and mix. Transfer 1 ml. of this diluted plasma to a small beaker containing 1 ml. of Buffer Solution II. Place in a thermostatically regulated water bath at 25° C. for 10 minutes; then measure the pH as described under (b) above. Note the time; then add 0.2 ml. of 0.165 M acetylcholine solution with rapid mixing. Carry out the subsequent steps as described under (b) above.

CALCULATION. The cholinesterase activity of the sample in units of ΔpH per hour is calculated as follows:

$$\Delta\text{pH/hr.} = \left( \frac{\text{pH}_1 - \text{pH}_2 - b}{t} \right) f$$

where pH<sub>1</sub> and pH<sub>2</sub> are the initial and final pH readings respectively, *t* is the time in hours between the mixing with acetylcholine and the time of reading pH<sub>2</sub>, and *b* and *f* are correction factors obtained from the following table, *b* being a correction for non-enzymatic hydrolysis of substrate, and *f* correcting for the effect of pH change on enzyme activity relative to buffer capacity.

The results obtained by the procedure described here represent the cholinesterase activity for 0.02 ml. of red cells or plasma, expressed in units of ΔpH per hour. If the activity per ml. of red cells or plasma is desired, multiply the results by 50. To express results in terms of per cent activity relative to some normal or previous value on the same individual, multiply the ΔpH/hour value found by 100 and divide by the normal or previous ΔpH/hour value. For example, Michel found the mean normal ΔpH/hour value for red cell cholinesterase activity in 12 subjects to be 0.753. If an unknown sample gave a value of 0.550, then the activity in terms of *per cent of normal* would be 0.550/0.753 × 100, or 73 per cent.

---

buffer solution should be prepared. Pure acetylcholine chloride solutions will produce a pH change of less than 0.01 pH units when added to Buffer I or Buffer II in the proportions specified in the text and in the absence of enzyme. Any greater change indicates decomposition of the solution, and a fresh solution should be prepared.

<sup>232</sup> Beakers which are supplied with most commercial pH meters for determining pH on small volumes (2–5 ml.) of solution are very satisfactory. It is necessary to shake the beaker containing the reaction mixture for a few seconds after immersing the electrodes in order to obtain rapid equilibrium.

## CORRECTION FACTORS FOR CHOLINESTERASE DETERMINATION

| pH <sub>2</sub> | <i>Red Cell Cholinesterase</i> |          | <i>Plasma Cholinesterase</i> |          |
|-----------------|--------------------------------|----------|------------------------------|----------|

**Interpretation.** In a series of 12 normal adult males, Michel found a mean value of 0.703  $\Delta$ pH per hour units for plasma and a value of 0.753 for red cells, by the method described here. Studies by a variety of methods on the red cell and plasma enzyme activities of normal adults have shown that there is no sharply defined level of cholinesterase activity which may be called "normal"; though the enzymatic activity of the blood of a particular individual does not vary significantly during health, wide variations exist between individuals in a normal group. The method is therefore more satisfactory when used for following changes in cholinesterase activity within a particular individual than for establishing whether enzymatic activity is normal or abnormal. The factors determining the maintenance of cholinesterase activity are not too clearly understood, particularly with regard to the red cell enzyme. The plasma enzyme appears to be similar to the other plasma proteins which originate in the liver, since it decreases during liver disease and returns to normal levels on recovery. Low plasma levels have also been reported in malnutrition<sup>233</sup> and pernicious anemia.<sup>234</sup> The most striking lowering of both plasma and red cell enzyme is found after treatment with the anticholinesterase drugs (DFP, physostigmine, neostigmine, etc.; see p. 298) and after exposure to certain organic insecticides such as Parathion and Schradan. Determination of blood cholinesterase levels is of significant diagnostic value in these conditions.

## DETERMINATION OF SULFUR

**Introduction.** Of the total sulfur of whole blood, a portion is present as the inorganic sulfate ion, another portion is in the form of various nonprotein organic compounds which may be present (glutathione,

<sup>233</sup> McCance: *Proc. Roy. Soc. Med.*, **43**, 272 (1950). See however Saunders *et al.*: *J. Nutrition*, **47**, 191 (1952).

<sup>234</sup> Cline, Johnson. and Johnson: *Southern Med. J.*, **41**, 374 (1948).

ergothioneine, etc.), most of which are found chiefly in the red cells, and the remainder is represented by the sulfur-containing amino acids of the proteins present. In the analysis of serum or plasma, inorganic sulfate is ordinarily determined by isolation as the benzidine salt, followed by colorimetric<sup>235</sup> or titrimetric<sup>236</sup> estimation of the benzidine component. Nephelometric<sup>237</sup> and gasometric<sup>238</sup> methods for inorganic sulfate have also been described. Ethereal or conjugated sulfate (i.e., the increment in inorganic sulfate produced by acid hydrolysis of the protein-free sample) appears to be present, if at all, in such small amount in human plasma as to come within the limits of error in the two analyses necessary for its estimation. Significant values may be found for the plasma of species other than man. Total sulfur is determined by complete oxidation of organic matter, followed by estimation of inorganic sulfate present.

**1. Determination of Inorganic Sulfate in Serum (Method of Letonoff and Reinhold):**<sup>239</sup> **Principle.** Serum is deproteinized with uranium acetate. The sulfate in the filtrate is precipitated as benzidine sulfate, then washed, dissolved, and determined colorimetrically after treatment with sodium  $\beta$ -naphthoquinone-4-sulfonate.

**Procedure.** Six ml. of 0.4 per cent uranium acetate solution are measured into a 15-ml. centrifuge tube, 2 ml. of nonhemolyzed serum are added slowly, and, after mixing by inverting four times, the mixture is centrifuged for 10 minutes. Four ml. of clear centrifugate are measured into another centrifuge tube (selected so that the tip will retain precipitates). One ml. of glacial acetic acid and 9 ml. of benzidine solution<sup>240</sup> are added. The tube is capped, placed in ice water for at least  $\frac{1}{2}$  hour, then centrifuged for 15 minutes at 3000 r.p.m. The supernatant fluid is decanted and discarded, and the tube permitted to drain in an inverted position for 3 minutes. Fourteen ml. of acetone are added. The precipitate is suspended in the acetone, then again centrifuged for 15 minutes at high speed. The acetone is decanted and the tube allowed to drain 5 minutes. After the mouth of the tube has been wiped, 1 ml. of a 1 per cent solution of sodium borate in 0.1 N sodium hydroxide is added and the precipitate dissolved by stirring. (The tube may be placed in warm water at 60° C. if solution is slow.) Finally, 10 ml. of water and 1 ml. of the color reagent<sup>241</sup> are added. The solutions are mixed and allowed to stand 5 minutes, then 2 ml. of acetone are added. At the same time, 2 standards are prepared by measuring 2 and 5 ml. of benzidine hydrochloride solu-

<sup>235</sup> For a colorimetric method different from the one described in the text, see Cuthbertson and Tompsett: *Biochem. J.*, **25**, 1237 (1931); Pirie: *Biochem. J.*, **28**, 1063 (1934).

<sup>236</sup> Power and Wakefield: *J. Biol. Chem.*, **123**, 665 (1938).

<sup>237</sup> Denis and Reed: *J. Biol. Chem.*, **71**, 191 (1926).

<sup>238</sup> Van Slyke, Hiller, and Berthelsen: *J. Biol. Chem.*, **74**, 659 (1927).

<sup>239</sup> Letonoff and Reinhold: *J. Biol. Chem.*, **114**, 147 (1936). This method is said to give lower results than other methods because of the absence of the hydrolytic effect of acid protein precipitants.

<sup>240</sup> One per cent benzidine in acetone, filtered and stored in a brown bottle in the refrigerator. It should be discarded when it becomes highly colored.

<sup>241</sup> *Color Reagent.* Dissolve 0.15 g. of pure sodium  $\beta$ -naphthoquinone-4-sulfonate in 100 ml. of distilled water. The solution will keep about 2 weeks in the cold. Each sample of this reagent should be tested by treating 2 ml. and 4 ml. of the working standard solution of benzidine hydrochloride with the color reagent, borate, water, and acetone as described below. Acceptable preparations do not deviate from the theoretical Beer's law relationship by more than 5 per cent.

tion<sup>242</sup> into 2 test tubes. One ml. of borate solution is added to each, followed by 8 ml. and 5 ml. of water respectively. One ml. of color reagent is added and the development of color carried out as described. The unknown solutions are compared with standards in the colorimeter.

CALCULATION. When *colorimetric* comparison is made with the 2-ml. benzidine standard:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{1} = \text{mg. sulfate sulfur per 100 ml. serum}$$

For the stronger standard, replace 0.02 in the above equation by 0.05.

Precise *photometric* data for this color are not available. Since the reagent and reaction resemble that for the amino-acid determination (p. 565), satisfactory photometric measurement should be possible at 490 m $\mu$ , against a blank prepared by treating 10 ml. of water with 1 ml. of borate, 1 ml. of color reagent, and 2 ml. of acetone.

**Interpretation.** Normal human blood serum contains approximately 1 mg. of inorganic sulfate (as S) per 100 ml. In nephritis with retention, the inorganic sulfate values are increased. High values have also been reported in pyloric or intestinal obstruction, in leukemia, and in diabetes.

**2. Determination of Total Sulfur in Biological Material (Method of Stockholm and Koch):**<sup>243</sup> *Principle.* The complete oxidation of biological material for the sulfur determination is often a difficult procedure. The following method in which strong hydrogen peroxide and nitric acid are used is believed to be the most effective.

*Procedure.* Into a 100-ml. nickel crucible (50  $\times$  70 mm.) containing 10 ml. of 25 per cent sodium hydroxide solution, introduce 0.5 to 2.0 g. of the substance. The covered crucible is then heated on the steam bath until the mass is almost dry. This requires several hours, but causes considerable decomposition of the complex substances present, so that the sulfur in particular can later be easily oxidized. In case the evaporation has proceeded too rapidly, it is best to add again 10 ml. of water and to repeat the slow evaporation. To the slightly moist material 5 ml. of 30 per cent H<sub>2</sub>O<sub>2</sub><sup>244</sup> are added very gradually. In some cases it is necessary to stir the mass with a glass rod or to add a few drops of water so as to distribute the reagent properly. During this treatment the heating is continued on the steam bath.

The material thus partially oxidized is next transferred to a 300-ml. Kjeldahl flask, acidified with nitric acid, and concentrated over a free flame until salts begin to separate. This concentrated solution is then oxidized, while boiling,

<sup>242</sup> *Standard Benzidine Hydrochloride Solution.* 0.1606 g. of benzidine hydrochloride, purified as described below, is transferred to a 200-ml. volumetric flask, dissolved in water previously warmed to about 50° C., cooled, and diluted to volume. The solution should be stored in the cold. Ten ml. are equivalent to 1.0 mg. of sulfur. For a working standard, 10 ml. of this solution are diluted to 100 ml. with water. One ml. contains benzidine equivalent to 0.01 mg. of sulfur. The solution should be stored in the cold.

The benzidine hydrochloride is purified as follows: 5 g. of benzidine hydrochloride are dissolved in 200 ml. of 5 per cent hydrochloric acid by warming to about 50° C. Any insoluble residue is filtered. Twenty ml. of concentrated hydrochloric acid are added with continuous stirring. The solution is cooled in ice water for about 30 minutes, when the crystals that have formed are collected on a Buchner funnel. The material is washed with cold diluted hydrochloric acid (15 ml. of concentrated acid to 100 ml. of water). After removing the hydrochloric acid by suction, the crystals are washed with two 25-ml. portions of cold ethyl alcohol and four portions of ether. After all traces of ether are removed, the dry crystals are transferred to a brown bottle.

<sup>243</sup> Stockholm and Koch: *J. Am. Chem. Soc.*, **45**, 1953 (1923).

<sup>244</sup> Merck's Superoxol.

by the gradual addition of fuming nitric acid and bromine until 10 ml. of acid and 40 to 50 drops of bromine have been used. With material low in, or free from, fat this treatment is usually sufficient to bring about complete oxidation of the organic matter. The solution is next evaporated almost to dryness and, after water has again been added, evaporation is repeated to remove most of the nitric acid. When the water solution of this material is not absolutely clear it is filtered and after it has been neutralized with sodium hydroxide and diluted to about 600 ml. it is acidified by the addition of 10 ml. of concentrated hydrochloric acid. Ten ml. of 0.1 N sulfuric acid are added, the mixture heated to boiling and 10 ml. of a 10 per cent barium chloride solution added, drop by drop. The boiling is continued for 10 to 15 minutes and then the mixture is heated for 10 to 12 hours before it is filtered and washed as usual. The filter paper and precipitate are cautiously burned and weighed. Blank estimations are made in exactly the same way thus correcting for the sulfuric acid added to facilitate precipitation.

## DETERMINATION OF CALCIUM

**Introduction.** The calcium of blood is found entirely in the plasma, red cells apparently being devoid of calcium. Since most of the common anticoagulants for blood act by reaction with calcium, serum from clotted blood is ordinarily used for analysis; heparinized plasma may also be used. Of the total serum calcium, about half appears to be combined with protein in some way, and little is known of its physiological significance. The remainder is dialyzable, and, according to McLean and Hastings, largely in the ionic form. The symptoms of hypo- and hypercalcemia appear to be associated chiefly with variations in this diffusible fraction. Serum calcium is usually determined by precipitation as an insoluble calcium salt, such as oxalate or phosphate, for which specific analytical methods are available.

**1. Clark-Collip Modification of the Kramer-Tisdall Method:**<sup>245</sup> **Principle.** Calcium is precipitated directly from the serum as oxalate and the latter is titrated with potassium permanganate. Sendroy<sup>246</sup> has shown that direct precipitation as oxalate from diluted serum gives accurate results, and that preliminary removal of protein is not necessary.

**Procedure.** Introduce into a graduated 15-ml. centrifuge tube 2 ml. of clear serum, 2 ml. of distilled water, and 1 ml. of 4 per cent ammonium oxalate solution. Mix thoroughly. Mixing is aided by holding the tube at the mouth and giving it a circular motion by tapping the lower end. The centrifuge tube should have an outside diameter of 6 to 7 mm. at the 0.1 ml. mark. Let stand for 30 minutes or longer.<sup>247</sup> Again mix the contents. Centrifuge for about 5 minutes at 1500 revolutions per minute. Carefully pour off the supernatant liquid and while the tube is still inverted let it drain in a rack for 5 minutes, resting the mouth of the tube on a pad of filter paper.<sup>248</sup> Wipe the mouth of the tube dry with a soft cloth. Stir up the precipitate and wash the sides of the tube with 3 ml. of dilute ammonia (2 ml. of concentrated am-

<sup>245</sup> Clark and Collip: *J. Biol. Chem.*, **63**, 461 (1925); Tisdall: *J. Biol. Chem.*, **56**, 439 (1923); Kramer and Tisdall: *J. Biol. Chem.*, **47**, 475 (1921); Clark: *J. Biol. Chem.*, **49**, 487 (1921).

<sup>246</sup> Sendroy: *J. Biol. Chem.*, **152**, 539 (1944).

<sup>247</sup> Overnight standing is preferred, otherwise precipitation is sometimes incomplete.

<sup>248</sup> To insure uniform drainage the tubes should always be cleaned thoroughly by heating at approximately 100° C. for a few minutes in a cleaning mixture made by adding 1500 ml. of concentrated sulfuric acid to a solution of 200 g. of sodium dichromate in 100 ml. of water.

monia to 98 ml. of water)<sup>249</sup> directed in a very fine stream, from a wash bottle. Centrifuge the suspension and drain again as before. Add 2 ml. of approximately normal sulfuric acid (28 ml. of concentrated acid to a liter) by blowing it from a pipet directly upon the precipitate so as to break up the mat and facilitate solution. Place the tube in a boiling water bath for about 1 minute. Titrate with 0.01 normal potassium permanganate<sup>250</sup> to a definite pink color which persists for at least 1 minute. If necessary during the course of the titration warm the tube by placing in a water bath kept at 70° to 75° C. A microburet graduated in 0.02 ml. should be used.

CALCULATION. One ml. of 0.01 N  $\text{KMnO}_4$  is equivalent to 0.2 mg. of Ca.

$$(x - b) \times 0.2 \times \frac{100}{2} = \text{mg. calcium per 100 ml. serum}$$

where  $x$  equals the number of ml. of permanganate required in the titration, and  $b$  is the blank, i.e., the number of ml. of permanganate required to titrate 2 ml. of the sulfuric acid solution to the usual end point.

**Interpretation.** Normal human blood serum contains from 9 to 11.5 mg. of calcium per 100 ml. corresponding to 4.5–5.7 milliequivalents per liter. Values for children are slightly higher than for adults. A slight decrease may be observed during the late months of pregnancy. After parathyroidectomy the blood calcium falls to a low level and the injection of parathyroid extract results in a considerable increase. In infantile tetany values of 3.5 to 7.0 mg. have been observed. In severe nephritis the calcium content may decrease to 7.0 mg. or less. There is apparently a reasonably close relationship between serum calcium, phosphate, and protein. Except in children and in cases where the calcium metabolism *per se* is abnormal, this relationship may be expressed by the following equation:<sup>251</sup>

$$\begin{aligned} \text{Ca (in mg. per cent)} = & 7 - 0.255 \text{ P (in mg. per cent)} \\ & + 0.566 \text{ protein (in grams per cent)} \end{aligned}$$

Thus interpretation of pathological variations in serum calcium should

<sup>249</sup> Wang (*J. Biol. Chem.*, **111**, 443 (1935)) recommends as the washing solution, 2 per cent ammonia in equal parts of alcohol, ether, and water, to avoid flotation of the precipitate. Stanford and Wheatley (*Biochem. J.*, **19**, 710 (1925)) wash twice with a thoroughly filtered, saturated aqueous solution of calcium oxalate, 15 ml. of which, upon acidifying and titrating with 0.01 N  $\text{KMnO}_4$ , should require not more than 0.25 ml.

<sup>250</sup> 0.01 N  $\text{KMnO}_4$ . See Halverson and Bergeim: *J. Ind. Eng. Chem.*, **10**, 119 (1918). Dissolve 0.4 g. of pure potassium permanganate in 1 liter of redistilled water in a thoroughly clean Florence flask. Insert a funnel covered with a watch glass as a condenser and digest for several hours at near the boiling point. Cool, let stand overnight, and filter with gentle suction through a 3-inch Buchner funnel lined with ignited asbestos. Transfer to a perfectly clean glass stoppered bottle and keep in a dark place. (Permanganate solution prepared by dilution of 0.1 N solution must be standardized immediately before use as it deteriorates rapidly and comes to a constant value only after several days.) The 0.01 N permanganate is standardized against 0.01 N sodium oxalate which should keep for several months. Dry highest purity sodium oxalate in an oven at 100° to 105° C. for 12 hours. Dissolve exactly 0.67 g. of the oxalate in redistilled water, add 5 ml. of concentrated  $\text{H}_2\text{SO}_4$ , and dilute to 1 liter. Mix well. Transfer exactly 25 ml. of this solution to a 100-ml. Erlenmeyer flask, add 1 ml. of concentrated  $\text{H}_2\text{SO}_4$ , warm to about 70° C., and titrate with the  $\text{KMnO}_4$  solution. The permanganate solution should be frequently restandardized although after the first few days, if carefully prepared and kept, it should not deteriorate more than 0.1 per cent per week.

<sup>251</sup> Peters and Eiserson: *J. Biol. Chem.*, **84**, 155 (1929); Oberst and Plass: *J. Biol. Chem.*, **92**, xiii (1931). See, however, Stearns and Knowlton: *J. Biol. Chem.*, **92**, xii (1931).

be based upon knowledge of the serum phosphate and protein values, unless these are known to be normal.

**2. Method of Roe and Kahn:<sup>252</sup> Principle.** Calcium is precipitated from the protein-free serum filtrate as tricalcium phosphate, which is then determined colorimetrically by a procedure similar to that used for the determination of blood inorganic phosphate (p. 630). Kuttner and Cohen have described a micromodification using this principle, in connection with their method for phosphorus determination.

**Procedure.<sup>253</sup>** To 8 ml. of 10 per cent trichloroacetic acid in a small flask, add 2 ml. of serum. Mix well by shaking. Filter through a Ca-free filter paper (Whatman No. 42 is satisfactory). Transfer 5 ml. of filtrate to a 15-ml. conical graduated centrifuge tube, add 1 ml. of 25 per cent Ca-free sodium hydroxide solution, mix by tapping, and let stand 5 minutes. Add 1 ml. of 5 per cent trisodium phosphate solution, mix thoroughly by tapping, and set aside for 1 hour. Centrifuge for 2 minutes. Decant supernatant liquid, place tube in an inverted position in a small beaker containing a mat of clean gauze or filter paper, and allow to drain 2 minutes. Wipe mouth of tube dry with a clean cloth. Add from a bulb pipet with a fine tip 5 ml. of alkaline-alcoholic wash reagent, forcing the wash fluid in at first so as to break up the mat of tricalcium phosphate, and then washing down the sides of the tube. If necessary, use a stirring rod to break up the precipitate, rinsing down the rod with a little of the wash fluid. Centrifuge 2 minutes, decant, drain, and wipe the mouth of the tube as before. Repeat the washing procedure,<sup>254</sup> centrifuging, etc., with a second 5-ml. portion of wash reagent, centrifuging, decanting, draining, and wiping off excess fluid as above. To the residue in the centrifuge tube add 1 ml. of acid molybdate reagent and tap against the palm of the hand to effect complete disintegration and solution of the precipitate. When dissolved, add 10 ml. of water, mix by tapping, and set aside. Prepare a standard by transferring 10 ml. of the standard phosphate solution, containing phosphate equivalent to 0.1 mg. of calcium, to a second similar graduated tube, add 1 ml. of the acid molybdate reagent, and mix. For photometric measurement, prepare a blank tube containing 10 ml. of water and 1 ml. of acid molybdate. When all the tubes are ready, add to each 0.5

<sup>252</sup> Roe and Kahn: *J. Biol. Chem.*, **81**, 1 (1929). Kuttner and Cohen: *J. Biol. Chem.*, **75**, 517 (1927). The latter procedure as applied to the Roe and Kahn method is described in the eleventh edition of this book.

<sup>253</sup> Reagents Required: The trichloroacetic acid, sodium hydroxide, and trisodium phosphate ( $\text{Na}_3\text{PO}_4 \cdot 12 \text{ H}_2\text{O}$ ) solutions are prepared on the indicated basis from reagent-grade chemicals. The two alkaline solutions should be decanted occasionally from any sediment which forms and which might lead to errors if included in the analysis.

*Alkaline-Alcoholic Wash Reagent.* Mix 58 ml. of ethyl alcohol with 10 ml. of amyl alcohol and dilute to 100 ml. with water. Add 2 drops of 1 per cent phenolphthalein and 5 per cent Ca-free NaOH a drop at a time to a distinct pink (usually 2 to 3 drops).

*Acid Molybdate Reagent.* Dissolve 12.5 g. of reagent-grade ammonium molybdate in 400 ml. of water in a 500-ml. volumetric flask. Add slowly with shaking 100 ml. of concentrated sulfuric acid. Stable indefinitely.

*Aminonaphtholsulfonic Acid Reagent.* The same as described on p. 631 for the determination of inorganic phosphate.

*Standard Phosphate Solution.* Dissolve 2.265 g. of pure dry monopotassium phosphate in water, dilute to 1 liter in a volumetric flask, and mix. Add a little chloroform as a preservative. This stock solution contains 0.517 mg. of P per ml., equivalent to 1 mg. of Ca as calcium phosphate. The working standard is prepared by diluting 1 ml. of stock solution to 100 ml. with water. This standard should be prepared fresh daily. 10 ml. contain phosphate equivalent to 0.1 mg. of Ca.

<sup>254</sup> Roe and Kahn state that only one washing is necessary. Two washings provide a greater margin of safety.

ml. of aminonaphtholsulfonic acid reagent, followed by water to the 15-ml. mark, and mix immediately by inversion. Allow to stand 10 minutes before reading in the colorimeter or photometer. For photometric measurement, set the photometer to zero density at 660  $m\mu$  with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.1 \times \frac{100}{1} = \text{mg. calcium per 100 ml. serum}$$

The standard corresponds to 10 mg. per cent serum calcium, and will be satisfactory for practically all values encountered in analyses. For very low values (below 5 mg. per cent) dilute the unknown after color development to 12 ml. instead of 15 ml., and correct the calculations accordingly.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.1 \times \frac{100}{1} = \text{mg. calcium per 100 ml. serum}$$

The characteristics of the color and the conditions of photometric measurement are the same as those described for the determination of inorganic phosphate (p. 632). At 660  $m\mu$ , in a 1-cm. cuvette, the standard has a density of approximately 0.400, and all values of serum calcium may be accurately determined under these conditions.

The photometric blank will correct for any phosphate present in the color-producing reagents, but not for contamination by calcium in the earlier stages of the procedure. Since it is very difficult to obtain absolutely Ca-free reagents or filter paper, for precise work a correction for calcium already present should be made. This is best done by running a standard calcium solution<sup>255</sup> through the entire procedure (treatment with trichloroacetic acid, filtering, etc.) and comparing the value obtained with that expected. Thus if a standard equivalent to 10 mg. per cent calcium gives on analysis a value of 10.5 mg. per cent, the correction to be subtracted from serum results is 0.5 mg. per cent. It is sometimes suggested that using such a calcium standard, instead of a phosphate standard as described, will include the calcium present in the reagents and hence serve as a correction. This is only true if the unknown and standard should happen to contain exactly the same amounts of calcium; otherwise it is in error, since the constant calcium correction becomes a variable and unknown fraction of the total calcium present in the unknown.

**Interpretation.** See previous method.

**Other Methods.** Numerous other methods have been proposed for the determination of serum calcium, some of which require only very small quantities of serum. Instead of titrating the oxalate directly, Fiske and Adams<sup>256</sup> redissolve the washed oxalate in nitric acid, dry, add oxalic acid, dry again, ignite, and titrate the residue as calcium oxide. Kuttner and Cohen (*loc. cit.*), in a method applicable to 0.1 ml. of serum, ash the material, precipitate the calcium as phosphate, and analyze for phosphate colorimetrically. Gasometric methods include measurement of the carbon dioxide evolved in the reaction between oxalate and permanganate<sup>257</sup> or ceric sulfate,<sup>258</sup> or in the combustion of calcium picrolonate;<sup>259</sup> the latter

<sup>255</sup> Suspend 0.250 g. of pure dry calcium carbonate in a little water in a 1-liter volumetric flask, add dilute (1:10) HCl to dissolve, add a few ml. of acid in excess, dilute to 1 liter with water, and mix. This solution is stable indefinitely and contains 0.1 mg. of Ca per ml. It corresponds therefore to a serum with a Ca content of 10 mg. per cent.

<sup>256</sup> Fiske and Adams: *J. Am. Chem. Soc.*, **53**, 2498 (1931).

<sup>257</sup> Van Slyke and Sendroy: *J. Biol. Chem.*, **84**, 217 (1929).

<sup>258</sup> Sendroy: *J. Biol. Chem.*, **152**, 557 (1944).

<sup>259</sup> Van Slyke and Kreysa: *J. Biol. Chem.*, **142**, 765 (1942).

procedure is applicable to as little as 0.02 ml. of serum. Sendroy<sup>260</sup> has described photometric methods likewise applicable to 0.02 ml. of serum.

**Determination of Calcium in Tissues and Other Biological Materials.** Where the amount of organic matter to be destroyed is small, the material may be ashed in silica or platinum crucibles with the aid of a few drops of nitric acid to destroy the last carbon. Feces, milk, and bone may usually be handled in this way. Tissues low in calcium present a more difficult problem and Corley and Denis have suggested autoclaving such materials with alkali.<sup>261</sup> By using a microcalcium determination the amount of organic matter necessary to be destroyed is greatly decreased.

## DETERMINATION OF MAGNESIUM

**Introduction.** Magnesium is found constantly in small amount in blood, being distributed about equally between cells and plasma. Plasma or serum is ordinarily used for analysis, usually after the calcium has been precipitated to prevent interference in the analysis. Most methods proposed depend upon the precipitation of magnesium as phosphate, followed by colorimetric phosphate analysis. Precipitation of magnesium with 8-hydroxyquinoline has also been used.<sup>262</sup> Hirschfelder and Serles<sup>263</sup> have described a colorimetric method based upon the color formed in alkaline solution in the presence of certain dyes. The clinical significance of blood magnesium is relatively unknown; in tissues (such as muscle) the magnesium ion has been shown to play an important part in certain enzyme systems associated with intermediary metabolism (see Chapter 33).

**Method of Denis<sup>264</sup> Modified: Principle.** After removal of calcium as oxalate the magnesium is precipitated as magnesium ammonium phosphate and the latter is estimated by a colorimetric phosphate determination. In the method here described, the Fiske-SubbaRow phosphate method is used. For a procedure based on Youngburg's adaptation of Kuttner's colorimetric phosphate method, see the eleventh edition of this book.

**Procedure.** Precipitate the calcium from 2 ml. of serum as in the procedure for calcium in serum (see p. 644). After centrifuging, pipet 3 ml. of the supernatant fluid into a 15-ml. graduated centrifuge tube and add with stirring 0.5 ml. of a 5 per cent solution of ammonium phosphate containing 5 ml. of concentrated  $\text{NH}_4\text{OH}$  per liter, followed by 2 drops of concentrated  $\text{NH}_4\text{OH}$ . Let stand overnight. Centrifuge. Siphon off the supernatant fluid and wash the tube with 5 ml. of a mixture of 1 part of concentrated  $\text{NH}_4\text{OH}$  (sp. gr. 0.9) and 2 parts of water. Centrifuge and siphon off wash liquid. Repeat the washing a second and third time and then wash finally with 5 ml. of 75 per cent alcohol containing 10 ml. of concentrated  $\text{NH}_4\text{OH}$  per liter. Siphon off again and let stand in a warm place until the ammonia has evaporated.

To the residue in the centrifuge tube add 1 ml. of the Molybdate I reagent used in the Fiske-SubbaRow phosphate method (p. 630), and tap to dis-

<sup>260</sup> Sendroy: *J. Biol. Chem.*, **144**, 243 (1942). See also Sendroy: *J. Biol. Chem.*, **152**, 539 (1944). This latter paper contains an extensive bibliography of serum Ca methods.

<sup>261</sup> Corley and Denis: *J. Biol. Chem.*, **66**, 601 (1925).

<sup>262</sup> Glomaud: *Ann. chim. anal.*, **24**, 166 (1942).

<sup>263</sup> Hirschfelder and Serles: *J. Biol. Chem.*, **104**, 635 (1934).

<sup>264</sup> Denis: *J. Biol. Chem.*, **52**, 411 (1922). See also Briggs: *J. Biol. Chem.*, **52**, 349 (1922).

solve. When dissolved, add 5 ml. of water and set aside. Prepare a standard by placing 1 ml. of the Molybdate I reagent in a second graduated tube and adding 3 ml. of the standard phosphate solution (equivalent to 0.03 mg. of magnesium)<sup>265</sup> plus 2 ml. of water. For photometric measurement prepare a blank by placing 1 ml. of Molybdate I reagent plus 5 ml. of water in a third graduated tube. When all the tubes are ready, add to each 0.4 ml. of aminonaphtholsulfonic acid reagent, followed immediately by water to the 10-ml. mark. Mix and allow to stand 5 minutes before reading in the colorimeter or photometer. For photometric measurement, set the photometer to zero density at 660 m $\mu$  with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{100}{1.2} = \text{mg. magnesium per 100 ml. serum}$$

The value 1.2 represents the fact that 3 ml. of supernatant obtained from 2 ml. of serum, after precipitating the Ca as oxalate, correspond to 1.2 ml. of the original serum.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{100}{1.2} = \text{mg. magnesium per 100 ml. serum}$$

The characteristics of the color and the conditions of photometric measurement are the same as for the determination of inorganic phosphate (p. 630). At 660 m $\mu$ , the standard has a density of approximately 0.500 in a 1-cm. cuvette. Since this standard corresponds to a serum Mg content of 2.5 mg. per cent, up to 5 mg. per cent may be accurately determined under these conditions. For higher values, or for photometric measurement at a greater depth of solution, add 2 ml. of molybdate reagent to unknown, blank, and standard instead of the 1 ml. specified (use the same 3-ml. portion of standard) followed by water in each case to about 12 ml., then add 0.8 ml. of aminonaphtholsulfonic acid reagent and water to a 20-ml. final volume. There is no change in the calculations. Color development at a greater dilution is recommended rather than the analysis of a smaller portion of serum because it is not known whether or not precipitation of magnesium in this procedure will be quantitative at conditions other than those specified.

**Interpretation.** Normally about 1 to 3 mg. of Mg are found in 100 ml. of serum and about 1.6 mg. per 100 ml. of blood. No characteristic changes have been observed in pathological conditions.

## DETERMINATION OF SODIUM

**Introduction.** The sodium of whole blood appears to be present entirely in the form of the sodium ion, with over 90 per cent of the total blood sodium present in the plasma. Plasma or serum is therefore ordinarily used for analysis, and for precise work precautions should be taken against the transfer of water and electrolytes between cells and plasma brought about by changes in the blood gas content. Sodium is commonly determined by precipitation in the form of uranyl zinc sodium acetate, which, while soluble in water, is relatively insoluble in alcohol or acetone.

<sup>265</sup> Dissolve 0.560 g. of pure dry monopotassium phosphate in water to make 1000 ml. Add a few drops of chloroform to prevent growth of molds. Dilute 10 ml. of this stock solution to 100 ml. 1 ml. = 0.01 mg. of Mg. For other solutions, see the phosphate method (p. 630).

Prior to isolation of the sodium as the triple salt indicated, the proteins are precipitated<sup>266</sup> or the sample is ashed;<sup>267</sup> electro dialysis may also be used for separation of the sodium from interfering material.<sup>268</sup> The triple salt may be determined by gravimetric,<sup>267</sup> titrimetric,<sup>266</sup> or colorimetric<sup>269</sup> methods. Another reagent which has been proposed for the determination of sodium is pyroantimonate.<sup>270</sup> In the analysis of serum sodium, precision is essential because of the relatively small variations which are of clinical significance. The determination of sodium in tissues is similar to the procedures used for blood.<sup>271</sup>

**1. Determination by Flame Photometry: Principle.** The sample in solution is introduced in the form of a fine continuous spray into a nonluminous gas flame. The various ions present produce their characteristic flame spectra. By the use of proper color filters or other means, the emitted light characteristic of the ion being determined is isolated and allowed to excite a photoelectric cell. The response of the photoelectric cell is measured on a suitable meter. Under controlled conditions, the meter reading is a measure of the concentration of ion being determined. A calibration curve is established by analyzing a series of standard solutions of the ion being determined. From the meter reading of the sample being analyzed, the concentration is established by reference to the calibration curve.

**Procedure.** The procedure varies with different types of instrument. Ordinarily a dilution of 1:250 is used for sodium analyses, i.e., 1 ml. of plasma or serum is diluted to 250 ml. with water. If an internal standard, e.g., a lithium salt, is required for the successful operation of the photometer, the required aliquot of a stock solution of such a substance is added to the volumetric flask before diluting to the mark. The solution is then analyzed according to the directions which accompany the instrument. In order to get the sodium content of the sample, the reading obtained is referred to a calibration curve previously obtained by the same procedure on a series of solutions of known sodium content.

**STANDARDS.** Standard solutions covering the range from 100 to 150 milliequivalents of sodium per liter, at a dilution of 1:250, are usually adequate for calibration purposes. Prepare a stock standard containing 100 milliequivalents of sodium per liter by dissolving 5.85 g. of NaCl in water and diluting to 1 liter. Working standards are prepared from this stock standard by measuring out 4.0, 5.0 and 6.0 ml. aliquots into 1-liter volumetric flasks, and diluting to the mark with water. These standards represent respectively 100, 125, and 150 milliequivalents of sodium per liter at a 1:250 dilution. If the analytical procedure requires an internal standard such as lithium sulfate solution, add to each working standard 4 times the volume of lithium sulfate solution routinely added to the diluted plasma or serum, before diluting to

the mark and mixing. To prepare a calibration curve, read each of these standards in the photometer, plot readings against equivalent sodium content in milliequivalents per liter, and draw a smooth curve to include the points.

Standards should always be run both before and after analyzing a series of unknown solutions, to be sure that the calibration is constant; if there is considerable fluctuation, each unknown solution should be followed by a standard closely equivalent to it.

Routine precautions in the use of flame photometers include the use of gas and air for the flame which are as free from contaminating ions as possible; maintenance of a constant gas and air pressure; installation of the photometer in a room free from airborne contamination, particularly tobacco smoke; and continual checking of the zero setting and standard readings. Cleaning of the atomizer and flame chimney may also be necessary from time to time.

**Interpretation.** See under 2, below.

**2. Method of Weinbach:**<sup>266</sup> **Principle.** After deproteinization, the sodium in the filtrate is precipitated in alcoholic medium as the triple salt, uranyl zinc sodium acetate, which is washed, dissolved in water, and titrated with standard sodium hydroxide. It is claimed that phosphates present do not interfere. For a similar method in which phosphates are first removed, see Dregus.<sup>266</sup>

**Procedure.**<sup>272</sup> To 1 volume of whole blood or cells (or 2 volumes of serum or plasma) in a small flask, add 7 (or 6) volumes of water, shake, and let stand until hemolysis is complete. Add rapidly, with shaking, 2 volumes of 20 per cent trichloroacetic acid, making a total of 10 volumes. (This deproteinization may be done with as little as 0.1 to 0.2 ml. of material.) Mix, let stand 10 minutes, and filter through ashless filter paper (or centrifuge if the sample is small). Transfer 1 ml. of the whole blood filtrate (or 0.5 ml. of the serum filtrate) to a 15-ml. centrifuge tube and add 5 ml. of the uranyl zinc acetate reagent. From a 1-ml. graduated pipet add 0.3 ml. of 95 per cent alcohol and let stand for 5 minutes. Again add 0.3 ml. of alcohol and let stand for a few minutes. This procedure is repeated, without greatly disturbing the precipitate, until 2.1 ml. of alcohol have been added, the entire process of precipitation taking about  $\frac{1}{2}$  hour. Centrifuge, decant, drain by inversion on a pad of filter paper, and wipe the mouth of the tube with a cloth. Wash the precipitate once by blowing in 10 ml. of acetone wash reagent; centrifuge, decant, drain on filter paper, and wipe the mouth of the tube. The precipitate, which is readily soluble in water, is then transferred quantitatively to a 100-ml. Erlenmeyer flask by blowing in three or four 5-ml. portions of water, which has been recently boiled and cooled, to drive off dissolved carbon diox-

---

<sup>272</sup> Reagents Required: *Uranyl Zinc Acetate Reagent.* Solution A: 77 g. uranyl acetate,  $\text{UO}_2(\text{CH}_3\text{COO})_2 \cdot 2\text{H}_2\text{O}$ , and 14 ml. of glacial acetic acid are dissolved in about 400 ml. of water by stirring and heating on a steam bath, and diluted to 500 ml. in a volumetric flask. Solution B: 231 g. of zinc acetate ( $3\text{H}_2\text{O}$ ) and 7 ml. of glacial acetic acid are likewise dissolved and made up to 500 ml. The two solutions are mixed while hot, allowed to stand at least 24 hours, and filtered.

*Acetone Wash Reagent.* A small amount of the triple salt, uranyl zinc sodium acetate, is prepared by adding 15 ml. of the uranyl zinc acetate reagent to 1 ml. of approximately 5 per cent NaCl with subsequent addition of about 5 ml. of 95 per cent alcohol in small portions. Filter with suction and wash the precipitate with 4 or 5 small portions of 95 per cent alcohol and then with 4 or 5 small portions of ether, sucking dry after each addition of alcohol or ether. Add this amount of triple salt to a liter of acetone, shake, let stand overnight, and filter.

*Standard Sodium Solution.* Exactly 1 g. of c.p. sodium chloride is dissolved in water and made up to a liter in a volumetric flask. Each ml. of this solution contains 0.393 mg. of sodium.

ide. Add approximately 50 ml. of water free from carbon dioxide and 0.5 ml. of 1 per cent phenolphthalein solution and titrate with 0.02 N NaOH to a just barely perceptible pink, with a microburet graduated in 0.02 ml. A blank should be run to determine the amount of 0.02 N NaOH which will just give the end point with distilled water. Determine sodium on 0.5 ml. of standard sodium solution to standardize the procedure (see footnote 272, p. 651) and to facilitate determining the end point.

CALCULATION. According to Weinbach, the equation for the titration reaction is:

Hence 8 moles of NaOH are required for each mole of Na.<sup>273</sup> Each ml. of 0.02 N NaOH is thus equivalent to  $(0.02 \times 23)/8 = 0.0575$  mg. of Na in the sample. If 1 ml. of a 1:10 filtrate is used,

$(\text{Titration} - \text{Blank}) \times 0.0575 \times 100/0.1 = \text{mg. sodium per 100 ml. blood or serum}$

To convert mg. per cent sodium into milliequivalents per liter, divide by 2.3.

**Interpretation.** Normally, the range of serum or plasma sodium content is approximately 300 to 330 mg. per 100 ml., or 130 to 143 milliequivalents per liter.<sup>274</sup> The sodium content of red cells is much less, ranging from 4 to 16 milliequivalents per liter.<sup>275</sup> Whole-blood sodium determinations have little clinical value. Sodium is the chief base of the plasma; its function there appears to be primarily physicochemical, in connection with the maintenance of osmotic pressure and acid-base balance. The organism has such a strong tendency to maintain a constant level of total base content that only slight changes are ordinarily found, even under pathological conditions; hence the need for precision in analyses. Significant decreases in plasma sodium content have been noted in pregnancy, in obstruction of the pylorus and other parts of the gastrointestinal tract, in pneumonia, in severe nephritis, and in Addison's disease. In the latter case, the decrease in the blood sodium level brought about by withdrawal of salt from the diet is of diagnostic significance.

## § DETERMINATION OF POTASSIUM

**Introduction.** Potassium, like sodium, is found in blood entirely in the form of the potassium ion. The distribution of blood potassium between cells and plasma is just opposite to that of sodium, potassium being much more abundant in the cells. Whole-blood potassium determinations have relatively little clinical significance; hence plasma or serum is ordinarily used for analysis. In obtaining plasma or serum, hemolysis must be avoided and separation from the cells should be carried out as soon as possible to minimize error due to diffusion of potassium from cells to surrounding fluid. Weichselbaum, Somogyi, and Rusk<sup>276</sup> advise that a syringe be dispensed with in obtaining blood, and allow the

<sup>273</sup> According to Dregus, the titration yields sodium uranate,  $\text{Na}_2\text{U}_2\text{O}_7$ , zinc acetate, and sodium acetate at the end point, and 9 moles of NaOH are required instead of 8 for each mole of sodium present. To eliminate uncertainty, the best procedure is to determine the sodium equivalent of the sodium hydroxide by analysis of a standard sodium solution, and to use this factor in the calculations.

<sup>274</sup> Values are about 10 per cent higher if expressed in terms of a liter of plasma water.

<sup>275</sup> Snyder and Katzenelbogen: *J. Biol. Chem.*, **143**, 223 (1942).

<sup>276</sup> Weichselbaum, Somogyi, and Rusk: *J. Biol. Chem.*, **132**, 343 (1940).

blood to flow directly from the needle in the vein into a small test tube, followed by standing for not over 20 minutes to permit clotting, and centrifuging to obtain the serum. The determination of potassium is usually based upon precipitation as the insoluble chloroplatinate<sup>277</sup> or cobaltinitrite<sup>278</sup> followed by titrimetric or colorimetric<sup>279</sup> estimation. Titrimetric and gravimetric methods based upon precipitation as the insoluble phospho-12-tungstate salt have also been described.<sup>280</sup>

**1. Determination by Flame Photometry: Principle.** See p. 649, "Determination of Sodium." Since the potassium content of serum or plasma is much lower than the sodium content, the sample is ordinarily diluted 1:100 instead of 1:250. In the analysis of other tissues where the potassium content may be high and variable, suitable dilutions of the sample are usually established by trial.

**Procedure.** Dilute 1 ml. of serum or plasma to 100 ml. with water and mix. Continue with the analysis as described on p. 650 for sodium. If an internal standard is used, add the required aliquot of stock solution to the volumetric flask containing the sample, before diluting to the 100 ml. mark. Ordinarily, the same concentration of internal standard is used for both sodium and potassium analyses; because of the lower total volume of diluted sample used in potassium analyses, proportionately less of the internal standard stock solution is required.

**STANDARDS.** Standard solutions covering a range from 3 to 6 milliequivalents of potassium per liter, at a dilution of 1:100, are usually adequate for calibration purposes. Prepare a stock standard containing 10 milliequivalents of potassium per liter by dissolving 0.746 g. of KCl in water and diluting to 1 liter. Working standards equivalent to 3.0, 4.0, 5.0, and 6.0 milliequivalents of potassium per liter, at a dilution of 1:100, are prepared by diluting respectively 3.0, 4.0, 5.0, and 6.0 ml. of stock solution to 1 liter with water. If the analytical procedure requires an internal standard such as lithium sulfate solution, add to these working standards 10 times the volume of such solution routinely added to the diluted plasma or serum before diluting to the 1-liter mark and mixing. Prepare a calibration curve from these standards as described for the determination of sodium.

**Interpretation.** See under 2, below.

**2. Method of Looney and Dyer:<sup>281</sup> Principle.** Potassium is precipitated from the protein-free, chloride-free serum filtrate as the insoluble potassium silver cobaltinitrite of the Breh and Gaebler procedure. The washed precipitate is decomposed by alkali to liberate the nitrite, which is then determined colorimetrically by an application of the Bratton-Marshall sulfonamide method (see p. 658). The method has the advantage of not requiring a preliminary ashing of the sample, and yields a stable color.

---

<sup>277</sup> Shohl and Bennett: *J. Biol. Chem.*, **78**, 643 (1928). The chloroplatinate methods usually require a preliminary ashing; for the use of electrodialysis to avoid ashing, see Sobel, Hanok, and Kramer: *J. Biol. Chem.*, **144**, 363 (1942), and other references cited for the determination of sodium by electrodialysis (p. 650). Micro-methods include those of Cunningham, Kirk, and Brooks: *J. Biol. Chem.*, **139**, 21 (1941), and Clark, Levitan, Gleason, and Greenberg: *ibid.*, **145**, 85 (1942). These methods are applicable to small amounts of tissue.

<sup>278</sup> Breh and Gaebler: *J. Biol. Chem.*, **87**, 81 (1930). This method is described in the eleventh edition of this book. See also Weichselbaum, Somogyi, and Rusk: *loc. cit.*

<sup>279</sup> Albanese and Wagner: *J. Lab. Clin. Med.*, **30**, 280 (1945).

<sup>280</sup> Van Slyke and Rieben: *J. Biol. Chem.*, **156**, 743 (1944); Rieben and Van Slyke: *ibid.*, **156**, 765 (1944).

<sup>281</sup> Looney and Dyer: *J. Lab. Clin. Med.*, **28**, 355 (1942).

**Procedure.**<sup>282</sup> Transfer 0.5 ml. of serum to a small clean test tube containing 7 ml. of distilled water, add 1 ml. of 1.5 per cent sodium tungstate, mix by tapping, and follow with 1 ml. of 2.5 per cent copper sulfate solution. Stopper and shake well; then add 0.5 ml. of 2.5 per cent silver nitrate solution. Stopper and shake again; then allow to stand 15 to 20 minutes. Pour onto a small dry filter (Whatman No. 5 is recommended), returning the first portion of filtrate to the funnel to ensure obtaining a clear filtrate.

Transfer 3 ml. of the filtrate to a clean 15-ml. graduated conical centrifuge tube,<sup>283</sup> and in a second similar tube place 3 ml. of the standard potassium solution, containing 0.03 mg. of potassium. Add 1 ml. of 95 per cent alcohol and 1 ml. of distilled water to each tube, mix by tapping, and place in a water bath at 18° to 22° C. for five minutes. Add 2 ml. of the freshly prepared and filtered silver cobaltinitrite reagent, mix by tapping, and replace in the water bath. Allow to stand 2 hours, then centrifuge for 15 minutes at 2800 r.p.m. Carefully remove the supernatant fluid down to the 0.2-ml. mark with a capillary pipet. Add 7 ml. of wash reagent down the sides of the tube, slanting the tube but disturbing the precipitate as little as possible. Again centrifuge for 15 minutes, decant the supernatant fluid, invert the tube, and allow to drain on filter paper for 5 minutes. Wipe excess fluid from the mouth of the tube, and repeat the washing and draining twice more.

To the washed precipitate in the centrifuge tube, add 10 ml. of 0.2 normal sodium hydroxide, breaking up the precipitate by blowing the alkali in or by tapping the tube. Place in a boiling water bath for 10 minutes. Remove, cool, and make up to 10 ml. with water. Mix well and centrifuge. Transfer 2 ml. of supernatant to a 100-ml. volumetric flask. Add 5 ml. of water, followed by 1 ml. of 50 per cent hydrochloric acid, and 2 ml. of 0.5 per cent sulfanilamide solution. Mix by lateral shaking, allow to stand 3 minutes, then add 1 ml. of the naphthylethylenediamine reagent. Dilute with water to the 100-ml. mark, and allow to stand 5 minutes before reading in the

---

<sup>282</sup> Reagents Required: The sodium tungstate, copper sulfate ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ), and silver nitrate solutions are prepared on the indicated basis from reagent-grade chemicals. Keep the silver nitrate solution in a brown bottle.

*Standard Potassium Solution.* Prepare a stock standard by dissolving 2.229 g. of pure dry potassium sulfate in water in a 1-liter volumetric flask, dilute with water to the mark, and mix. Preserve with a little toluene. This solution contains 1 mg. of potassium per ml. and is stable indefinitely. Prepare a working standard fresh daily by diluting 1 ml. of stock standard to 100 ml. with water in a volumetric flask. This solution contains 0.03 mg. of potassium in 3 ml.

*Silver Cobaltinitrite Reagent.* Prepare a sodium cobaltinitrite solution as follows: (A) Dissolve 25 g. of crystalline cobalt nitrate in 50 ml. of water, and add 12.5 ml. of acetic acid. (B) Dissolve 120 g. of reagent-grade sodium nitrite in 180 ml. of water. Add 210 ml. of B to all of A, place in the hood, and blow air through the solution until all of the nitrous oxide fumes have been driven off. This solution is stable for about 1 month if stored in the refrigerator. It must be filtered each time before using. To prepare the silver cobaltinitrite reagent, add 1 ml. of 40 per cent silver nitrate solution to 20 ml. of filtered sodium cobaltinitrite solution, shake well and filter. Prepare fresh for each series of analyses.

*Wash Reagent.* Mix 2 volumes of 95 per cent ethyl alcohol with 1 volume of ether and 2 volumes of water.

*50 Per Cent Hydrochloric Acid.* Mix 1 volume of water and 1 volume of concentrated hydrochloric acid.

*Sulfanilamide Solution.* Dissolve 0.5 g. of pure sulfanilamide powder (*not* the tablets) in a mixture of 30 ml. of glacial acetic acid and 70 ml. of water. Prepare fresh weekly.

*Naphthylethylenediamine Reagent.* Dissolve 0.1 g. of N-(1-naphthyl)-ethylenediamine dihydrochloride (obtainable from Eastman Kodak Co., Rochester, N.Y.) in a mixture of 30 ml. of acetic acid and 70 ml. of water. Prepare fresh weekly.

<sup>283</sup> Tubes should be cleaned with bichromate-sulfuric acid cleaning mixture and rinsed well with distilled water just before using. The presence of even traces of ammonia must be avoided, since ammonia likewise forms an insoluble cobaltinitrite.

colorimeter or photometer. For photometric measurement, set the photometer to zero density at 520  $m\mu$  with a blank prepared by treating 2 ml. of water in a 100-ml. volumetric flask by the procedure described above for 2 ml. of supernatant from the alkali treatment.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.03 \times \frac{10}{3} \times \frac{100}{0.5} = \text{mg. potassium per 100 ml. serum}$$

The standard corresponds to a serum potassium of 20 mg. per cent, covering the range from 10 to 40 mg. per cent satisfactorily. To convert mg. per cent potassium into milliequivalents per liter, divide by 3.9.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.03 \times \frac{10}{3} \times \frac{100}{0.5} = \text{mg. potassium per 100 ml. serum}$$

At 520  $m\mu$ , and in a 1-cm. cuvette, the standard has a density of approximately 0.160, and the agreement with Beer's law is such that up to 35 mg. per cent may be accurately determined. For higher values, or for photometric measurement at greater depth of solution, develop the color on 1-ml. instead of 2-ml. portions of the final standard and unknown supernatants. No change in calculations is involved.

**Interpretation.** The potassium concentration of human blood serum or plasma is relatively constant, ranging from about 16 to 22 mg. per cent, or 4.1 to 5.6 milliequivalents per liter. The potassium content of red cells is from 15 to 20 times as great as that of plasma. This indicates the essential uselessness of whole blood potassium determinations, depending as they must largely on the red cell count, and also emphasizes the importance of preventing hemolysis in obtaining serum or plasma for potassium analyses. The potassium content of plasma gradually increases on standing in contact with red blood cells; this is of importance in connection with the storage of whole blood in blood banks. Pathologically, increased serum potassium has been noted in acute bronchial asthma, in uremia, and in Addison's disease. Decreases have been noted at the time of seizure in familial periodic paralysis. The role of potassium in plasma is unknown; the plasma level may reflect to some extent the level in the body tissues and cells where potassium is abundant, being in fact the chief base present. In the body tissues and cells potassium appears to be the physiological equivalent of the plasma sodium in osmotic pressure regulation and acid-base balance.

## DETERMINATION OF IRON

**Introduction.** The iron-containing compounds of biological material may be divided into two main groups, heme compounds and non-heme compounds. Heme iron is found in such substances as hemoglobin, cytochrome, catalase, etc., where it is firmly bound in organic combination with the porphyrin nucleus (see Chapter 22) and does not react with iron reagents until after liberation from such combination. Nonheme iron on the other hand appears to be largely extractable from tissues by suitable means and can be determined directly in the extracts as inorganic iron. There appears to be a rough correlation between the extractable iron of

tissues and the fraction of the total iron which is absorbable and utilizable by the animal.<sup>284</sup>

Total iron is determined after wet or dry ashing, the iron being estimated in the ash solution by titrimetric<sup>285</sup> or colorimetric methods. Of the many color reagents for iron, the best appear to be thiocyanate,<sup>286</sup> thio-glycollic (mercaptoacetic) acid,<sup>287</sup> *o*-phenanthroline,<sup>288</sup> 2,2'-bipyridyl ("α, α'-bipyridine"),<sup>289</sup> and protocatechuic acid.<sup>290</sup>

The total iron of blood is present almost entirely in the form of hemoglobin; the amount present will therefore vary with the hemoglobin content, and may be used as a measure of the latter (see p. 617). The amount of nonhemoglobin iron in blood is a matter of dispute, particularly with regard to that portion which is said to be in the red cells. According to Shorland and Wall,<sup>291</sup> the total nonhemoglobin iron of human blood is somewhat under 1 mg. per 100 ml. of whole blood, corresponding to about 2 per cent of the total blood iron; other investigators give higher values. Blood plasma contains about 0.1 mg. per cent of iron;<sup>292</sup> plasma iron may be of significance in iron transport and metabolism.

**Determination of Total Iron in Blood, Foods, and Other Biological Material (Methods of Elvehjem and of Kennedy): Principle.** The material is oxidized by ignition or by wet ashing. The acid solution is made alkaline and boiled to change pyrophosphate to orthophosphate. Thiocyanate is added, the ferric thiocyanate extracted with amyl alcohol<sup>293</sup> and determined colorimetrically. The method is suitable for substances relatively high in phosphate (such as milk) and for most biological material. For substances high in iron (as blood) the original procedure of Kennedy or the method of Wong may be used (see p. 617).

**Method of Elvehjem.**<sup>294</sup> Ash a sample of the dried material containing 0.1 to 0.3 mg. of iron.<sup>295</sup> A few drops of nitric acid may be used to get rid of last traces of carbon. Dissolve by digesting with diluted HCl (1:1) at near the boiling point for 15 minutes or longer. Cool, make distinctly alkaline with 40 per cent NaOH (iron-free) and boil for 1 hour. Make acid with about 5 ml. of concentrated HCl and dilute to a volume of 50 ml. To 1 ml. of standard solution of iron<sup>296</sup> (equivalent to 0.1 mg. of Fe), add 5 ml. of concentrated HCl and dilute to 50 ml. Measure 10 ml. portions of standard and unknown

<sup>295</sup> Farrar (*J. Biol. Chem.*, **110**, 685 (1935)) dusts tissue materials with iron-free calcium carbonate prior to ashing, in order to avoid loss of iron as chloride by volatilization.

<sup>296</sup> *Standard Iron Solution.* See p. 617.

into 50-ml. glass-stoppered cylinders. Add to each 10 ml. of amyl alcohol and 5 ml. of 20 per cent potassium thiocyanate. Shake thoroughly. Remove the colored layers of amyl alcohol with a pipet and compare in the colorimeter or determine the densities of standard and unknown in a photometer at 480  $m\mu$ . Set the photometer to zero density with a blank prepared as follows: dilute 5 ml. of concentrated HCl to 50 ml. with water, mix, and treat a 10-ml. portion with amyl alcohol and thiocyanate, shaking as described for standard and unknown. Remove the amyl alcohol layer and use as a photometric blank.

**Method of Kennedy.**<sup>297</sup> Transfer 1 ml. of blood or a weighed piece of tissue to a 100-ml. Kjeldahl flask. Add 5 ml. of concentrated  $H_2SO_4$  and 2 ml. of 60 per cent perchloric acid. Digest over a low flame until solution is colorless and dense fumes of  $SO_3$  come off (about 10 minutes). Perhydrol may be used instead of perchloric acid. Cool, add a drop of nitric acid, and dilute to 100 ml. Carry out the same procedure on standard iron solution. Determine iron in 10-ml. aliquots exactly as in the preceding method.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. Fe in standard} \times \frac{100}{\text{aliquot used}} = \text{mg. iron per 100 g. or ml.}$$

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. Fe in standard} \times \frac{100}{\text{aliquot used}} = \text{mg. iron per 100 g. or ml.}$$

The photometric characteristics of the thiocyanate color in amyl alcohol are similar to those already given in connection with the Wong blood iron method (p. 618). Any of the other color reagents for iron which have already been mentioned (thioglycollic acid, *o*-phenanthroline, etc.) may be used instead of thiocyanate, under the proper conditions. For details, see original papers.

## DETERMINATION OF SULFONAMIDES ("SULFA DRUGS")

**Introduction.**<sup>298</sup> The "sulfa drugs" in clinical use are derivatives of the parent compound, sulfanilamide or *p*-aminobenzenesulfonamide. The structures of sulfanilamide, acetylsulfanilamide, and sulfapyridine are shown here, representing the general structures of the many "sulfa" drugs.

Sulfanilamide

Acetylsulfanilamide

Sulfapyridine

<sup>297</sup> Kennedy: *J. Biol. Chem.*, 74, 385 (1927).

<sup>298</sup> For historical reviews, see Krantz: *J. Am. Dent. Assoc.*, 31, 634 (1944); Fosbinder: *J. Am. Pharm. Assoc.*, 33, 1 (1944).

No sulfonamides are found in blood or urine unless they have been administered; the level attained depends upon such factors as the size and rate of administration of the dose, the body weight of the individual, and the rates of absorption and elimination. The therapeutically effective level depends upon both the disease and the drug; blood analysis permits definition of blood sulfonamide concentration so that a given level may be altered or maintained as conditions warrant. A variable portion of the total blood sulfonamide, the exact amount depending largely upon the type of sulfonamide being used, is usually present as the acetylated derivative<sup>299</sup> (e.g., acetylsulfanilamide). Acetylation involves the amino group attached to the benzene ring. Marked differences exist between the free and the acetylated compound in respect to both therapeutic and toxic properties; distinction is therefore important. Acetylation appears to occur largely in the liver. Other metabolic derivatives of certain of the sulfonamides are known, such as hydroxy derivatives, possibly combined with glucuronic acid;<sup>300</sup> the significance of these is somewhat obscure.

**Determination of Sulfonamides (Method of Bratton and Marshall):**<sup>301</sup>

**Principle.** Blood is deproteinized with trichloroacetic acid. The protein-free filtrate is treated with nitrous acid to diazotize any free sulfonamide present, excess nitrous acid is destroyed, and the diazotized sulfonamide is coupled with N-(1-naphthyl)-ethylenediamine to form a stable red color which is then compared with that developed in a standard treated in the same way. The procedure is the same for all the common sulfonamides which have a diazotizable amino group in the molecule, the only difference being that a standard containing the particular sulfonamide being determined is used in each case. Since acetylation renders the sulfonamide incapable of diazotization, only the unacetylated sulfonamide will react in the colorimetric procedure. To determine acetylated sulfonamide, total sulfonamide is determined after acid hydrolysis, which frees the amino group. The difference between free and total sulfonamide represents acetylated sulfonamide.

**Procedure.**<sup>302</sup> Measure 2 ml. of oxalated blood into a small flask and from a

<sup>299</sup> Marshall, Bratton, and Litchfield: *Science*, **88**, 597 (1938).

<sup>300</sup> Scudi: *Science*, **91**, 486 (1940); also Scudi and Jelinek: *J. Pharmacol.*, **81**, 218 (1944).

<sup>301</sup> Bratton and Marshall: *J. Biol. Chem.*, **128**, 537 (1939).

<sup>302</sup> Reagents Required: *Saponin Solution*. Dissolve 0.5 g. of saponin in water and dilute to 1 liter. This solution is not absolutely necessary, the saponin merely serving to hasten hemolysis of the red cells. The blood may be laked with water instead of saponin solution, in which case the diluted blood is allowed to stand 15 minutes before adding the trichloroacetic acid.

*15 Per Cent Trichloroacetic Acid*. Dissolve 150 g. of reagent-grade trichloroacetic acid in water and dilute to 1 liter. Stable indefinitely. To prepare a 3 per cent solution from this, dilute 1 volume with 4 volumes of water.

*Sodium Nitrite Solution*. Dissolve 0.1 g. of pure sodium nitrite in water and dilute to 100 ml. Prepare fresh daily.

*Ammonium Sulfamate Solution*. Dissolve 0.5 g. of ammonium sulfamate in water and dilute to 100 ml. Stable indefinitely.

*N-(1-Naphthyl)-ethylenediamine Solution*. Dissolve 0.1 g. of N-(1-naphthyl)-ethylenediamine dihydrochloride (obtainable from Eastman Kodak Co., Rochester, N.Y.) in water and dilute to 100 ml. Store in a dark glass bottle in the cold. Prepare fresh each week.

*4 N Hydrochloric Acid*. Dilute 40 ml. of concentrated hydrochloric acid to 100 ml. with water. Mix and titrate a 5-ml. portion with standard 1 N sodium hydroxide. Adjust to exactly 4 N. Stable indefinitely.

*Standards*. Prepare a *stock standard* as follows: dissolve in water exactly 0.1 g. of the particular sulfonamide being determined, and transfer with rinsings to a 1-liter volumetric flask. Dilute to the mark with water, and mix. In preparing this standard, use the pure pow-

buret add 30 ml. of saponin solution. Allow to stand for several minutes, then add 8 ml. of 15 per cent trichloroacetic acid solution. Mix well, allow to stand 5 minutes, and pour onto a dry filter.

**Free Sulfonamide.** Transfer 10 ml. of the protein-free filtrate to a small flask or wide test tube, add 1 ml. of sodium nitrite solution, and mix. Allow to stand 3 minutes, then add 1 ml. of ammonium sulfamate solution and again mix. After 2 minutes' standing, add 1 ml. of the N-(1-naphthyl)-ethylenediamine solution and mix. The color develops almost immediately and is stable for several hours if not exposed to direct sunlight. Read the color in a colorimeter or photometer as described below.

**Total Sulfonamide.** Transfer 10 ml. of the protein-free filtrate to a test tube or other container graduated at 10 ml. and add 0.5 ml. of 4 N hydrochloric acid. Place in a boiling water bath for 1 hour, cool, and adjust the volume to 10 ml. with water. Treat with sodium nitrite solution, etc., just as described above for free sulfonamide.

#### CALCULATION.<sup>303</sup>

For colorimetric measurement, compare the color developed on the unknown with that obtained by treating a 10-ml. portion of standard solution in the same manner as the unknown. Since the concentration of sulfonamide in blood may vary widely, several standards should be prepared and the unknown matched against the most suitable one. Satisfactory standards contain 1.0, 0.5, and 0.2 mg. per cent of the sulfonamide. At a blood dilution of 1:20, these standards correspond to blood levels of 20, 10, and 4 mg. per cent respectively. It is convenient to set the 1-mg. standard at 10 mm. in the colorimeter, the 0.5 mg. standard at 15 mm., and the 0.2 mg. standard at 20 mm.

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 20 \times \text{mg. per cent concentration of standard} \\ = \text{mg. per cent free (or total) sulfonamide in blood}$$

For photometric measurement, transfer the colored solution to a suitable container and read in a photometer at 530 m $\mu$ .<sup>304</sup> Set the photometer to zero density with a blank obtained by treating a 10-ml. portion of 3 per cent trichloroacetic acid with nitrite, sulfamate, etc., as in the treatment of the unknown. From the photometric density of the unknown, and the density of a known standard, preferably determined at the same time, calculate as follows:<sup>303</sup>

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 20 \times \text{mg. per cent concentration of standard} \\ = \text{mg. per cent free (or total) sulfonamide in blood}$$

---

dered drug, *not* the tablets. This standard is stable for months in the cold. To prepare *dilute standards* containing 1.0, 0.5, and 0.2 mg. per cent, measure 10, 5, and 2 ml. respectively of the stock standard into 100-ml. volumetric flasks containing 18 ml. of 15 per cent trichloroacetic acid. Dilute with water to the 100 ml. mark and mix. Store in the cold, and prepare fresh every few days.

<sup>303</sup> With some of the sulfonamides, correction factors are necessary to correct for drug lost during the precipitation of the proteins. With sulfanilamide, sulfaguanidine, sulfapyridine at levels less than 5 mg. per cent, and free sulfathiazole, no correction factors are needed. For sulfapyridine levels greater than 5 mg. per cent, multiply the results for both free and total drug by 1.1 to obtain the correct values. For acetylated sulfathiazole, subtract the uncorrected free value from the uncorrected total value and multiply the difference by 1.3.

<sup>304</sup> Filters or wavelength settings from 520 to 540 m $\mu$  give equally satisfactory results (see Fig. 167).

The density of a standard containing 0.2 mg. per cent sulfonamide in a 1-cm. cuvette is approximately 0.300 at 530  $m\mu$  (Fig. 167). This means that at this solution thickness, bloods containing up to about 10 to 12 mg. per cent sulfonamide may be read satisfactorily, since agreement with Beer's law is excellent over a wide range. Higher concentrations produce colors which are too deep for precise measurement, and in such cases the determination must be repeated at a greater dilution of the blood (or of the 1:20 filtrate, diluted with 3 per cent trichloroacetic acid). If a solution thickness greater than 1 cm. is used in the photometer, the range of reading is proportionately reduced. If some dilution other than 20 is used, this dilution should replace the 20 in the above calculations. Bratton and Marshall point out that dilutions of 1:50 or 1:100 may be employed in this procedure if photometric measurement is used, thus permitting

FIG. 167. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN BRATTON-MARSHALL SULFONAMIDE METHOD.

For standards containing (a) 0.25 mg. per cent, and (b) 0.50 mg. per cent sulfadiazine. Solution depth, 1 cm.

the use of fingertip blood (0.1 to 0.2 ml.). The only precaution is that the final concentration of trichloroacetic acid in the protein-free aliquot taken for analysis should be 3 per cent.

**Interpretation.** The major factors influencing the level of blood sulfonamide content have already been presented (p. 658); depending upon circumstances, the total blood sulfonamide concentration may range from a trace to as high as 20 mg. per cent or more, with a variable proportion of this in the acetylated form. It is the level of *free* drug which is of therapeutic importance; it is usually considered clinically that effective levels of free sulfonamide range from 3–7 mg. per cent for sulfathiazole to as high as 15 mg. per cent for sulfanilamide and sulfadiazine. Those metabolic derivatives other than acetylated forms which have thus far been recognized do not appear to require hydrolysis before reacting in the colorimetric procedure, and will therefore be included in the value for free sulfonamide content; the extent to which this occurs, and the precise significance of these derivatives has not as yet been evaluated.

## DETERMINATION OF PROTEIN-BOUND IODINE

**Method of Chaney:**<sup>305</sup> **Principle.** The iodine-containing hormones (thyroxine and triiodothyronine), along with other organic compounds containing iodine, if present, are precipitable with serum proteins by tungstic acid, zinc hydroxide, etc.

By digestion of the protein precipitate with chromic-sulfuric acids, the iodine is oxidized to iodic acid which remains in the acid digest. Other halides and volatile products of oxidation are distilled off during the digestion.

On adding an excess of reducing agents, the iodic acid is reduced, and iodine distilled off in a special still and collected in dilute alkali and arsenite. The concentration of iodine in the distillate is measured by its catalytic effect on the rate of reduction of ceric salts by arsenious acid. This may be done by a series of colorimeter readings at 5-minute intervals, or by a continuous recording colorimeter. The method is suitable for determination of trace quantities of iodine in serum, tissue, or other biological material, in the range of 0.01 to 1  $\mu\text{g}$ .

**Procedure.** The proteins in 3 ml. of serum or plasma are precipitated by 30 ml. of tungstic acid (1 volume  $\frac{2}{3}$  N sulfuric acid, 1 volume 10 per cent sodium tungstate, 16 volumes water), or 24 ml. of zinc sulfate (1.25 per cent) and 3.0 ml. of sodium hydroxide (0.75 N) in a 50-ml. centrifuge tube, and the clear supernatant liquid is tested by the catalytic method (see below) for the presence of interfering quantities of inorganic iodide. If the serum contains more than 25  $\mu\text{g}$ . of inorganic iodine per 100 ml., additional washing of the protein precipitate is required.

The protein precipitate is then dissolved in 20 ml. of sulfuric acid (78 per cent by weight and iodine-free) and transferred with the aid of 15 ml. additional sulfuric acid to a 300-ml. two-necked digestion flask containing 2 ml. of chromic acid (concentration 100 g./100 ml.). Digestion is carried out for a period of about 10 minutes over a 350 watt electric heater till the temperature reaches about 230° C. The digest is allowed to cool, 15 ml. of water added, and the flask reheated to a temperature of 200° C.

After cooling and diluting with 20 ml. of water, the flask is attached to the special still and condenser and each of the following added through a side tube, to reduce iodic acid and the excess chromic acid in the digest: 1 ml. 8 M phosphorous acid, 1 ml. 0.45 N arsenious acid and 1 ml. 1.5 per cent hydrogen peroxide. To the still trap is added 1 ml. of 1 N potassium hydroxide and distillation is carried out for 6 minutes. The distillate in the trap is run into a tube calibrated at 12 ml., containing 0.25 ml. of 0.15 N arsenious acid, and diluted to volume.

FIG. 168. IODINE DISTILLATION APPARATUS.

Courtesy, Dr. Albert L. Chaney.

<sup>305</sup> Chaney: *Ind. Eng. Chem. Anal. Ed.*, **12**, 179 (1940); Taurog and Chaikoff: *J. Biol. Chem.*, **163**, 313 (1946); Barker: *J. Biol. Chem.*, **173**, 715 (1948); Connor, Curtis, *et al.*: *Surgery*, **25**, 510 (1949); Kydd, Man, and Peters: *J. Clin. Invest.*, **29**, 1033 (1950); Chaney: *Anal. Chem.*, **22**, 939 (1950).

The iodine concentration in the distillate is measured by taking a 4 ml. aliquot in a colorimeter tube, adding 0.5 ml. of 0.15 N arsenious acid, and 0.5 ml. of 0.10 N ceric sulfate in 3.5 N sulfuric acid, and measuring the rate of color fading at a constant temperature (30° C.), and comparing this rate with that of known quantities of iodine (0.01-0.6  $\mu\text{g.}$ ) diluted with similar amounts of alkali, arsenious acid, and ceric sulfate. Color measurements are made at 5-minute intervals, using a blue filter (480  $\text{m}\mu$ ), and the rate of color change calculated or plotted.

Reagents should be specially selected and purified if necessary so that iodine content of quantities required for a complete determination does not exceed 0.03-0.05  $\mu\text{g.}$

**Interpretation.** Normal serum protein-bound iodine values range from 4 to 8  $\mu\text{g.}$  per 100 ml. In hyperthyroidism, values range from 8 to 30  $\mu\text{g.}$  per 100 ml., while in hypothyroid states, levels are 0 to 4  $\mu\text{g./100 ml.}$  Low values are also sometimes found in nephrosis and other conditions with very low serum proteins. In pregnancy a mild elevation of protein-bound iodine occurs. False high values may occur following administration of "Lipiodol," x-ray diagnostic agents ("Priodax," "Neo-Iopax," "Skiodan"), "Itrumil," and "Diodoquin."

## CLINICAL MICROCHEMICAL ANALYSIS

The following discussion of clinical microchemical analysis is a brief introduction to the field, offered to the reader to encourage him to venture in and apply his ingenuity in solving problems related to the analysis of small amounts of biological fluids. Brevity precludes adequate

† 1 liter = 1,000 milliliters = 1,000,000 microliters.

recognition of the numerous original workers who did the pioneering. The definition of microchemical analysis is difficult because of the prevalence of numerous descriptive terms. The table on page 662 contains some of the terms, abbreviations, and usages. The examples of analytical microtechniques used in clinical chemistry reflect the range of measurements encountered. Where concentrations **are** high (e.g., protein in plasma = 70,000  $\mu\text{g./ml.}$ ), minute volumes **may** be used for analysis; however, where low (e.g., protein-bound iodine in plasma = 0.05  $\mu\text{g./ml.}$ ), larger volumes must be used.

It should be noted that many clinical chemical determinations of necessity are microtechniques, because they deal with trace amounts of material. For example, quantities as small as 0.5  $\mu\text{g.}$  of coproporphyrin in 5 ml. of urine, 0.1  $\mu\text{g.}$  of tryptophan in 0.02 ml. serum, or 0.05  $\mu\text{g.}$  of iodine in 1 ml. serum may be concerned in a routine analysis. These figures indicate that minuteness of sample volume is not a consistent guide to the minuteness of substance measured.

The advantages of microchemical procedures in clinical chemistry are numerous. For example, where serial chemical data on infants are desired, standard procedures and their required volumes of blood are impractical. Sobel<sup>306</sup> and Natelson<sup>307</sup> have developed routine procedures requiring but a few drops of blood, readily obtained from the fingertip or heel of the infant. Lowry, Bessey, and co-workers developed micro-methods for mass nutritional surveys, using fingertip blood for serum proteins,<sup>308</sup> alkaline phosphatase,<sup>309</sup> vitamin A,<sup>310</sup> vitamin C,<sup>311</sup> iron,<sup>312</sup> riboflavin,<sup>313</sup> tocopherols,<sup>314</sup> and thiamine.<sup>315</sup>

In addition to savings in equipment (syringes, glassware, reagents, and laboratory, refrigerator, and centrifuge space) it was possible to make great savings in time and perform these analyses at the commendable rate of 50 per hour. Blood chemistry in small animals also requires microtechniques.

Certain characteristics of microchemical analysis are uniquely favorable. For example, dry ashing of 10  $\mu\text{l.}$  of serum takes a few minutes, whereas larger amounts require considerably more time. In the analysis for calcium, if proteins are to be removed, ashing is easier than protein precipitation and collection of the supernatant fluid. In analyses using microdiffusion for separation, the rates of diffusion can be increased by reducing the reaction volumes.

Some disadvantages are the special requirements of apparatus, skills, and methodology. Kirk<sup>316</sup> has pointed out, however, that there is no sacrifice of accuracy in microchemistry.

<sup>316</sup> Kirk: *Quantitative Ultramicroanalysis*, New York, John Wiley & Sons, Inc., 1950.

No new physicochemical laws apply to microchemistry. In classical methods requiring about 1 millimole of material,  $6 \times 10^{20}$  molecules are measured; in microchemistry about  $6 \times 10^{15}$  molecules are measured, which is still a large number of molecules. This implies that reactions which take place stoichiometrically with large quantities of substance ought to work with smaller amounts, and in practice, almost all good clinical chemical procedures can be performed on smaller amounts of material. Most of the facilities for measurement are limited by final concentrations of the desired substance. A major device, then, in microchemistry is to limit the volume of the final reaction mixture. For example, in the titration of 50 ml. of 0.01 N HCl with 0.01 N NaOH using methyl red as the indicator, 100 ml. of final reaction mixture is obtained at the end point. With the addition of 0.05 ml. (0.1 per cent of the titrating agent) a visible change in end point occurs. By reducing the volume from 100 ml. to 0.1 ml., an increment of 0.1 per cent of the titrating agent should visibly affect the end point. If there is no sacrifice in accuracy of measurement, the analysis is reduced from the measurement of 500  $\mu$ eq. to 0.5  $\mu$ eq. with no loss in sensitivity at the small scale of analysis. The same is true for colorimetry. For example, 50  $\mu$ l. of normal blood (1.0 ml. of 1:20 filtrate) containing about 50  $\mu$ g. of glucose, when analyzed for glucose, will give sufficient blue color in a final volume of 25 ml. to be measured in any colorimeter. Reducing the reaction mixture to 1 ml. and measuring the color in a suitable colorimeter allows the measurement of 2  $\mu$ g. of glucose (equivalent to 2  $\mu$ l. of blood).

Other approaches include the use of special sensitive measurements such as fluorimetric, microbiologic, catalytic, enzymatic, spectrophotometric, and other methods of analysis which use specific chemical, biological, or physical properties of the substance being measured. The possible adaptations to microclinical chemistry are innumerable and are facilitated by the ingenuity of the analyst and good equipment.

## APPARATUS AND TECHNIQUES

Precise microweighing in clinical chemistry is possible but not essential. Measurements involving microprecipitates are made colorimetrically or titrimetrically. For example, calcium precipitated as the phosphate is measured colorimetrically, and calcium precipitated as the oxalate is measured titrimetrically. Most standards are weighed on ordinary analytical balances and diluted to suitable volumes.

Trace materials can usually be isolated, purified, and concentrated by chromatography (resin, paper, silica gel, alumina, etc.) or countercurrent distribution (see Chapter 1). Special methods may require special equipment which can either be made by the analyst or purchased.

**Micropipets.** Several excellent micropipets<sup>317</sup> have been described and successfully used. Three are shown in Fig. 169. The pipet (A) of Sisco, Cunningham, and Kirk,<sup>318</sup> which delivers from 1 to 1000  $\mu$ l. is widely used

<sup>317</sup> Microchemical Specialties Co., 1834 University Ave., Berkeley, Calif., lists about 12 types of micropipets ranging in volume from 0.25 to 1000  $\mu$ l.

<sup>318</sup> Sisco, Cunningham, and Kirk: *J. Biol. Chem.*, **139**, 1 (1941).

and readily available commercially. The straight tube pipet (*B*) is simple, is easy to construct and calibrate, and can deliver accurately volumes of 1 to 1000  $\mu\text{l}$ . or more. *C* represents a self-filling pipet used for automatically measuring 1 to 10  $\mu\text{l}$ . This type may also be used as an overflow pipet. The constriction-type pipet made by Levy<sup>319</sup> is a very convenient micropipet delivering from 1 to 500  $\mu\text{l}$ . when properly made and used. Levy,<sup>319</sup> Lowry,<sup>309</sup> and Natelson<sup>307</sup> provide details of construction. As an alternative, straight-tube blowout pipets (Fig. 169, *B*) with fine tips may be used. When rinsed with water or reaction mixture, they will deliver contained volumes with errors of 0.1 to 0.5 per cent. Pipets of over 20  $\mu\text{l}$ .

when emptied by drainage alone will deliver volumes with 1 per cent error or less. The error is smaller in the larger pipets. Siliconed pipets deliver the contained volume without drainage error;<sup>320</sup> hence they can achieve excellent replicability down to 0.1 per cent error. Furthermore, the complete drainage eliminates the need for rinsing between samples. This advantage fails with whole blood but holds with blood filtrates. Pipets are calibrated to contain or to deliver, depending upon their use. The delivered or contained (as desired) weight of water is a convenient basis for calibrating pipets. The weight of water in mg.  $\times 1.004$  (at 25° C.) gives the volume in  $\mu\text{l}$ . Mercury weight (in mg.) delivered  $\times 0.0739$  is the volume in  $\mu\text{l}$ . Other convenient methods involve measuring the delivered quantity of chloride, acid, or dye from a solution of known concentration. Unsiliconed pipets

used to deliver should be emptied slowly and for the length of time specified in the calibration, and then the remaining contents should be emptied by gently blowing while the pipet is rotated slowly to transfer the tip contents onto the wall of the container. A fine tip allows excellent replication.

**Microburets.** There are a number of suitable, ingenious microburets described in the literature, many of which are made commercially. Especially satisfactory is the Scholander<sup>321</sup> type, an example of which is shown in Fig. 170. This buret was made from a machinist's 1-inch microm-

FIG. 169. MICROPIPETES.

*A*, Pipet of Sisco, Cunningham, and Kirk; *B*, straight tube pipet; *C*, self-filling or overflow pipet, depending upon how it is used.

<sup>319</sup> Levy: *Compt. rend. trav. lab. Carlsberg, Ser. chim.*, **21**, 101 (1936).

<sup>321</sup> Scholander: *Science*, **95**, 177 (1942).

eter, which can be obtained with a scale calibrated in very small fractions of a millimeter or inch. As the micrometer is turned clockwise it propels the spindle into the mercury as shown in Fig. 170 and displaces a volume equivalent to the volume of the shaft that enters the mercury, simultaneously displacing an equal volume of the standard solution above the mercury. A fine opening in the buret tip prevents back diffusion of the reaction mixture into the buret. A titration is made to the desired end

FIG. 170. SCHOLANDER MICROBURET AS USED WITH THE MICROTITRATION TABLE SHOWN IN FIG. 171.

The setup shown is for the electrometric determination of chloride: *a*, 1-inch micrometer and rod used for holder; *b*, gasket; *c*, set screw and metal plate; *d*, glass buret; *e*, mercury; *f*, carbon tetrachloride; *g*, special electrodes; *h*, 15 × 15 mm. vial which holds 1 ml. of reaction mixture; *i*, vial-holder attached to shaft of titrator.

point, whereupon a reading of the micrometer is made and a new titration is begun. The tip is not washed between titrations. After the buret is emptied, more standard reagent is added by turning the micrometer handle counterclockwise. The tip should be wide enough to allow rapid filling without pulling in air through the joint. The usual micrometer will deliver about 30  $\mu$ l. per mm. (or 75  $\mu$ l. per 0.1 inch) and the buret will deliver this volume to  $\pm 0.03$   $\mu$ l. or 0.1 per cent. For ordinary work one filling of standard solution will provide for 8 to 25 continuous titrations. Smaller deliveries with equal precision can be achieved by reducing the diameter of the shaft which enters the mercury.

The mercury displacement buret has been criticized on three points:

(1) expansion with heat, (2) leaks through couplings, and (3) reaction of mercury with reagents above it. Expansion errors are negligible when wide temperature fluctuations are avoided. Leaks are rare in properly maintained burets. The problem of reagent interaction with mercury is com-

FIG. 171. MICROTITRATION TABLE WITH MOUNTED SCHOLANDER BURET.

The vial fits into a holder attached to the rotator. The latter can be raised and lowered. The buret tip functions as a stirring rod.

Courtesy, Walter Reed Army Medical Center, Washington, D. C.

pletely eliminated for most aqueous reagents by interposing a 3 to 5 mm. (about 0.3 ml.) layer of carbon tetrachloride between reagent and mercury.

A microtitration table,<sup>322</sup> devised so that the buret described here can readily be mounted, is shown in Fig. 171. When the vessel into which the

<sup>322</sup> Made by H. Kugler, College Park, Md.

buret tip is immersed is rotated rapidly the buret tip stirs the reaction mixture. Reaction vessels from 0.1 to 5 ml. may be used, and rotated at 300 to 900 r.p.m. Any sensitive indicator or special electrodes using standard equipment and circuits can be used for titrations. At the end point the rotating shaft is lowered, a new titration vessel is inserted into the holder, and the shaft is raised into position for the new titration. Glass vials of a suitable diameter are cut to vertical size for titration vessels. A white penicillin-bottle stopper<sup>323</sup> is suitable for holding volumes of 100  $\mu$ l. Acidimetric titrations in 1-ml. volumes may be performed using a standard pH meter fitted with glass, quinhydrone, or antimony electrodes; the latter two kinds of electrodes have been used routinely in 100  $\mu$ l. volumes. Titration curves of excellent quality and

FIG. 172. DIAGRAM OF CONWAY DIFFUSION CELL.

accuracy are obtained. The calomel half cell (see p. 47) is made from a sidearm test tube with the sidearm bent and drawn out to a fine tip. Agar is used to plug the tip, which is inserted into the titration vessel along with the opposite electrode and the buret tip.

**Reaction Vessels.** Titration vessels can be made from glass vials cut to a suitable size. Standard small test tubes of 3-ml. (10  $\times$  75 mm.) or 1-ml. (6  $\times$  50 mm.) volume serve as reaction vessels which can be heated, cooled or otherwise manipulated. Such test tubes can also be made into volumetric flasks. Small centrifuge tubes from 0.1 ml. up and high speed microcentrifuges are available commercially.

**Microdiffusion Apparatus.** The Conway cell<sup>324</sup> (Fig. 172) for diffusion has been well and universally studied and applied. In conventional use, the reaction mixture is placed in the outer chamber and the receiving solution in the inner chamber. The dish is sealed with a lubricated glass plate. Any liberated gas diffuses from the outer to the inner chamber. In the determination of  $\text{NH}_3$ , the inner chamber contains HCl or other suitable acid; for the determination of  $\text{CO}_2$ , the inner chamber contains  $\text{Ba}(\text{OH})_2$ . The determination is made by titrating the solution in the inner chamber or withdrawing the contents for colorimetric analysis.

In Fig. 173 is shown a similar cell made from a 15 mm.  $\times$  15 mm. vial

FIG. 173. MICRODIFFUSION CELL.

A, 15  $\times$  15 mm. vial; B, reaction mixture which liberates gas or absorbs it; C, rubber penicillin-bottle stopper; D, well in the stopper which contains solution that receives gas or liberates it. In the determination of  $\text{CO}_2$ , gas is liberated with lactic acid at B and received in  $\text{Ba}(\text{OH})_2$  at D. In the determination of ethanol, blood is placed at D and the liberated ethanol is oxidized by acid dichromate at B.

<sup>323</sup> Type S-46 obtained from T. C. Wheaton Co., Millville, N. J.

<sup>324</sup> Conway: *Microdiffusion Analysis and Volumetric Error*, London, Crosby Lockwood & Son, Ltd., 1950.

(A) to contain the reaction mixture, and a penicillin-bottle stopper (C) for the receiver. In the determination of bicarbonate,<sup>325</sup> acid is placed at B, and a measured quantity of  $\text{Ba}(\text{OH})_2$  is placed at D. The sample (blood) is introduced into the vial and the liberated  $\text{CO}_2$  is received by diffusion into the  $\text{Ba}(\text{OH})_2$  above. The stopper (D) is inverted and placed on the titrator and the excess  $\text{Ba}(\text{OH})_2$  is measured acidimetrically. Another example of the use of this cell is in the measurement of blood alcohol where 50 to 100  $\mu\text{l}$ . of blood are placed in stopper D and 0.500 ml. of standard

FIG. 174. DIFFUSION BOTTLES FOR THE DETERMINATION OF  $\text{NH}_3$ .

A, Penicillin-type bottle; B, streptomycin-type bottle; C, glass receiving rod,  $6 \times 90$  mm., with a constriction 10–15 mm. from the end. The stippled area represents a roughened surface (ground) to aid in retaining the film of acid which receives the diffused  $\text{NH}_3$ . D, cap for bottle B.

acid dichromate in the vial at B. The diffused alcohol is measured by titrating the excess dichromate remaining after oxidation of the ethanol.

Another group of diffusion cells<sup>326</sup> is shown in Fig. 174. A is a standard penicillin bottle.<sup>327</sup> C is a glass rod fitted into a penicillin-bottle stopper. The rod has a constriction at one pole. The tip surface is ground so that when inserted into acid it will retain a film of the acid. A sample containing  $\text{NH}_3$  is introduced into A. The final volume is adjusted to 1.0 ml. The solution is made alkaline with  $\text{K}_2\text{CO}_3$  crystals; the receiving rod, previously dipped into 1 N  $\text{H}_2\text{SO}_4$  to the constriction, is inserted into A and closed. The entire cell may be placed in a rotator (Fig. 175) and rotated so that diffusion is accelerated. The  $\text{NH}_3$  collected on the receiv-

<sup>327</sup> Type S-205, NO-SOL-VIT bottle, T. C. Wheaton Co., Millville, N. J.

ing rod is measured colorimetrically. *B* is a streptomycin<sup>328</sup> bottle in which a Kjeldahl determination may be carried out.

**Photometry.** Any one of the several available photoelectric colorimeters may be used for microchemistry. The Lowry and Bessey adaptation for the Beckman spectrophotometer has the advantage that volumes down to 25  $\mu$ l. can be examined over a wavelength range from 235 to 935  $m\mu$ . Microcuvettes<sup>329</sup> ( $3 \times 10 \times 25$  mm. inside measurements) hold 0.8 ml. and may be used in some of the newer instruments without

FIG. 175. ROTATOR FOR FACILITATING DIFFUSION OF  $\text{NH}_3$  IN BOTTLES SHOWN IN FIG. 174.

Courtesy, Walter Reed Army Medical Center, Washington, D. C.

special carriers. For smaller volumes a sheet of metal with a 1.0–1.4 mm. hole narrows the beam of light so that it will pass through 100  $\mu$ l. or less. Lowry states that rinsing between samples is often unnecessary in serial determinations of similar samples. Siliconed cuvettes eliminate the need for rinsing.

## CLINICAL MICROCHEMICAL PROCEDURES

**Determination of Urinary Ammonia Nitrogen:**<sup>326</sup> **Principle.** Ammonium ions are converted to  $\text{NH}_3$  by alkalization; the liberated  $\text{NH}_3$  gas is collected by diffusion and measured colorimetrically. The working range is 5 to 15  $\mu$ g. of  $\text{NH}_3\text{-N}$ ; it may be reduced to 0.5–1.5  $\mu$ g. by suitable adjustments. This basic method is applicable to

<sup>328</sup> Type S-281, NO-SOL-VIT bottle, T. C. Wheaton Co., Millville, N. J.

<sup>329</sup> Pyrocell Manufacturing Co., 207 E. 84th St., N. Y. C.

every system which liberates  $\text{NH}_3$  stoichiometrically. For example, urease will hydrolyze urea, acid will hydrolyze amides (glutamine, urea, etc.), and ninhydrin will oxidize amino acids to liberate  $\text{NH}_3$ . The classical Kjeldahl method can also be applied as illustrated below.

**Procedure.**<sup>330</sup> Add 50  $\mu\text{l}$ . of urine to a diffusion bottle (A, Fig. 174); add water to 1.0 ml. and 1 g.  $\text{K}_2\text{CO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$ . Stopper with the receiving rod (C, Fig. 174) previously dipped to the indentation in 1 N  $\text{H}_2\text{SO}_4$ . Place the bottle on the rotator (Fig. 175) and rotate for 30 minutes (complete diffusion). Transfer the rods to clean bottles or cuvettes and wash the acid into the bottle or cuvette with 10.0 ml. of diluted Nessler reagent. Read in 5 minutes at 420  $\text{m}\mu$  and compare with a standard (1.0 ml.) and a blank (1.0 ml. of water) treated as described for the diluted urine sample.

If speed is essential, rotation may be stopped at 10 minutes and the incomplete diffusion (90 per cent) corrected by comparing unknowns to similarly run standards. If smaller amounts of Nessler reagent are used, the working range diminishes accordingly. One  $\mu\text{g}$ . of nitrogen per ml. of Nessler reagent is a good ratio. After diffusion the collected  $\text{NH}_3$  on the receiving rod can be stored in a clean bottle and measured at the analyst's convenience. The error is 1–2 per cent. Where air contamination by  $\text{NH}_3$  is a problem, equipment should be rinsed and dried before use.

**Determination of Urea in Blood, Urine, Serum, or Other Biological Fluids:**<sup>331</sup>

**Principle.** The method above is applied by measuring the  $\text{NH}_3$  liberated by the hydrolysis of urea with urease. The same apparatus is used.

**Procedure.** Transfer 50  $\mu\text{l}$ . of serum or 10  $\mu\text{l}$ . of urine to a diffusion bottle, make to 1.0 ml. with 0.05 M phosphate buffer, pH 7.0, and add 1 drop of fresh 5 per cent urease suspension. After 15 minutes at 40° C., add 1 g.  $\text{K}_2\text{CO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$  and cap with a stopper and receiving rod previously dipped in 1 N  $\text{H}_2\text{SO}_4$ . Rotate for 30 minutes. Measure the collected  $\text{NH}_3$  as described above, comparing with  $\text{NH}_3$  standards and a reagent blank. Correct urine for contained  $\text{NH}_3$ , determined as described above. Fresh blood or serum requires no correction. Measurements can be made on 5  $\mu\text{l}$ . of sample if desired.

Analyses of a sample of urea on 8 different days produced a standard error of 0.5 per cent. All the usual precautions for protecting urease apply.

**Determination of Total Nitrogen by Kjeldahl Digestion and Microdiffusion:**<sup>326</sup> **Principle.** The sample is digested with a concentrated acid digestion mixture until all of the nitrogen present has been converted into ammonia. The ammonia is released by alkali as usual, and collected by microdiffusion. The collected ammonia is determined colorimetrically. The method as described is for the determination of non-protein nitrogen (NPN) in a protein-free plasma filtrate. It is equally applicable to the determination of total N in urine, plasma proteins, etc. The size of sample should be such as to contain not more than approximately 15  $\mu\text{g}$ . of total N.

<sup>330</sup> Reagents Required: Standard  $(\text{NH}_4)_2\text{SO}_4$ , 15  $\mu\text{g}$ . N per ml.

1 N  $\text{H}_2\text{SO}_4$ .

$\text{K}_2\text{CO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$  Crystals. Fit bottle with spoon to deliver about 1 g.

Nessler Reagent of Vanselow (Ind. Eng. Chem., Anal. Ed., 12, 516 (1940)). Dissolve 34.9 g. KI and 45.5 g.  $\text{HgI}_2$  in as little water as possible. Add 112 g. KOH and water to 1 liter; let stand 3 days; dilute 1:5 before using.

<sup>331</sup> Seligson and Bollier: To be published.

**Procedure.**<sup>332</sup> A protein-free filtrate is obtained by adding 9 parts of 3.0 per cent trichloroacetic acid to 1 part of plasma, and filtering. Add 0.5 ml. of 1:10 filtrate (equivalent to 50  $\mu$ l. of serum) or other sample to the hard glass bottle (B, Fig. 174) followed by 1.0 ml. of digestion mixture. Heat slightly on a hot plate to just short of boiling, and continue heating until all traces of water disappear from the bottle, as manifested by an absence of droplets at the sides. Slowly raise the hot-plate temperature to about 500° C. and add cap (D, Fig. 174) to prevent loss of spray. A suitable temperature is achieved when the sulfuric acid refluxes one-half way up the bottle. Heat for 2 hours. Cool and wash down caps and sides of flasks with 1.5 ml. of alkaline washing solution, using a fine-tipped pipet. Add 4 to 5 pellets of NaOH with tweezers and stopper with an acid-coated receiving rod (C, Fig. 174) as described on p. 671 for the determination of urinary ammonia. Rotate 90 minutes for complete diffusion. Wash the ammonia from the rod with 10.0 ml. of Nessler reagent and measure the color as described previously. Prepare standards and blanks as usual.

**Determination of Chloride:**<sup>333</sup> **Principle.** This is a modification of the Cunningham<sup>334</sup> procedure. The sample of plasma, urine, or other fluid is made strongly acid; the chloride is titrated with  $\text{AgNO}_3$  until the special electrodes give off current indicating the appearance of  $\text{Ag}^+$  and the disappearance of  $\text{Cl}^-$ .

**Procedure.**<sup>335</sup> Clean two electrodes<sup>336</sup> by repeated immersion in 10 per cent  $\text{HNO}_3$ . Amalgamate one electrode by repeated immersion in clean mercury beneath 10 per cent  $\text{HNO}_3$ . The silver electrode tip is stored in water, the amalgamated one in mercury. Place 50  $\mu$ l. of serum or urine in a vial; add 2 drops of 3.6 N  $\text{H}_2\text{SO}_4$ . Place the vial on the titration assembly (Fig. 171); add water to about 1 ml. Arrange electrodes and microburet as shown in Fig. 170. The electrodes should reach to about 2 mm. from the bottom of the vial, and the vial should rotate at about 600–800 r.p.m. The wiring diagram is shown in Fig. 176. Adjust the galvanometer to zero with the aid of back current from the potentiometer. Add  $\text{AgNO}_3$  from the buret until the galvanometer indicator moves to and remains for 15 seconds at a predetermined point on the scale. The buret and the contained  $\text{AgNO}_3$  can be calibrated against standard chloride solution to give readings of chloride content directly. The end point is chosen as the inflection point of a titration curve made by plotting galvanometer units against buret units.

Titration may be performed at the rate of one per minute with an error of less than 1 per cent. Equilibration is rapid because fast rotation of the vial brings the chloride, silver, and electrodes effectively together. Studies of the method reveal no interference from proteins, as shown by the agreement of results on protein-free filtrates, ashed serum, and whole serum. Urines analyzed directly and after ashing gave the same results.

<sup>332</sup> Reagents Required: *Digestion mixture.* Dissolve 12 g.  $\text{HgSO}_4$ , 100 g.  $\text{K}_2\text{SO}_4$ , and 180 ml.  $\text{H}_2\text{SO}_4$  in water and make up to 1 liter.

*Potassium iodide.* 20 per cent.

*Starch Solution.* 0.1 per cent.

$\text{K}_2\text{CO}_3 \cdot 1\frac{1}{2}\text{H}_2\text{O}$  C.P.

*Standard Alcohol.* 160 mg./100 ml. Dilute 2.00 ml. of absolute alcohol (sp. g. 0.800) to 1 liter with distilled water, and mix.

the standard chromic acid solution into a glass vial (A, Fig. 173). Pipet 50  $\mu$ l. of blood into the well of the rubber stopper (D). Add about 0.1 g.  $K_2CO_3$  (large crystals) to the well. When this is moistened by the blood, no carbonate will fall out. Stopper the vial and allow to stand overnight in an oven at 37° C., to allow diffusion and oxidation to become complete. Run a parallel determination on water alone (50  $\mu$ l.) as a blank, and on 50  $\mu$ l. of standard alcohol solution.

When diffusion is complete, remove the stoppers and titrate the chromic acid in each vial as follows: Add 1 drop of KI solution, place the vial on the titrating table, and titrate with standard (0.2 N) thiosulfate until the solution is faintly yellow. Add 1 drop of starch solution and titrate to the disappearance of the blue color.

CALCULATION. Subtract the buret units required for the standard from the value found for the blank. Call this value  $a$ . Subtract the buret units required for the sample from the value for the blank. Call this value  $b$ . Since the standard represents 160 mg. per cent alcohol, the calculation is as follows:

$$\text{mg. per cent alcohol in blood} = \frac{160}{a} \times b$$

The alcohol in as little as 10  $\mu$ l. of blood can be measured by reducing the concentration of chromic acid and thiosulfate. Higher temperatures will accelerate diffusion and oxidation. The error of the analysis is approximately 3 per cent.

**Microdetermination of Acid or Alkali: Principle.** The solution to be titrated is placed in a titration assembly fitted with a suitable pair of electrodes (calomel and either glass, quinhydrone, or antimony<sup>340</sup> electrodes) attached to a pH meter. The pH is measured after each increment of added standard alkali or acid, as the case may be. Titration is continued to the desired pH end point.

**Procedure.** Place 1.0 ml. of the solution to be titrated in a 15  $\times$  17 mm. vial. Place in the holder of the titration table (Fig. 171) and insert the electrodes, which are connected to a pH meter. Start the rotating shaft and read the pH as increments of standard alkali (or acid) are added. Read the buret when the desired pH is reached.

With this system, titrations can be carried out rapidly to the desired end point. For acid solutions approximately 0.01 N in strength, 0.2 N alkali is satisfactory. By reducing volumes and concentrations and employing antimony or quinhydrone electrodes, as little as 100  $\mu$ l. of solution may be titrated. Errors due to contamination by the  $CO_2$  of the air may be eliminated in most instances by blowing a gentle stream of  $CO_2$ -free air over the surface of the titrating vessel.

The procedure described here has been found particularly useful in microbiological assays based on measurement of acid production.<sup>341</sup> Titrations were carried out in a final volume of one ml., in 15  $\times$  15 mm. vials which were incubated in a Petri dish modified to hold 25 vials. A spatula tip of quinhydrone was added to each vial contents, and titration continued to pH 7.0, using a platinum-calomel electrode system. With one filling of alkali in the buret, from 25 to 50 vials could be titrated at a rate

of better than 1 per minute, with an accuracy exceeding the requirements of the method.

**Measurement of pH and Hematocrit.** Scholander<sup>342</sup> and others have devised accurate microgasimetric methods for CO<sub>2</sub>, N<sub>2</sub>, O<sub>2</sub>, and CO. For clinical purposes the method of Shock and Hastings (see p. 703) for pH, CO<sub>2</sub>, and hematocrit is very convenient and desirable. Singer and Hastings<sup>343</sup> provide a helpful nomogram and discussion for evaluation of various forms of acidosis and alkalosis, using the data obtained by this method.

**Measurement of Sodium and Potassium.** Suitable but relatively tedious microchemical techniques have been established for the determination of sodium and potassium. With the advent of flame photometry, rapid, accurate microm measurements are easily achieved (see pp. 650 and 653). Sodium (0.7  $\mu$ eq.) in 2.5 ml. of 1:500 serum (5  $\mu$ l.) can be measured in most available instruments. Potassium (0.1  $\mu$ eq.) in 2.5 ml. of 1:100 serum

A, Tube, 1.5–2.0 mm. O.D.  $\times$  100 mm. The end at B is sealed and the tube is centrifuged to pack the red cells. The hematocrit equals mm. packed red cells/mm. blood. Cutting the tube at the red cell–plasma interface allows exact separation of plasma for microanalyses.

(25  $\mu$ l.) can similarly be measured, both with an error of 1 to 2 per cent. Increased sensitivity can be achieved by including acetone in the diluent.

**Other Methods.** Natelson<sup>307</sup> has described a system for measuring hematocrit, plasma Na, K, Cl, protein, urea and glucose on 100  $\mu$ l. of fingertip blood. Blood is drawn by capillarity into a 1.5  $\times$  11 mm. tube<sup>344</sup> (ca. 0.1 ml., Fig. 177), sealed at one end, and centrifuged at 4,000 r.p.m. for 10 minutes. The fractions are measured with a rule and the volume of packed red cells calculated. The tube is cut at the red cell–plasma junction and analyzed for the constituents named above. Sobel<sup>345</sup> has described a microtitration method for calcium which appears to be more reliable than micro flame-photometry methods. Total serum proteins and albumin-globulin measurements may be made by the biuret<sup>346</sup> colorimetric technique except that reaction volumes are reduced to meet the need of sample size. For example, 100  $\mu$ l. of serum in a final volume of 10 ml. in the standard biuret procedure can be reduced to 10  $\mu$ l. in a final volume of 1.0 ml. Similar reductions in any desired salting-out procedure can be made; however, the usual precautions concerning denaturation of

## 24

# Respiratory Exchange and Neutrality Regulation

**General.** The major function of the lungs in respiration is to facilitate the addition of oxygen to the blood and to remove excess carbon dioxide from the blood. The oxygen is carried to all the tissues, where it is utilized in the metabolic processes taking place within the cells. The chief end products of these metabolic processes include  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ , urea, and various organic and inorganic acids such as lactic, uric, phosphoric, sulfuric, and the like. The production of end products which are bases, such as ammonia and the various organic amines, is relatively unusual or confined to lower species or to special tissues. Of the various end products listed, only  $\text{H}_2\text{O}$  and urea are neutral substances and can be excreted by the body without bringing into play the various mechanisms of neutrality regulation which are the subject of this discussion.

The  $\text{CO}_2$  produced in the tissues is removed by diffusion into the blood, where the major portion (approximately 70 per cent) at once undergoes hydration to form carbonic acid, the remainder combining with the blood proteins (including hemoglobin) to form carbamates (20 per cent), or remaining in physical solution (10 per cent). The newly formed carbonic acid must be immediately neutralized or the blood would become far more acid than is compatible with life; this neutralization is mediated largely through hemoglobin, as described below. The other acid end products of metabolism are neutralized as soon as they are formed and exist in the blood and tissues as salts, neutralization being effected through reaction with such ions as the  $\text{HPO}_4^{--}$  ion largely in the cells and the  $\text{HCO}_3^-$  ion largely in the blood plasma. Thus carbonic acid is not only an important end product of tissue oxidation, but it also plays a significant role in neutrality regulation. The level of the blood bicarbonate content is the most satisfactory single index of the ability of the body as a whole to neutralize acid end products of metabolism; hence the term "alkali reserve." The peculiar virtue of the carbonic acid-bicarbonate system in controlling the neutrality of the body lies in the volatility of carbon dioxide and hence its ready elimination by the lungs. The nonvolatile acids (uric, phosphoric, etc.) after conversion into their salts can be disposed of by the kidneys.

**Role of Oxygen.** A complete understanding of the mechanism of neutrality regulation and  $\text{CO}_2$  transport in the blood requires knowledge of

the part played by hemoglobin in the transport of oxygen (see Fig. 178). Oxygen is found in the blood in two forms, (a) in physical solution, and (b) in combination with the respiratory pigment hemoglobin to give the compound oxyhemoglobin. The amount of oxygen in physical solution in

FIG. 178. THE ROLE OF OXYGEN IN THE TRANSPORT OF CO<sub>2</sub> BY THE BLOOD.

the blood is relatively small, most of the oxygen present being in the combined form of oxyhemoglobin. An equilibrium exists between the free oxygen in solution, the hemoglobin which is not combined with oxygen (so-called reduced hemoglobin), and oxyhemoglobin; this relationship can be written as follows:

From this it can be seen that when the amount of free oxygen in the blood is lowered, as by diffusion into the tissues, the content of oxyhemoglobin will decrease and that of reduced hemoglobin will increase. This occurs when arterial blood is changed into venous blood. When venous blood reaches the lungs, it is distributed in the many capillaries of the alveoli, exposing a great surface to contact with the alveolar air. The alveolar air is separated from the blood in the pulmonary capillaries by membranes at most 2  $\mu$  in thickness; this, in addition to the fact that erythrocytes with a surface area of some 80 square meters pass through the lungs each second, accounts for the rapid and efficient uptake of oxygen. The oxygen tension of alveolar air (100 mm. Hg) is high enough to cause a considerable increase in the amount of dissolved oxygen in the blood. This in turn increases the amount of oxyhemoglobin at the expense of reduced hemoglobin, and when the aerated blood leaves the lungs as arterial blood practically all of the hemoglobin is normally in the form of oxyhemoglobin. This relation between oxygen tension and the degree of oxygenation of hemoglobin has been discussed in Chapter 22.

Now in addition to their relation to oxygen transport, the proteins oxyhemoglobin and reduced hemoglobin act as typical weak acids, being present in the blood partly in the unneutralized or free acid form (HHb, HHbO<sub>2</sub>) and partly as salt ions (Hb<sup>-</sup>, HbO<sub>2</sub><sup>-</sup>). At the pH of the blood, the reduced hemoglobin ion Hb<sup>-</sup> has a smaller base-binding capacity than has the oxyhemoglobin ion HbO<sub>2</sub><sup>-</sup>, i.e., reduced hemoglobin behaves as a weaker acid than oxyhemoglobin. When HbO<sub>2</sub><sup>-</sup> is converted into Hb<sup>-</sup> in the tissue capillaries by the loss of oxygen from the blood, the concomitant release of the extra base by the reduced hemoglobin would tend to make it slightly more alkaline, if it were not for the fact that carbonic acid is entering the blood at the same time. It has been shown that, under normal circumstances, about 50 per cent of the entering carbonic acid is equivalent to this potential increase in alkalinity of the blood, i.e., will be "neutralized" without any net pH change in the blood at all. Since the carriage of this portion of the entering carbonic acid does not involve a change in pH of the blood, it is known as the *isohydric* carriage. Naturally, the exact reverse of the above-described process occurs in the lung capillaries, where reduced hemoglobin is converted by oxygenation to oxyhemoglobin. This conversion increases the base-binding capacity of the hemoglobin, withdrawing the base from BHCO<sub>3</sub> to form H<sub>2</sub>CO<sub>3</sub>, which is then decomposed to CO<sub>2</sub> and H<sub>2</sub>O; the CO<sub>2</sub> diffuses out of the blood into the alveolar air of the lungs.

It may be noted here that, in addition to the carriage of a portion of the entering CO<sub>2</sub> by the isohydric reaction, hemoglobin enters into carbon dioxide transport in at least two other recognized ways. One of these is to act as a typical buffer, in the manner described in detail below. Another is due to the fact that hemoglobin, as a protein, is capable of combining directly with carbon dioxide to form a *carbamate*, the reaction involving

the free amino groups of the hemoglobin molecule:

The formation of carbamate in this manner is a general property of proteins and amino acids and is not specific for hemoglobin, but, since hemo-

FIG. 179. TITRATION CURVE FOR THE H<sub>2</sub>CO<sub>3</sub>:BHCO<sub>3</sub> SYSTEM.  
 From Van Slyke: *Endocrinology and Metabolism*, Vol. 4, New York, Appleton, 1924.

globin is by far the most abundant protein in blood, a major portion of the CO<sub>2</sub> which is carried as carbamate is due to hemoglobin.

The existence of such a direct combination of hemoglobin and CO<sub>2</sub> was at one time disputed, but the work of Henriques, of Roughton, and of Stadie and O'Brien has established the significance of carbamate-bound CO<sub>2</sub> in respiratory gas exchange. While the actual amount of carbamate-bound CO<sub>2</sub> in the blood is small relative to the amount of bicarbonate (see Table on p. 687), the ease of formation and breakdown of this type of compound in response to changes in CO<sub>2</sub> tension is such that from 20 to 30 per cent of the *extra* CO<sub>2</sub> added to the blood in the tissues and released in the lungs may be transported in this manner.

**Role of Buffers.** As has been indicated, the isohydric reaction accounts for only part of the CO<sub>2</sub>-carrying power of the blood. When more CO<sub>2</sub>

enters than can be neutralized in this manner, the blood becomes more acid, i.e., its hydrogen-ion concentration increases.

To understand the nature of this change, it is necessary to consider the general properties of buffer solutions (see also Chapter 1). A buffer solution ordinarily contains a weak acid and its salt, or a weak base and its salt. Such solutions are capable of taking up limited amounts of acid or base with much less change in hydrogen-ion concentration than would result from the same addition of acid or base to water or to sodium chloride solution, neither of which has buffer power. A buffer system can act therefore as a reservoir of alkali for the neutralization of the acid end products of metabolism. The efficiency of a buffer system in resisting change in reaction is greatest at the half-neutralization point, i.e., when the molar concentrations of salt and acid are equal. Fig. 179 represents a titration curve for a weak acid (carbonic), that is, a curve in which the per cent of total acid neutralized is plotted against the pH at each step in the titration. The S-shaped curve is characteristic of buffer acids or alkalies, and demonstrates that when 50 per cent of the acid is neutralized (ratio of salt to acid = 1), the slope (rate of change of pH) is least.

The relation between the reaction (pH) and the ratio of buffer acid (HA) to buffer salt (BA) is derived as follows. The equation for the electrolytic dissociation of a weak acid into hydrogen ions and anions is  $HA \rightleftharpoons H^+ + A^-$ . From the law of mass action we know that the velocity of this reversible reaction in either direction is proportional to the concentrations of the reacting constituents. That is,

$$\begin{aligned}\text{Velocity (left to right)} &= k_1 HA \\ \text{Velocity (right to left)} &= k_2 (H^+ \times A^-)\end{aligned}$$

in which the symbols also represent concentrations. At equilibrium the rate of reaction in each direction is the same, the equilibrium being dynamic. Therefore

$$k_1 HA = k_2 (H^+ \times A^-)$$

or transposing,

$$\frac{k_1}{k_2} = \frac{(H^+ \times A^-)}{HA} = K$$

$K$  being the *dissociation constant* of the acid. Transposing again,

$$H^+ = K \times \frac{HA}{A^-}$$

In a solution of a weak acid and its salt, only a very small fraction of the anion,  $A^-$ , originates from the dissociation of the free acid, the rest coming from the dissociation of the salt, BA, into  $B^+$  and  $A^-$ . Most salts in the concentration found in body fluids are ionized to the extent of 60 to 90 per cent. If the degree of dissociation is represented by  $\lambda$ , the concentration of anions  $A^- = \lambda BA$  and

$$H^+ = K \times \frac{HA}{\lambda BA}$$

Since  $\lambda$  varies to a relatively slight extent over ranges of concentration within such limits as are found in blood constituents, it may be stated as an approximation that

$$\frac{K}{\lambda} = K_1$$

and

$$H^+ = K_1 \frac{HA}{BA}$$

$K_1$  is called the “apparent dissociation constant.”

By definition  $pH = -\log H^+$  (see p. 30). (For example, the hydrogen-ion concentration  $[H^+]$  at neutrality is 0.000,000,1 normal =  $10^{-7}$ . Therefore the  $pH = -\log 10^{-7} = -(-7) = 7$ .) Taking the logarithms of both sides of the last equation,

$$\log H^+ = \log K_1 + \log \frac{HA}{BA}$$

and, changing signs,  $-\log H^+ = -\log K_1 - \log \frac{HA}{BA}$

Substituting  $pH$  for  $-\log H^+$ , and, for an analogous reason,  $pK_1$  for  $-\log K_1$ ,

$$pH = pK_1 + \log \frac{BA}{HA}$$

This equation is known as the Henderson-Hasselbalch equation and is a most fundamental concept in the understanding of acid-base equilibrium in the body. The value of the constant  $pK_1$  for various acids is numerically equal to the  $pH$  when the ratio of salt  $BA$  to acid  $HA$  is unity, since the  $\log 1 = 0$ . Under this condition, it will be recalled, the maximum efficiency of the buffer action obtains. The following table gives the  $pK_1$  values for the more important buffers in blood.

| Buffer System                                                         | $pK_1$ |
|-----------------------------------------------------------------------|--------|
| BHbO <sub>2</sub> :HHbO <sub>2</sub> .....                            | 7.16   |
| BHb:HHb.....                                                          | 7.3    |
| BHCO <sub>3</sub> :H <sub>2</sub> CO <sub>3</sub> .....               | 6.1    |
| B <sub>2</sub> HPO <sub>4</sub> :BH <sub>2</sub> PO <sub>4</sub> .... | 6.8    |

With the Henderson-Hasselbalch equation in mind, consider what happens when acid is added to a buffer system. The added acid reacts with the buffer salt present to produce an equivalent increase in the amount of buffer acid, at the expense of the buffer salt, together with the salt of the entering acid which plays little, if any part in  $pH$  change and may be disregarded. The decrease in buffer salt concentration and corresponding increase in buffer acid concentration, however, must necessarily change the  $pH$  of the solution in accordance with the demands of the Henderson-Hasselbalch equation. If the solution were not buffered, the change in  $pH$  on the addition of acid would correspond to the actual amount of added  $H^+$ ; in a buffered solution the change in  $pH$  is numeri-

cally much smaller, being equal to the change in the value of the logarithm of the ratio of buffer salt to buffer acid. It is for this reason that buffer solutions behave as they do in resisting gross changes in pH on the addition to the solution of acid or alkali, for it can be readily shown that an exactly analogous mechanism functions in the case of added alkali.

In a solution containing a number of different buffers, as is the case with the blood and tissues, the entering acid or alkali is buffered by all the buffer systems present, in proportion to their relative effectiveness at the given pH. Thus in the buffer systems of the blood:

the entrance of acid will cause a decrease in concentration of all the buffer salts (numerators) and an increase in concentration of all the buffer acids (denominators), accompanied by an equivalent change in pH as required by the Henderson-Hasselbalch equation.

It is well to note here that physiological limitations influence considerably the relative significance of the various buffers in the blood. Thus the chief buffer for *carbonic acid* is hemoglobin, since carbonic acid is formed from  $\text{CO}_2$  and  $\text{H}_2\text{O}$  only in the red cells where most of the buffering reactions for carbonic acid take place (see below). On the other hand, the major buffering action for *all acids other than carbonic acid* is exerted by the plasma bicarbonate, protein, and phosphate buffer systems.

It is significant that the pH of maximum efficiency of these buffers is below the normal pH for blood, since as the blood pH falls, change of reaction is opposed with an efficiency which increases as the danger point is approached. While the ratio  $\text{BHCO}_3:\text{H}_2\text{CO}_3$  at the pH of blood is about 20:1 and hence considerably removed from the ratio of maximum efficiency, the chief significance of this system rests in the fact that  $\text{H}_2\text{CO}_3$  promptly dissociates yielding  $\text{CO}_2$  which is expired; thus the actual efficiency of the  $\text{CO}_2$  system in neutrality regulation is greater than would appear to be the case from a consideration of the buffer theory alone.

**Role of the Red Cells.** Serum separated from the red corpuscles ("separated serum") has only a slight buffer effect and  $\text{CO}_2$ -carrying power as compared with serum in contact with the cells ("true serum"). Investigation has shown that this is because practically all of the reactions associated with the transport of  $\text{CO}_2$  by the blood take place primarily *within the red cell itself*, the serum (or plasma) being involved in a secondary manner only. The role of the red cell and of the plasma in the uptake of  $\text{CO}_2$  by the blood is summarized in the accompanying diagram (Fig. 180).

As indicated in the diagram,  $\text{CO}_2$  produced metabolically in the tissues diffuses as such into the plasma. Here a small amount remains in physical solution, and some possibly reacts also with the plasma proteins ( $\text{PrNH}_2$ ) to form carbamate, the extra equivalent of acid thus formed being buffered by the plasma buffers ( $\text{A}^-$ ) in the usual way. By far the greater portion of the entering  $\text{CO}_2$  (upward of 90 per cent) does not remain in the plasma, however, but diffuses rapidly through the red cell wall into the red cell itself.

Here it comes under the influence of the enzyme *carbonic anhydrase*. This enzyme is present in abundance in the red cell (and in certain other specialized tissues, such as the pancreas and the gastric mucosa) but is absent from the blood plasma. Its function is to act as a catalyst in the reaction  $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ . By virtue of its presence within the red cell, much of the entering  $\text{CO}_2$  is converted into  $\text{H}_2\text{CO}_3$ , which immediately dissociates to give  $\text{H}^+$  and  $\text{HCO}_3^-$  ions. A portion of the entering  $\text{CO}_2$  (about 20 per cent) escapes hydration, however, reacting rapidly with the hemoglobin present to form carbamate. The net effect of these two reactions, therefore, is the production within the cell of an excess of  $\text{H}^+$  and  $\text{HCO}_3^-$  ions, together with a small amount of carbamate ions. The

FIG. 180. PROCESSES INVOLVED IN THE UP-TAKE OF CARBON DIOXIDE BY BLOOD.

amounts of these ions thus produced are such as to greatly alter the normal pH and osmotic equilibrium of the cell if they were not removed in some manner.

The  $\text{H}^+$  ions are removed in two ways, by the isoshydic reaction and by buffer action. It has already been pointed out that oxyhemoglobin ( $\text{HbO}_2$ ) is a stronger acid than reduced hemoglobin ( $\text{Hb}$ ) at the pH of the blood. This means in effect that hemoglobin which has lost its oxygen has a lesser base-binding capacity at a given pH than has oxyhemoglobin. Thus the liberation of oxygen from the blood to the tissues creates a situation which brings about the release of base from the hemoglobin without involving any pH change at all. This process, under the conditions prevailing in normal blood, accounts for the disposal of over 50 per cent of the extra  $\text{H}^+$  ions produced within the red cell from the entering  $\text{CO}_2$ . The remaining  $\text{H}^+$  ions react with the various buffer salt ions present in the cell to form an equivalent amount of un-ionized buffer acids. Since

this typical buffer reaction involves a change in the ratio of buffer salt to buffer acid, the pH of the cell contents will change as demanded by the Henderson-Hasselbalch equation, and it is this which accounts for the slight change in pH which follows the uptake of  $\text{CO}_2$  by the cells.

The fate of the extra  $\text{HCO}_3^-$  ions must now be considered. If they remained within the cell, the increased osmotic pressure would cause the cell to take up water and swell to a size far beyond physiological limits. It has been found by chemical analysis of cells and plasma that most of the extra  $\text{HCO}_3^-$  ions diffuse out of the cell into the plasma, being replaced by an equivalent amount of  $\text{Cl}^-$  ions which diffuse from the plasma into the cell. This process is called the *chloride shift* and it has been estimated that as much as 80 per cent or more of the *extra* bicarbonate of venous plasma (as compared to arterial plasma) is due to diffusion from the red cells.

The chloride shift has been attributed by Van Slyke to the existence of a Donnan equilibrium (see p. 12) across the red cell membrane. It can be shown that, in the case of the red cell, it is a consequence of the Donnan theory that at osmotic equilibrium the ratio of bicarbonate-ion concentrations in cell and plasma is proportional to the ratio of chloride-ion concentrations in cell and plasma, i.e.,

$$\frac{[\text{HCO}_3^-]_{\text{cells}}}{[\text{HCO}_3^-]_{\text{plasma}}} = k \cdot \frac{[\text{Cl}^-]_{\text{cells}}}{[\text{Cl}^-]_{\text{plasma}}}$$

An increase of bicarbonate-ion concentration within the cell disturbs this equilibrium and it is partially restored by migration of bicarbonate ions from the cell to the plasma, accompanied by an equivalent migration of chloride ions from the plasma to the cell.<sup>1</sup> At the same time, a certain amount of water diffuses from the plasma into the red cell, and this accounts for the slight increase in size of the cells of venous blood as compared to arterial blood.

The phenomena that have just been described take place during the uptake of  $\text{CO}_2$  by the blood in the tissue capillaries to form venous blood. When the venous blood reaches the lungs, the entrance of oxygen reverses all of these processes. Bicarbonate in the cell is converted into carbonic acid which is dehydrated to  $\text{CO}_2$  and diffuses out of the cells into the plasma, from whence it passes into the alveolar air of the lungs. Bicarbonate ions migrate from the plasma to the cell and undergo the same reactions, chloride ions returning from the cell to the plasma at the same time. The various other reactions are likewise reversed in an analogous manner. Thus the red cell is carried through the entire mechanism first in one direction and then in the other direction as it makes a complete circuit of the body.

The quantitative nature of the changes that normally take place in the

<sup>1</sup> The hemoglobin ions likewise enter into this equilibrium. For a detailed discussion of the Donnan equilibrium as it is applied to the chloride shift, the reader is referred to Peters and Van Slyke: *Quantitative Clinical Chemistry*, Vol. I; see also Hitchcock: *Physical Chemistry for Students of Biology and Medicine*, 3d ed.

blood in its transition from the arterial to the venous state is illustrated by the data of the following table, adapted from Stadie and O'Brien.<sup>2</sup>

|                                            | Arterial Blood |       |             | Venous Blood |       |             | Difference |       |             |          |

Study of this table shows the following:

1. In its passage through the tissues of the body, the arterial blood of the subject being studied has picked up about 3.8 ml. of CO<sub>2</sub> per 100 ml. of whole blood. This is an increase of about 8 per cent in the total CO<sub>2</sub> content of the blood. With the R.Q. assumed to be 0.85, a normal value, this corresponds to the liberation of about 4.5 ml. of O<sub>2</sub> from the blood at the same time, which is responsible for the change in oxygen saturation from 96 per cent to 74 per cent.
2. The increased CO<sub>2</sub> content of venous blood is accompanied by a rise in CO<sub>2</sub> tension of about 5 mm. of Hg, and a fall in pH of about 0.01 to 0.02 pH units.
3. Of the total CO<sub>2</sub> of blood, almost 90 per cent is in the form of bicarbonate, of which about three-fourths is found in the plasma and one-fourth in the cells. The remaining 10 per cent of the total CO<sub>2</sub> is about equally distributed between the forms of free CO<sub>2</sub> and carbamate. Plasma contains about twice as much free CO<sub>2</sub> and about half as much carbamate-bound CO<sub>2</sub> as is found in the cells.
4. Of the 3.8 volumes per cent of CO<sub>2</sub> added to the blood in the change from arterial to venous blood, which are ultimately released in the lungs, about three-fourths appears as extra bicarbonate, about one-fifth as carbamate, and the remainder as an increase in the free CO<sub>2</sub> content. The extra free CO<sub>2</sub> and extra bicarbonate are both distributed between cells and plasma in about the same proportion as that already present; almost all of the extra carbamate is found in the cells.

<sup>2</sup>*J. Biol. Chem.*, **117**, 439 (1937).

5. Most of the extra bicarbonate of venous blood is found in the *plasma*. Now it has been shown that the passage of blood through the capillaries is far too rapid to permit any appreciable hydration of  $\text{CO}_2$  to  $\text{H}_2\text{CO}_3$  (a necessary preliminary to the formation of bicarbonate) without the intervention of carbonic anhydrase, and this enzyme is found only in the cells. It follows, therefore, that most of the *extra* bicarbonate of venous plasma must have come from the cells. This is accomplished by virtue of the "chloride shift" mechanism, an equivalent amount of chloride leaving the plasma and entering the cells.

**Relative Importance of the Various  $\text{CO}_2$ -Carriers of the Blood.** A  $\text{CO}_2$ -carrier of the blood has been broadly defined by Van Slyke as any substance present in the blood which increases the amount of  $\text{CO}_2$  that may be taken up by arterial blood without a change in pH beyond the normal difference between venous and arterial blood. From this definition it is clear that the major  $\text{CO}_2$ -carriers of the blood include hemoglobin, bicarbonate, the plasma proteins, and phosphates. It is also clear that by far the most important  $\text{CO}_2$ -carrier of normal blood is hemoglobin, since 80 per cent or more of the  $\text{CO}_2$  carriage by the blood is mediated directly or indirectly through the presence of hemoglobin. Thus this compound plays as important a part in neutrality regulation and the transport of  $\text{CO}_2$  as it plays in its more obvious function in  $\text{O}_2$  transport.

**Role of the Lungs.** Due to the ease of elimination of  $\text{CO}_2$  by respiration, the regulation of the neutrality of the blood is largely controlled by the  $\text{H}_2\text{CO}_3:\text{BHCO}_3$  system. From 20 to 40 liters of N/1 acid as  $\text{CO}_2$  is lost each day by way of the lungs. By means of variation in the rate and depth of respiration and the rate of blood flow through the lungs, opportunity is afforded for very delicate adjustment of the hydrogen-ion concentration. The nervous control of the respiratory mechanism resides in the respiratory center in the medulla. Increases in  $\text{CO}_2$  tension or hydrogen-ion concentration call forth corresponding responses in the ventilation of the lungs, and since changes in either factor take place concurrently, it is difficult to distinguish the effects of one from the other. It is probable that an increase in hydrogen ions in the respiratory center itself, secondary to that of the blood, may be the activating factor. Such increases may come about through diffusion of  $\text{CO}_2$  or  $\text{H}^+$  from the blood or by acid production within the center. The latter may explain the greater respiratory response which results from an insufficient oxygen supply to the center.

The rate of elimination of waste products through the lungs and the kidneys is partly controlled by the rate of blood flow through those organs. The diminished blood pressure following excessive pulmonary ventilation has been shown to be due to the loss of  $\text{CO}_2$  rather than to the resultant rise in pH *per se*. There is, however, no constant relation between blood pressure and  $\text{CO}_2$  tension among different individuals.

**Role of the Kidneys.** The role of the kidneys in neutrality regulation is concerned chiefly with the conservation of "fixed base" (sodium, potassium) to the organism. If a strong acid produced by metabolism within the tissues is neutralized by reaction with bicarbonate or basic phosphate to produce a salt, the base component of the salt thus formed (e.g., the Na of  $\text{NaCl}$ ) is no longer a direct part of the alkali reserve

of the body, and if present in excess will be excreted in the urine. If, however, the alkali reserve is low so that the organism needs to conserve fixed base, as when acid production exceeds the supply of available base, the kidney has the ability to excrete an acid urine (down to a pH as low as 4.8) as one means of conserving base. According to Pitts, this is probably accomplished by the reabsorption of base ions from the glomerular ultrafiltrate and their replacement by hydrogen ions secreted into the tubular lumen. In effect, the following reaction occurs:

The increase in the relative amount of acid phosphate to basic phosphate in the urine accounts for the more acid pH of the urine. If the urine is titrated with alkali back to the pH of the blood (see "Titratable Acidity of Urine" in Chapter 31), a measure of the extent to which the above reaction has contributed to base conservation will be obtained.

A second and equally important mechanism whereby the kidneys conserve fixed base is by the synthesis of ammonia, probably from glutamine and amino acids.<sup>3</sup> The ammonia is excreted in preference to fixed base, as follows:

The extent of ammonia excretion is related to the need for base conservation, ordinarily being low or zero in alkalosis and high in acidosis. Thus by determining both the ammonia excretion and the titratable acidity of the urine, the extent of acid excretion by the body may be evaluated, and hence knowledge be gained concerning the state of acid-base balance.

It sometimes happens that there is an excess of base requiring excretion, as on diets high in alkaline ash or after administration of bicarbonate. In this event, extra base and bicarbonate will be found in the urine and the pH may rise to as high as 8.0.

**The pH and  $\text{H}_2\text{CO}_3$ : $\text{BHCO}_3$  Ratio.** Inasmuch as the chief factor in the regulation of blood reaction is the  $\text{H}_2\text{CO}_3$ : $\text{BHCO}_3$  system, the relationship of variations in the latter to pH should yield valuable information concerning changes in the acid-base balance of the body. Applying the equation for the dissociation of a weak acid (see p. 682) to this case, the so-called Henderson-Hasselbalch equation is obtained.

$$\text{pH} = \text{p}K_1 + \log \frac{\text{BHCO}_3}{\text{H}_2\text{CO}_3}$$

The value of the constant  $\text{p}K_1$  for blood plasma is 6.10. By measuring any two of the remaining variables, the third is of course determined. If we

<sup>3</sup> Van Slyke, Phillips, Hamilton, Archibald, Fitcher, and Hiller: *J. Biol. Chem.*, **150**, 481 (1943).

plot changes in bicarbonate concentration  $[\text{BHCO}_3]$  as ordinates, against carbonic acid  $[\text{H}_2\text{CO}_3]$  as abscissas, a straight line will result for any given ratio of the two, and hence for any given pH. The slope of this line will increase or decrease with corresponding changes in the  $[\text{BHCO}_3]:[\text{H}_2\text{CO}_3]$  ratio. The maximal as well as the normal ranges of these factors are depicted in Fig. 181, constructed by Van Slyke. Since it was desired to use the customary form of  $\text{CO}_2$  absorption curves, the coordinates are expressed in terms of total  $\text{CO}_2$  values,  $[\text{BHCO}_3 + \text{H}_2\text{CO}_3]$ , as ordinates, and  $\text{CO}_2$  tensions as abscissas. It will be noted that nine areas are set off by the three levels (high, normal, or low) of each of the two variables. The nine areas represent conditions of acid or alkali excess or deficit, which are

FIG. 181. NORMAL AND ABNORMAL VARIATIONS OF THE  $\text{BHCO}_3$ ,  $\text{H}_2\text{CO}_3$ ,  $\text{CO}_2$  TENSION, AND pH IN OXYGENATED HUMAN WHOLE BLOOD DRAWN FROM RESTING SUBJECTS AT SEA LEVEL. (VAN SLYKE.)

The bicarbonate  $\text{CO}_2$  at any point is obtained by subtracting from the total  $\text{CO}_2$  the relatively small amount present as  $\text{H}_2\text{CO}_3$  indicated by the slanting line near the bottom of the illustration.

either *compensated* (pH normal) or *uncompensated* (pH above or below normal). That is, a condition of alkali deficit (low alkali reserve) may be either compensated by a corresponding diminution in carbonic acid so that the  $[\text{BHCO}_3]:[\text{H}_2\text{CO}_3]$  ratio remains normal (about 20:1), or it may be uncompensated by the failure to remove sufficient  $\text{CO}_2$ , in which case the pH falls and the condition of uncompensated alkali deficit results. It is therefore obvious that acidosis cannot be regarded as merely a lowering of the pH, since the acidosis may accompany a deficit of  $\text{CO}_2$  so marked as to result in a more alkaline reaction of the blood. Moreover, an abnormally acid reaction may occur even with an increase of alkali reserve provided  $\text{CO}_2$  is present to excess. In order, therefore, to combine the effects of both alkali reserve and reaction, Van Slyke has broadly defined acidosis as a condition caused "by the formation or absorption of acids at a rate exceeding that of their elimination . . . [which] . . . may be considered to have caused an abnormal state when it has either

DISTURBANCES OF ACID-BASE EQUILBRIUM OF BLOOD

increased the hydrion concentration of the blood or lowered its alkali reserve below the extreme normal limits." The conditions which fall into the different areas have been observed both clinically and experimentally.

**Disturbances of the Acid-base Balance.** These are divided into two clinical types by Peters and Van Slyke, viz., (1) metabolic types, in which the primary disturbance is in the relation between alkali and acids other than  $\text{H}_2\text{CO}_3$ , and (2) respiratory types, in which the primary disturbance involves the  $\text{CO}_2$  content of the blood. In the table on p. 691 the more important conditions associated with disturbance of acid-base balance are shown, together with their causes and the physiological mechanisms brought into play for their compensation.

**KETOSIS.** Ketosis is the condition in which abnormal amounts of  $\beta$ -hydroxybutyric acid, acetoacetic acid, and acetone accumulate in the body fluids and may be readily detected in the urine. These three compounds are commonly known as the *acetone bodies*. Of the three acetone bodies,  $\beta$ -hydroxybutyric acid and acetoacetic acid are primary products, acetone being derived from the decarboxylation of acetoacetic acid. They appear to have their origin principally from the metabolism of the fatty acids of fats, and to a lesser degree from certain amino acids resulting from protein cleavage. This is discussed in detail in Chapter 33. They are apparently formed in the liver, and then further oxidized in the other tissues of the body where they are capable of furnishing a large amount of energy. In diabetes mellitus, the body either does not possess the normal power of oxidizing these substances or else they are produced in excessive amounts. At any rate, we find them in the blood and urine in abnormal quantity. Likewise, in the absence of dietary carbohydrate and in other conditions of faulty carbohydrate metabolism, they are also increased in amount in both blood and urine. Ketosis as it appears in the human organism is not entirely the same as in other species, such as the rat, dog, rabbit, goat, pig, and cow. Rats are very resistant to the development of ketosis.

The significance of ketosis in connection with acid-base balance lies in the fact that acetoacetic acid and  $\beta$ -hydroxybutyric acid exist in the blood and urine largely in the form of their alkali salts. Their production has therefore required an equivalent amount of body base for neutralization. Excessive amounts produce a severe demand on available base, and when they are excreted in the urine most of this base is lost to the organism. The acidosis of diabetes mellitus may be largely due to ketosis. Acidosis occurs in many conditions, however, without a concomitant ketosis.

The presence of acetone bodies in the urine in appreciable quantity was originally taken as an index of acidosis, the severity of which was judged by the estimation of the amount of these substances present in the urine. That this is not a reliable index is shown by the occasional observation of a pronounced acidosis with no appreciable increase in urinary acetone bodies. A high urinary ammonia coefficient (ammonia N:total N) was once looked upon as an indication of acidosis. However, this factor is not specific in diagnosis in spite of the fact that the majority of such cases show a high urinary ammonia value because certain dietetic changes may produce high urinary ammonia. Fatal acidosis has been observed in uremia, and in nutritional disorders of infants, with no pronounced in-

crease in the ammonia coefficient. In this connection, it is possible that in renal disability the ammonia-forming function of the kidneys is impaired.

Conditions of disturbed acid-base balance are best diagnosed and their course followed not by the determination of acetone bodies or ammonia in either urine or blood, but by the determination of certain other factors which are more or less typical of acidosis, such as the quantitative estimation of the alkali reserve of the blood and of its pH.

## METHODS

**1. Simple Demonstration of the Presence of Carbon Dioxide in Expired Air.** Into each of two small flasks or large test tubes introduce 25 ml. of a clear saturated solution of barium hydroxide. After an ordinary inspiration, expire through a bent glass tube or pipet dipped beneath the surface of the solution in the first flask. Repeat the experiment with the second flask, but hold the breath as long as possible after the inspiration before breathing out through the tube. Note the relative amounts of precipitate of barium carbonate formed. To another flask add 30 ml. of water, 1 or 2 drops of barium hydroxide solution, and a few drops of 0.04 per cent phenol red. Expire into this solution until a change takes place. What does this change indicate?

### **2. Alkali Reserve: Direct Method.**

(a) CARBON DIOXIDE CAPACITY OF THE PLASMA (VAN SLYKE AND CULLEN): PRINCIPLE. The plasma from oxalated blood is shaken in a separatory funnel filled with an air mixture whose carbon dioxide tension approximates that of normal arterial blood, by which treatment it combines with as much carbon dioxide as it is able to hold under normal tension. A known quantity of the saturated plasma is then acidified within a suitable pipet, and its carbon dioxide is liberated by the production of a partial vacuum. The liberated carbon dioxide is then placed under atmospheric pressure, its volume carefully measured, and the volume corresponding to 100 ml. of plasma calculated.

*Apparatus.* The apparatus used in the estimation of the carbon dioxide content of the plasma is illustrated in Figs. 182 and 183. It is made of strong glass in order to stand the weight of mercury without danger of breaking, and is held in a strong screw clamp the jaws of which are lined with thick pads of rubber. In order to prevent accidental slipping of the apparatus from the clamp, an iron rod of 6 or 8 mm. diameter should be so arranged as to project under cock *f* between *c* and *d*.

Three hooks or rings at the levels, 1, 2, and 3 serve to hold the leveling bulb at different stages of the analysis. The bulb is connected with the bottom of the apparatus by a heavy-walled rubber tube.

It is necessary, of course, that both stopcocks should be properly greased and airtight, and it is also essential that they (especially *f*) shall be held in place so that they cannot be forced out by pressure of the mercury. Rubber bands may be used for this purpose but elastic cords of fine wire spirals, applied in the same manner as rubber bands, are stronger and more durable. Later models of this apparatus are equipped to overcome this difficulty.

After a determination has been finished, the leveling bulb is lowered without opening the upper cock, and most of the mercury is withdrawn from the pipet through *c*. The water solution from *d* is readmitted and the leveling bulb being raised to position 1, the water solution, together with a little mercury, is forced out of the apparatus through *a*.<sup>4</sup>

<sup>4</sup> It is well to have a funnel draining into a special vessel to catch the water residues and mercury overflow from *a*. A considerable amount of mercury is thus regained if many analyses are run. It requires only straining through cloth or chamois skin to prepare it for use again.

FIG. 182. VAN SLYKE VOLUMETRIC CARBON DIOXIDE APPARATUS.

**Procedure. Drawing the blood.**<sup>5</sup> About 6 or 7 ml. of venous blood are aspirated into a centrifuge tube (see Fig. 183) containing a little powdered potassium oxalate and some paraffin oil. The tube is subjected to a minimum of agitation after the blood is in it. The slight amount of agitation necessary to assure mixture with the oxalate is accomplished by stirring with the inlet tube, rather than by inverting or shaking. The tube and contents are then centrifuged.

**Saturation of Plasma with Carbon Dioxide.** After centrifuging, about 3 ml. of the plasma<sup>6</sup> are transferred to a 300-ml. separatory funnel, arranged as in Fig. 184, and the air within the funnel is displaced by either alveolar air from the lungs of the operator or a 5.5 per cent carbon dioxide-air mixture from a tank. This latter procedure is preferred, since error due to incomplete filling of the separatory funnel with air containing carbon dioxide at the proper tension is less likely to occur. The gas must be passed through a wash bottle containing water before entering the funnel.

When alveolar air is used, the operator, without inspiring more deeply than normal, expires as quickly and as completely as possible through the glass beads and separatory funnel. The stopper of the funnel should be inserted just before the

FIG. 183. ASPIRATING TUBE USED TO COLLECT BLOOD.

FIG. 184. SEPARATORY FUNNEL USED IN SATURATING BLOOD PLASMA WITH CARBON DIOXIDE.

Courtesy, *J. Biol. Chem.*, 30, 289 (1917).

expiration is finished, so that there is no opportunity for air to be drawn back into the funnel. In order to saturate the plasma the separatory funnel

<sup>5</sup> For at least an hour before the blood is drawn the subject should avoid vigorous muscular exertion as this, presumably because of the lactic acid formed, lowers the bicarbonate of the blood.

<sup>6</sup> If it is desired to keep the plasma for the estimation of carbon dioxide at a later time, it should be transferred to a paraffined tube, covered with a layer of paraffin oil, stoppered, and kept cold; under which conditions it is claimed that, if sterile, it may be kept for over a week without alteration of its carbon dioxide capacity.

is turned end over end for 2 minutes, the plasma being distributed in a thin layer as completely over the surface of the funnel's interior as is possible. After saturation is completed, the funnel is placed upright and allowed to stand for a few minutes until the fluid has drained from the walls and gathered in the contracted space at the bottom of the funnel.

*Determination of Carbon Dioxide.* The cup should be washed out with water and 1 ml. of distilled water run in, and together with the entire apparatus should be filled with mercury to the top of the capillary tube by placing the leveling bulb of mercury in position 1. A sample of 1 ml. (or 0.5 ml. in case the amount of plasma available is very small) accurately pipeted, is allowed to run into the cup *b* in the apparatus represented in Fig. 182, the tip of the pipet remaining below the surface of the water as it is added. Add 1 drop of caprylic alcohol.<sup>7</sup>

With the mercury bulb at position 2 and the cock *f* in the position shown in the illustration, the plasma, water, and alcohol are admitted from the cup into the 50-ml. chamber, leaving just enough above the cock *e* to fill the capillary so that no air is introduced when the next solution is added. In the case of whole blood, some corpuscles settle to the bottom of the cup. These are suspended in the water by stirring them up with the last 0.5 ml. of water after the first 0.5 ml. has passed into the chamber. Finally, 0.5 ml. of 5 per cent sulfuric acid is run in.<sup>8</sup>

It is not necessary that exactly 1 ml. of wash water and 0.5 ml. of acid shall be taken, but the total volume of the water solution introduced must extend exactly to the 2.5-ml. mark on the apparatus, if the table on p. 700 is to be used.

If the amount of plasma available is small, a little more than 0.5 ml. is saturated in a 50-ml. funnel, and exactly 0.5 ml. used for the estimation of carbon dioxide. In this case, the volume of distilled water and acid used to wash the plasma into the apparatus is halved, so that the total volume of water solution introduced is only 1.25 ml., and in the calculation the observed volume of gas is multiplied by 2.

After the acid has been added, a drop of mercury is placed in *b* and allowed to run down the capillary as far as the cock in order to seal the latter. A copper wire may be used to expel a bubble of air which may be trapped in the capillary. Whatever excess of sulfuric acid remains in the cup is washed out with a little water, using a medicine dropper.

The mercury bulb is now lowered and hung at position 3, and the mercury in the pipet is allowed to run down to the 50-ml. mark, producing a Torricellian vacuum in the apparatus. When the mercury (not the water) meniscus has fallen to the 50-ml. mark, the lower cock is closed and the pipet is removed from the clamp. Equilibrium of the carbon dioxide between the 2.5 ml. of water solution and the 47.5 ml. of free space in the apparatus is obtained either by mechanical shaking for 1 minute, or by turning the pipet upside down 15 or more times, thus thoroughly agitating the contents. The pipet is then replaced in the clamp.

After extraction of the gas the lower cock is opened, admitting the mercury into the extraction chamber rapidly until the meniscus of the water solution

<sup>7</sup> It is desirable to keep the amount of caprylic alcohol small, as larger amounts may appreciably increase results. With plasma 0.02 ml. is sufficient to prevent foaming and is measured most conveniently from a buret made by fusing a capillary stopcock to a pipet graduated in 0.01-ml. divisions.

<sup>8</sup> With whole blood, in place of sulfuric acid use lactic acid made by diluting 1 volume of concentrated acid (specific gravity 1.20) to 10 volumes with water.

reaches the contracted upper portion of the chamber. At this moment the lower cock is partially closed and the remainder of the mercury is admitted at a rate sufficiently retarded to prevent oscillation of the water column in the calibrated portion of the apparatus when pressure equilibrium is reached. The pressure is then adjusted by placing the mercury surface in the leveling bulb above the mercury meniscus in the chamber by a height equal to one-thirteenth that of the water column, in order to balance the latter. After some practice controlled by a centimeter rule, one can estimate this level with the eye to within 2 mm. of mercury, which is sufficiently accurate for most purposes. When the pressure has been adjusted, the lower cock of the apparatus is closed. The gas volume may then be read at leisure.

When, as in most plasma analyses, the CO<sub>2</sub> is not reabsorbed, no washing of the apparatus is necessary before using it for another determination, since the acid solution which wets the walls of the chamber contains a negligible amount of CO<sub>2</sub>.

CALCULATION. For most clinical purposes, results within 1 or 2 volumes per cent of the true values for CO<sub>2</sub> capacity may be obtained by multiplying the observed volume (uncorrected) by 100 and subtracting 12. More accurate results are obtained by means of the table on p. 700, in which the observed volume (corrected for pressure) is directly transposed into ml. of carbon dioxide chemically bound by 100 ml. of plasma. The value obtained from this table must be multiplied by 1.017 to correct for CO<sub>2</sub> reabsorbed by the solution after release of pressure. The barometer reading and room temperature are taken at the time of the determination. For convenience in the calculation, values are given below for the ratio  $\frac{B}{760}$  over the range usually encountered.

In case the volume of plasma taken for estimation of carbon dioxide content was 0.5 ml., the observed volume of gas is multiplied by 2 before it is used to calculate the volume per cent of carbon dioxide bound.

**Interpretation.** The carbon dioxide capacity of the plasma as determined by this method appears to indicate not only the alkaline reserve of the blood but also that of the entire body. The average normal value for man is 65 volumes per cent of carbon dioxide. The table on p. 701 shows the range of results obtained with normal and pathological plasma, as well as the relationship of the plasma bicarbonate to acid excretion, alkali tolerance, and alveolar carbon dioxide tension.

(b) PLASMA BICARBONATE (TITRATION METHOD) VAN SLYKE:<sup>9</sup> PRINCIPLE. Plasma is treated with an excess of standard acid which is titrated back with standard alkali to the original pH of the plasma as drawn.

**Procedure.** Blood is drawn without stasis and without exposure to air into a glass syringe or tube coated with potassium oxalate and containing mineral oil (see Fig. 183). Then without exposure to air the blood is run into a tube under oil until the tube is completely filled. A one-hole rubber stopper is inserted into the tube, expelling through the hole the oil that remains over the blood. The hole is closed with a glass plug and the tube centrifuged. The plug is then taken out and as the stopper is removed from the tube, oil is allowed to run in through the hole in the stopper to cover the surface of the plasma, so that it is never exposed to air. The plasma is then transferred under oil to another tube. Simply covering the blood with oil is not sufficient to prevent loss of CO<sub>2</sub> during centrifuging.

A standard for the end point is prepared in accordance with Cullen's original directions for colorimetric hydrogen-ion determination. 20 ml. of neutral 0.9 per cent NaCl containing 7 drops of 0.03 per cent phenol red is placed in a round flask of about 100 ml. capacity and covered with a layer of mineral oil. 1 ml. of the plasma is then introduced under the oil and the mixture is then stirred gently with a glass rod.

Another 1-ml. sample of the plasma is transferred to a similar round flask, 5 ml. of 0.01 N HCl, which is made up in neutral 0.9 per cent NaCl, is added, and the CO<sub>2</sub> is removed by whirling the mixture vigorously about the flask for at least 1 minute with a rotary motion so that the solution is whirled in a thin layer about the inner wall. 10 ml. of 0.9 per cent NaCl and 7 drops of the 0.03 per cent phenol red solution are added and 0.01 N NaOH is run in from a buret, which permits readings to 0.01 ml., until the color matches that of the standard. As the end point is approached, sufficient 0.9 per cent NaCl is added to bring the volume to 20 ml.

The 0.01 N NaOH, like the 0.01 N HCl, is made up by diluting 1 volume of 0.1 N solution to 10 volumes with neutral CO<sub>2</sub>-free 1 per cent NaCl. The use of saline solution instead of water has the advantage of preventing the formation of a permanent cloudy precipitate of globulin.

A peculiar phenomenon occurs as the end point is approached. Each drop appears to change the color past the end point, but within a few seconds the color shifts back, and it is seen that at least another drop is needed. Consequently, the final color comparison should not be made until at least 30 seconds after the last drop of 0.01 N NaOH has been added. When in doubt, it is better to overrun the end point by a drop rather than stop short of it.

**CALCULATIONS.** The number of ml. of 0.01 N NaOH used in the titration is subtracted from the ml. required to neutralize to the same indicator 5 ml. of the 0.01 N HCl used. The number is approximately 5 but usually varies from it slightly because of difference in factors of acid and alkali and because of the calibration error of the 5-ml. pipet used in measuring the acid. The maximum accuracy is obtained by performing a preliminary titration on 5 ml. of the acid plus 15 ml. of distilled water, using the same pipet, indicator, and end point as in the plasma titration. The titration result represents ml. of 0.01 M NaHCO<sub>3</sub> per ml. of plasma and it is transformed into terms of molecular concentration of NaHCO<sub>3</sub> by merely dividing by 100. If the NaHCO<sub>3</sub> molecular concentration is multiplied by 2240 or the number of ml. of 0.01 N HCl used in the titration by 22.4, the volume per cent of bicarbonate CO<sub>2</sub> in the plasma is obtained and the results can thus be compared with those obtained by the CO<sub>2</sub> method.

<sup>9</sup> Van Slyke: *J. Biol. Chem.*, 52, 495 (1922).

The standard 0.01 N NaOH must be protected from atmospheric CO<sub>2</sub> and kept in paraffined bottles to prevent solution of alkali from the glass.<sup>10</sup> The buret should be filled with fresh solution each day. The carbonate-free solution is made by dissolving the NaOH in an equal volume of H<sub>2</sub>O. On standing, the Na<sub>2</sub>CO<sub>3</sub> settles to the bottom. 2.75 ml. of the clear supernatant solution are diluted to 5 liters and standardized by titration with neutral red against 0.01 N HCl. It is preferable to run the acid into the alkali as the color change occurs without the time lag observed when alkali is added to acid.

**Interpretation.** The results agree closely with those of the CO<sub>2</sub> capacity method over the range of bicarbonate concentrations (0.03 to 0.01 M) ordinarily encountered in man, even in severe acidosis. Below this range the titration continues to give accurate results, while the CO<sub>2</sub> capacity method gives somewhat higher values. For clinical and most experimental purposes, however, it appears that the two methods give results so nearly identical that they may be used interchangeably.

### 3. Hydrogen-ion Concentration of Blood:

(a) COLORIMETRIC METHOD OF CULLEN<sup>11</sup> AS MODIFIED BY HAWKINS:<sup>12</sup> PRINCIPLE. Blood is collected with precautions against loss of CO<sub>2</sub>. The plasma is diluted with saline solution containing phenol red and the color obtained compared with that of standard phosphate mixtures of known hydrogen-ion concentration.

**Procedure.** Prepare two test tubes of the same diameter as have those used to contain the standards (see below), one containing 5 ml. of 0.9 per cent sodium chloride solution and the other 5 ml. of saline indicator solution,<sup>13</sup> each covered with a 1-cm. layer of neutral mineral oil. Connect a Luer needle adapter, by means of a short piece of rubber tubing, to a 1-ml. Mohr pipet. Without stasis, insert the needle into the subject's vein, attach the adapter, and allow the blood to fill the pipet past the zero mark. (A tourniquet may be used to aid in finding the vein, but the blood should flow into another tube a few seconds after the release of the tourniquet, so that stasis is absent when the adapter is inserted into the needle.) Withdraw the needle from the vein and at once disconnect the rubber tubing from the pipet. Wipe the tip and introduce into each tube, under the oil, 0.4 ml. of the blood. Stir the contents carefully with a fine glass rod.

---

<sup>10</sup> *Testing Standard 0.01 N NaOH for Carbonate.* The solutions should be made up using only boiled water, be kept in paraffin-lined bottles, and be protected from atmospheric CO<sub>2</sub> by soda-lime tubes. They should be tested for carbonate as follows:

To 5 ml. of 0.01 N HCl in a 200-ml. round flask, add from a freshly filled buret about 4.8 ml. of the 0.01 N NaOH to be tested and 0.3 ml. of neutral red solution. The mixture should be strongly acid to the indicator. The solution is rotated for 1 minute in the flask to permit the escape of CO<sub>2</sub>, and is then transferred to a 50-ml. Erlenmeyer flask and titrated as in plasma analyses, the total amount of 0.01 N NaOH required to give the end point being noted.

A duplicate titration is performed in the same way except that there is no agitation to remove carbon dioxide, the 0.01 N HCl plus 20 ml. of water being placed directly in the 50-ml. Erlenmeyer flask, and the 0.01 N NaOH being added with a minimum of stirring.

If there is no carbonate in the standard NaOH solution the two titrations give identical results. The difference should preferably not exceed 0.1 ml., and if it exceeds 0.2 ml. the alkali should not be used.

<sup>11</sup> Cullen: *J. Biol. Chem.*, 52, 501 (1922).

<sup>12</sup> Hawkins: *J. Biol. Chem.*, 57, 493 (1923).

<sup>13</sup> Prepare fresh for each determination. Add 2.1 ml. of 0.03 per cent phenol red solution to 100 ml. of 0.9 per cent sodium chloride solution. Adjust to approximately pH 7.4 by stirring with a fine glass rod dipped into 0.02 N alkali or acid, as the case may be.

\* The temperature figures at the heads of columns represent in degrees centigrade the room temperature at which the samples of plasma are saturated with alveolar carbon dioxide and analyzed. It is assumed that both operations are performed at the same temperature. The figures have been so calculated that, regardless of the room temperature at which saturation and analysis are performed, the table gives the volume (reduced to 0°, 760 mm.) of carbon dioxide that 100 ml. of plasma are capable of binding when saturated at 20° with carbon dioxide at approximately 41 mm. tension. If the figures in the table are multiplied by 0.94 they give within 1 or 2 per cent the carbon dioxide bound at 37°.

RELATIONSHIP OF THE PLASMA BICARBONATE TO ACID EXCRETION, ALKALI TOLERANCE, AND ALVEOLAR CARBON DIOXIDE TENSION\*

*Color Standards.* These are prepared by adding 0.3 ml. of 0.03 per cent phenol red (phenol-sulfonphthalein) to 15 ml. of each of the standard buffer solutions. The concentration of dye required varies somewhat with different lots. It is best to prepare a concentrated stock solution, and determine by experiment the dilution required to give satisfactory depth of color over the desired pH range. The indicator solution must be neutral. After the addition of 1 drop to 3 ml. of redistilled water, the water must not be red.

The color standards must be renewed or checked against a fresh tube of dye at least once every week as there is a slow fading of color.

*Apparatus.* The comparator required is conveniently made from a block 3 × 6 inches. The holes for the tubes are of 1 inch diameter. The slits for the light are best made by boring two ½ inch holes and gouging out the remaining wood with a chisel. The tube

tions at 20° C., by placing the plasma tubes, together with the necessary standard tubes, in a large beaker of water at 20°.

CALCULATION. The pH of the blood (human) at 38° C. is obtained from the following equation:

$$\text{pH}_{38^\circ} = \text{Colorimetric pH}_{t^\circ} + 0.01(t^\circ - 20) - 0.23$$

in which  $t^\circ$  represents the observed temperature. If the tubes are adjusted to 20° C., the middle factor naturally drops out.

The empirical correction,  $-0.23$  ("Cullen correction"), applied to adjust the colorimetric pH values to those determined electrometrically at 38°, compensates for the protein and salt errors in the colorimetric determination. The correction varies with the species of animal, but unfortunately is not as constant in each species as could be desired.

Hastings and Sendroy claim that the Cullen correction is unnecessary when the readings are made with the tubes at body temperature. Austin, Stadie, and Robinson have shown, however, that under pathological conditions in man, and in the dog, there is considerable variation in the Cullen correction, and Hastings and Sendroy's procedure does not eliminate it. For these cases, they state, corrections must be determined on each serum if colorimetric readings are to be relied upon.

According to Cullen and Earle the colorimetric method gives results at 20° C. 0.08 pH higher than the hydrogen electrode, and 0.14 pH higher than the quinhydrone electrode. The electrometric method using the glass electrode (see (c) below) affords the most precise as well as most convenient method for measuring pH of the blood.

**Interpretation.** The normal pH range of blood is between 7.30 and 7.50. The extreme limits of pathological variation which have been observed are 6.95 to 7.80. For the significance of abnormal pH values, see the table on p. 691.

(b) METHOD OF SHOCK AND HASTINGS.<sup>15</sup> This is an adaptation of the preceding method employing a special pipet which not only permits the determination of cell volume as well as plasma pH, but also makes possible the transfer of the diluted plasma to the manometric apparatus for CO<sub>2</sub> determination. Blood is collected by finger puncture under paraffin oil in the conical receiver containing oxalate (Fig. 185). The Shock-Hastings pipet is filled to the 0.1-ml. mark, followed by phenol red saline solution to the 2-ml. mark. A control pipet is filled with 0.1 ml. of blood diluted with indicator-free saline solution. The tip of each pipet is covered with a bit of adhesive tape and a heavy rubber band (Eberhard Faber No. 84). The cell volume is read after centrifuging. The pH is read in a special colorimeter block containing comparator

---

must be of clear, nonalkaline glass of *uniform* diameter. Tubes 20 mm. in diameter are convenient.

*Light.* Either daylight or "Daylite" lamps are satisfactory.

*Test for Neutrality.* The redistilled water is usually about pH 6.2 to 6.5. The easiest test is that of using both phenol red and methyl red. The water should give no red color with either indicator.

The syringe, pipets, and tubes should be rinsed with redistilled water and dried. Syringes, tubes, and pipets, washed and sterilized in the usual manner employed in bacteriological laboratories, are often dried from alkaline water.

The saline solution must be adjusted to pH 7.4 as described above. The oxalate, when dissolved in water to a 0.5 per cent solution, should not be more alkaline than pH 7.2 to 7.4. The oil is tested by shaking with water containing phenol red and methyl red. The water must remain neutral.

<sup>15</sup> Shock and Hastings: *Proc. Soc. Exptl. Biol. Med.*, **26**, 780 (1929). Also described in greater detail by Peters and Van Slyke: *Quantitative Clinical Chemistry*, Vol. 2, p. 804, Baltimore, The Williams & Wilkins Co., 1932.

tubes of the same internal diameter as the bulb of the pipets. The contents of the pipet may then be transferred to the Van Slyke-Neill apparatus.

(c) **ELECTROMETRIC METHOD.**<sup>16</sup> The potentiometric method for the determination of pH has been applied to blood. The usual precautions must be observed in obtaining

FIG. 185. APPARATUS FOR SHOCK-HASTINGS METHOD.

the sample to prevent the loss of carbon dioxide, and similar care must likewise be taken during the actual measurement. To this end, glass-electrode vessels have been devised so that the sample of blood is maintained out of contact with air. Fig. 186

FIG. 186. GLASS-ELECTRODE ASSEMBLY FOR USE WITH BECKMAN pH METER.

FIG. 187. GLASS ELECTRODE FOR USE WITH THE COLEMAN ELECTROMETER.

Courtesy, A. S. Aloe Company, St. Louis, Mo.

shows such a glass-electrode assembly for use with the Beckman pH meter, so designed that the sample of blood can be transferred with minimum gas exchange directly from the hypodermic syringe to the electrode chamber. Another model of glass electrode, for use with the Coleman Electrometer, is shown in Fig. 187. In this assembly, the

<sup>16</sup> Craig, Lange, Oberman, and Carson: *Arch. Biochem. and Biophys.*, **38**, 357 (1952).

hypodermic needle is attached to the electrode chamber so that the sample of blood enters the chamber, which is then immediately made part of the electrometric circuit. With the due care ordinarily exercised in the electrometric measurement of pH, accurate values can be obtained on as little as 0.5 ml. of blood.

**4. Acetone Bodies.** For methods of determining acetone, acetoacetic, and  $\beta$ -hydroxybutyric acids in the blood see the References at the end of Chapter 23.

**5. Determination of Oxygen and Oxygen Capacity (or Hemoglobin) of Blood: Volumetric Methods.** It is possible to determine the oxygen of the blood using the same apparatus as that employed for the  $\text{CO}_2$  estimation (see p. 693), suitable precautions being taken in collecting the blood for analysis. The *oxygen content* of blood represents the total volume of oxygen, both physically dissolved and combined with hemoglobin, present in 100 ml. of blood in the condition in which it flows through the veins or arteries. For the determination of oxygen content it is, therefore, necessary to collect the blood so as to avoid the oxygenating effect of air, i.e., under oil. An aspirating tube of the type illustrated in Fig. 183 is suitable for this purpose.

The *oxygen combined with hemoglobin* in arterial or venous blood differs from the oxygen content in that a correction is made for free, physically dissolved oxygen. The same precautions in the collection of the sample must, of course, be taken.

The *oxygen capacity* of blood represents the volume of oxygen required to combine with all of its hemoglobin (oxyhemoglobin and reduced hemoglobin). It therefore constitutes a measure of hemoglobin since it is established that 1 g. of hemoglobin combines with 1.36 ml. of oxygen, or, in other words, each ml. of oxygen capacity represents 0.736 g. of hemoglobin. Blood for this determination may be collected without precautions to avoid contact with air, inasmuch as aeration (oxygenation) is the first step in the procedure.

The *oxygen unsaturation* of venous or arterial blood is a measure of the absolute concentration of reduced hemoglobin, and is obtained by subtracting from the oxygen capacity (total hemoglobin), the oxygen combined with hemoglobin as defined above. The distinction between this and the relative unsaturation, which is the *per cent* of total hemoglobin in the reduced state, should be kept in mind. The use of the absolute rather than the relative expression is due to the fact that cyanosis is regarded as the result of an increased absolute concentration of the bluish reduced hemoglobin.

**Determination of Oxygen Capacity.** Stir the special oxygen reagent (see p. 716) to obtain emulsification of the caprylic alcohol. Introduce 7.5 ml. into cup *b* (Fig. 182), and deaerate by shaking in the evacuated extraction chamber. Mix the blood thoroughly with a stirring rod, and transfer to a 250-ml. separatory funnel in which it is completely aerated by rotating in a thin layer over the interior surface of the funnel. (For oxygen determinations other than capacity, simply mix the blood under the oil and omit aeration.) Force 6 ml. of the gas-free reagent into the cup of the apparatus. By means of a differential pipet (graduated to deliver between marks, Fig. 190), transfer exactly 2 ml. of the blood directly into the extraction chamber by

keeping the tip of the pipet immersed to the bottom of the reagent in the cup and regulating the admission by the finger or stopcock on the pipet and cock of the apparatus. Never allow more than a few ml. of blood to accumulate in the cup. An Ostwald transfer pipet may be used for this purpose, the final drop of blood being forced out of the immersed tip by expanding the air in the pipet with the heat of the hand, keeping the mouth of the pipet closed. Admit the remaining blood and all but 1 ml. of the reagent from cup *b* into the extraction chamber. With a medicine dropper discard the excess reagent and introduce a few drops of mercury as a seal. Evacuate and shake until the volume of extracted gas ( $O_2 + CO_2 + N_2$ ) is constant. This will be found to consume from 5 to 10 minutes and should be determined by measuring the gas at atmospheric pressure. Create a slight negative pressure within the pipet by bringing the level of solution to the 2-ml. graduation. Rinse cup *b* with distilled water and introduce 0.5 ml. of a 2 per cent NaOH solution previously deaerated. By means of the negative pressure within the pipet, admit this solution slowly, followed by a thin stream of mercury, which serves to break the column of NaOH which usually forms in the capillary of the pipet. Allow 1 minute for drainage and bring the gas ( $O_2 + N_2$ ) to atmospheric pressure as described in the determination of  $CO_2$ . Read the volume of gas, the temperature, and the barometric pressure.

#### CALCULATIONS.

$V$  = observed volume of gas ( $O_2 + N_2$ )

$t$  = temperature in  $^{\circ}C$ .

$B$  = barometric pressure in mm. Hg

$w$  = tension of aqueous vapor (see p. 709)

$$\text{Volume per cent } O_2 \text{ capacity} = \left( \frac{(B - w)}{760(1 + 0.00367t)} \times \frac{100V}{2} \right) - 2.1$$

Values for the temperature and pressure correction factor are given in the table on p. 707. The following equation may also be used:

$$\text{Volume per cent } O_2 \text{ capacity} = \left( \frac{17.9(B - w)V}{t + 273} \right) - 2.1$$

The value 2.1 in these equations corrects for oxygen and nitrogen physically dissolved at atmospheric pressure. For oxygen content subtract 1.36 (per cent  $N_2$ ) instead of 2.1. For  $O_2$  combined with hemoglobin subtract 1.7 or 1.5 for arterial or venous blood respectively, which corrects for free  $O_2$  and  $N_2$  at arterial or venous tension.  $O_2$  unsaturation is obtained by subtracting  $O_2$  combined with hemoglobin from  $O_2$  capacity.

Hemoglobin (g. per 100 ml.) =  $0.736 \times$  volume per cent  $O_2$  capacity.

For colorimetric determination of hemoglobin, see p. 610.

**6. Determination of Carbon Monoxide in Blood—Volumetric Method of Van Slyke and Associates:**<sup>17</sup> **Principle.** A more exact quantitative procedure for the estimation of carbon monoxide than the colorimetric method given in Chapter 22 is a volumetric method based on the experiments of Van Slyke and his associates. The mixed gases are extracted from the sample of blood in a Van Slyke pipet (Fig. 182). the oxygen and carbon dioxide are absorbed, and the carbon monoxide estimated in the residual gas either by absorption with Winkler's reagent or by correction for the nitrogen.

| 30                 | $0.863 \times \frac{B}{760}$                                                                                                           | 0.738                   | 0.039                                                        | 0.078                      | $0.912 \times \frac{B}{760}$                                                                                                                                                                                                                                                | $0.950 \times \frac{B}{760}$ |

\* To calculate  $\text{O}_2$  or hemoglobin when  $\text{O}_2 + \text{N}_2$  volume is measured, multiply gas volume by  $f$ , to reduce to  $0^\circ$ , 760 mm., and by such factor as is necessary (100 when 1 ml. of blood is used, 50 when 2 ml. are used) to bring results to volume per cent basis. Then for

- a,  $\text{O}_2$  content, subtract.....

b,  $\text{O}_2$  bound by hemoglobin in venous blood, subtract.....

c,  $\text{O}_2$  bound by hemoglobin in arterial blood, subtract.....

d,  $\text{O}_2$  bound by hemoglobin in blood saturated with air at  $20^\circ \text{C.}$ , subtract.....
- 1.36 vol. per cent  $\text{N}_2$

1.5 vol. per cent  $\text{N}_2 +$  dissolved  $\text{O}_2$

1.7 vol. per cent  $\text{N}_2 +$  dissolved  $\text{O}_2$

2.1 vol. per cent  $\text{N}_2 +$  dissolved  $\text{O}_2$
- Per cent of normal hemoglobin (Haldane scale) =  $\frac{100d}{18.5} = 5.41d$

Grams of hemoglobin per 100 ml. of blood =  $0.736d$

Per cent of total hemoglobin saturated with  $\text{O}_2 = \frac{100b}{d}$  or  $\frac{100c}{d}$

Volumes per cent  $\text{O}_2$  unsaturation =  $d - c$  or  $d - b$

† The dissolved air is given as measured at room temperature. It is subtracted from the air +  $\text{CO}_2$  volume, measured after one extraction of plasma or aqueous carbonate solution, in order to obtain the  $\text{CO}_2$ , which is then multiplied by  $1.017f \left(1 + \frac{S}{50 - S} \alpha'_{\text{CO}_2}\right)$  in order to obtain the total volumes per cent of  $\text{CO}_2$  in the solution analyzed. When whole blood is analyzed, the air correction cannot be used, because of the  $\text{O}_2$  present, and the  $\text{CO}_2$  must be determined by absorption with  $\text{NaOH}$  solution. The volume of gas absorbed is then multiplied by the above factor.  
The factor 1.017, being empirical, may vary slightly for different apparatus.

**Procedure.** Blood should be collected under oil in an oxalated tube. A special CO reagent<sup>18</sup> is required which differs from the O<sub>2</sub> reagent in containing lactic acid as well as more potassium ferricyanide. The reagent (7.5 ml.) is made gas-free and the mixed gases are extracted from 2 ml. of blood exactly as described under the determination of oxygen capacity (p. 705). Longer shaking may be required to arrive at constant volume, since CO is not so readily dissociated from its combination with hemoglobin. After the extraction, a negative pressure is created in the extraction chamber by raising the solution level to a point 2 to 3 cm. below the 2.5-ml. graduation. About 0.5 ml. of mineral oil is introduced into the cup and below this 1 ml. of alkaline pyrogallate reagent.<sup>19</sup> The reagent is admitted until its level reaches the capillary of the cup, and the column that forms in the graduated capillary is broken by means of a stream of mercury as described in the determination of oxygen capacity. A few minutes are allowed for drainage, the gas is restored to atmospheric pressure, and the volume read. The absorption of CO<sub>2</sub> and O<sub>2</sub> is repeated until the residual volume is constant. The CO may be estimated from this volume reading, the temperature, and barometric pressure.

If it is desired to determine the CO directly by absorption, proceed from this point by first drawing the mixed solutions in the pipet into reservoir *d*. This is to avoid mixing the alkaline pyrogallate solution with Winkler's reagent<sup>20</sup> to be used. Establish a slight negative pressure within the extraction chamber as described above. Rinse the delivery cup with distilled water and introduce into the pipet 0.5 ml. of Winkler's reagent. Absorption of CO takes place rapidly and the final gas volume should be read at once.

A method of magnifying small volumes of gas by reducing the pressure a definite amount below atmospheric is described by Van Slyke and Stadie.<sup>21</sup>

Larger samples of blood may be used, the amounts of reagents being proportionately increased.

#### CALCULATIONS.

$V_1$  = Observed volume of gas from 2 ml. of blood, after absorption by alkaline pyrogallate solution

$V_2$  = Observed volume after absorption by Winkler's reagent

$B$  = Barometric pressure in mm. of Hg

$w$  = Tension of aqueous vapor in mm. of Hg (see table on p. 709)

$t$  = Temperature in ° C.

$$\text{Volume per cent CO} = \left( \frac{(B - w)}{760(1 + .00367t)} \times \frac{100V_1}{2} \right) - 1.36$$

or

$$\text{Volume per cent CO} = \left( \frac{(B - w)}{760(1 + .00367t)} \right) \frac{100(V_1 - V_2)}{2}$$

MANOMETRIC METHODS OF ANALYSIS OF GASES  
IN BLOOD AND OTHER SOLUTIONS<sup>22</sup>

**Principle.** The manometric methods of gas analysis differ from the more commonly used volumetric methods in that the latter involve reading the volume with the gas under a definite (usually atmospheric) pressure, whereas by manometric methods the pressure required to keep the gas at a fixed volume is observed. The advantages of this procedure are that a much lower degree of error is attainable, since in the former method the error in volume reading is many times greater than the error in reading of barometric pressure; calculation is greatly simplified, as barometric pressure and corrections for vapor tension and capillary attraction of mercury do not enter in; smaller quantities of material may be used; and accuracy is attainable over a wide range of gas concentration.

**Apparatus.** The apparatus consists of a short pipet with the upper stem closed by a stopcock, the lower connected with a glass tube. The latter descends, then turns to connect with a leveling bulb and a closed mercury manometer. The pipet is calibrated at two points to hold *a* ml. of gas for pressure measurement and *A* ml. of total volume, respectively, as shown in Fig. 188.

For analysis, the sample of blood or other solution is introduced into the chamber over mercury, together with the reagents to free the desired gases from combination. A Torricellian vacuum is obtained, as in the “volumetric” apparatus, by lowering the leveling bulb, and the gases are extracted from solution by 2 or 3 minutes’ shaking. The gas volume is then reduced to *a* ml. by admission of mercury and the reading *p*<sub>1</sub> is made on the manometer. The gases are either ejected or are absorbed by proper reagents, and the reading *p*<sub>2</sub> is taken, with the same gas volume. The partial pressure *P* of the gas at *a* ml. volume is then  $P = p_1 - p_2$  mm. of mercury, from which the gas volume at 0°, 760 mm. may be calculated. Methylene or ethylene glycol or glycerol may be used as a dehydrating agent to moisten the upper part of the manometer tube.

<sup>22</sup> Van Slyke and Neill: *J. Biol. Chem.*, **61**, 523 (1924); Van Slyke: *J. Biol. Chem.*, **73**, 121 (1927). In addition to the methods here to be described, these papers give the details of the technique for the combined determination of all the gases in a sample of blood: methods for micro-analyses of fractions of a ml. of blood; for determination of gases in liquids saturated at high tensions; for determination of dissolved gases in water; and for the use of the apparatus in air and general gas analyses. Principles and numerous applications of the manometric methods are completely described in Peters and Van Slyke: *Quantitative Clinical Chemistry*, Vol. 2, Baltimore, The Williams & Wilkins Co., 1932.

The extraction chamber differs from that of the "volumetric" apparatus in being calibrated at only three points, viz., 0.5, 2.0, and 50 ml. The mercury seal around the rubber joint at the bottom of the extraction chamber illustrated in Fig. 189 can be replaced by special heavy-walled rubber tubing. A mechanical shaker is provided. Air which diffuses through the rubber tubing of the leveling bulb is expelled through

FIG. 188. VAN SLYKE AND NEILL PORTABLE MANOMETRIC GAS-ANALYSIS APPARATUS.

stopcock *d*. The stopcock at the bottom of the manometer permits withdrawal of the mercury.

The bottle on top of the frame holds distilled water. The lower bottle is to receive waste solutions drained out of the chamber after analyses. The most rapid and convenient way to transfer solution to the waste bottle is to force it up into the cup above the chamber and then draw it over into the bottle by suction. If suction is not available, a narrow rubber drain can be run from the curved outlet capillary to the bottle.

For calibration of the apparatus and a method of constructing a simple but not necessarily inaccurate modification of the manometric apparatus, see the original papers.

**Measuring Samples.** In order to attain the advantage of precision offered by the manometric apparatus, accuracy in collecting and measuring samples is essential. Blood should be either (1) drawn directly from the vein, without stasis, into the differential pipet from which it is to be delivered into the extraction chamber, or,

FIG. 189. EXTRACTION CHAMBER.

FIG. 190. OPERATION OF DELIVERY PIPET.

better (2), collected under oil in an oxalated tube from which it can be drawn as needed. The corpuscles should be uniformly distributed with a fine stirring rod before each sample is withdrawn. A heavy-walled Ostwald pipet graduated to deliver between two marks ("differential" pipet) and preferably provided with a stopcock should be used (see Fig. 190).

Blood must be admitted at a rate slow enough to permit clear drainage of the pipet. Smooth delivery is usually obtained by using cock *e* or the cock of the pipet. Amounts of solution of 2 ml. or more may be run in under 1 ml. of mercury in the cup, the mercury then washing out the capillary. For smaller amounts, wash solution is necessary for complete transfer. An ordinary transfer pipet may be used, the final drop of blood being expelled by keeping the tip immersed, closing the mouth of the pipet with

the index finger, and grasping the bulb with the warm palm of the other hand. The expanding air drives out the remaining blood.

**Cleaning the Apparatus.** Preceding each analysis, the apparatus is cleaned by introducing 10 or 15 ml. of approximately 0.01 N lactic acid, shaking for 15 or 20 seconds in the evacuated chamber, and ejecting the extracted gas and solution. Adherent solution introduces no error in the subsequent analysis.

\* If calibration of an apparatus shows a value of *a* significantly different from the 0.500 or 2.000 ml. in the column heading, the factors in the column are corrected by multiplying them by  $\frac{a}{0.500}$  or  $\frac{a}{2.000}$ .

Occasionally the apparatus should be kept filled overnight with chromic-sulfuric acid mixture, admitted through cock *b* by regulation of cock *e*. The latter is kept closed but the former open to allow the escape of gas.

**Testing for Leaks.** Test for leaks by introducing *S* ml. of water (Fig. 189) and extracting dissolved air for two minutes. Reduce the gas volume to *a* and read the pressure. If the temperature is constant, the pressure should not increase when this extraction is repeated.

FACTORS BY WHICH MILLIMETERS  $P_{CO_2}$  ARE MULTIPLIED TO GIVE VOLUMES PER CENT  $CO_2$  IN SOLUTION ANALYZED—50-ML. APPARATUS\*

\* Van Slyke and Sendroy: *J. Biol. Chem.*, 73, 127 (1927).  
To obtain factor for a sample other than 1 ml., divide the above factors for 1 ml. by the ml. of sample analyzed: e.g., for a 2-ml. sample the factors are one-half of those for 1 ml.  
To calculate ml. of  $CO_2$  measured at 0°, 760 mm., in the actual portion of solution analyzed, use the above volume per cent factors for 1-ml. samples divided by 100.

**Lubrication.** Cocks *b* and *e* must turn smoothly but not leak. A thin layer of petrolatum is first applied, followed by a rubber paste (made by dissolving 1 part of unvulcanized rubber in 5 parts of petrolatum, with heat), using relatively less of the first coating in warm weather.

**Determination of Correction, *c*, for Manometer Depression Caused by Introduction of Absorbent Solution.** The introduction of absorbent solution causes a lowering of the mercury meniscus in the chamber and hence in the manometer, by

increasing the volume of fluid between the mercury and the *a* mark at the moment of reading (Fig. 188). This necessitates for the  $p_2$  reading a correction, which is determined by blank analyses. The shape of the apparatus causes the area of the meniscus of the mercury in the chamber to vary according to the values of *S* and *a*. The value of *c* for 1 ml. of added solution may accordingly be from 1 to 4 mm., depending on the shape of the chamber and the volume of *S*.

Dilute absorbents (N NaOH) or hydrosulfite (20 per cent solution) have no significant effect on the vapor pressure in the chamber. Special precautions are required for alkaline pyrogallate solution (p. 708) because of the strong KOH.

When the final manometer reading is obtained after expulsion of the gases instead of after addition of an absorbing solution, *c*, of course, is zero.

CALCULATION. The general equation for calculating total gas content of a solution from the volume of gas extracted in an evacuated chamber of definite volume, as developed by Van Slyke and Stadie,<sup>23</sup> has been subjected to certain modifications and made adaptable to manometric calculations.

Vapor pressure is eliminated as a factor since it is the same for both pressure readings and cancels out in the equation  $P = p_1 - p_2$ . An *i* correction for reabsorption of extracted gas during the release of the vacuum is required for CO<sub>2</sub> just as in volumetric measurements, and amounts to about 1.014. For less soluble gases (O<sub>2</sub>, N<sub>2</sub>, CO) it is practically 1.000, reabsorption being negligible. A correction is also included for the effect of temperature on the specific gravity of mercury.

The use of the rather involved final equation is expedited by the tables constructed by the authors, which give directly the factors by which *P*, read at any given temperature under the conditions ordinarily employed, must be multiplied to obtain the volumes per cent of gas (see the tables on pp. 712 and 713). To express results as millimoles per liter, either use the table of millimole per liter factors given in the original papers, or divide volumes per cent of gas by 2.24 or in the case of CO<sub>2</sub> by 2.226.

$$\begin{aligned}\text{Volumes per cent gas} &= P \times \text{vol. per cent factor} \\ \text{mM. gas per liter} &= \frac{P \times \text{vol. per cent factor}}{2.24}\end{aligned}$$

**Determination of CO<sub>2</sub> in Blood or Plasma.**<sup>24</sup> The apparatus having been cleaned (see p. 712), a drop of caprylic alcohol is drawn into the capillary above cock *b*, and 2.3 ml. of CO<sub>2</sub>-free water per ml. of blood or plasma to be added are put into the cup. Stopcock *b* is closed, with *e* open. The blood or plasma is delivered beneath the layer of water in the cup from a pipet as described under "Measuring Samples." After the delivery of the sample, the residue of blood in the cup is run into the chamber below, followed by the water layer. Finally, 0.2 ml. of CO<sub>2</sub>-free 0.1 N lactic acid per ml. of blood or plasma is added. Stopcock *b* is then sealed with a drop of mercury. The CO<sub>2</sub> is liberated by lowering the leveling bulb until the surface of the mercury has fallen to the *A* mark, closing cock *e*, and shaking the mixture for 3 minutes. The extracted gas is reduced to 2 ml. (*a*), the admission of mercury being regulated by stopcock *e* and the leveling bulb. If the fluid meniscus passes this point, readjustment must be made by first bringing the mercury meniscus to the *A* mark and equilibrating for a minute. Otherwise more reabsorption of CO<sub>2</sub> will take place than is provided for in the calculation. The adjustment being correct, the manometer is tapped with the finger, and the height of the mercury column read ( $p_1$  mm.).

<sup>23</sup> *J. Biol. Chem.*, 49, 30, 31 (1921).

<sup>24</sup> Shohl determines both CO<sub>2</sub> and pH on 0.1 to 0.2 ml. of plasma. See *J. Biol. Chem.*, 83, 759 (1929).

The variable amounts of  $O_2$  extracted from whole blood make it necessary to determine  $CO_2$  by absorption. This custom is also followed in plasma analyses, though it may be avoided by correcting for extracted air. The absorbent solution, 1 N NaOH<sup>25</sup> is admitted under reduced pressure. After measuring  $p_1$  the pressure is diminished so that a space of several ml. is left between the water meniscus and the lower *a* mark. Next, 2 ml. of gas-free alkali is measured into the cup from the reservoir, avoiding reabsorption of air, and 1 ml. of alkali is admitted into the chamber. Absorption is complete in 30 seconds.

In analyses of serum or aqueous solutions of carbonates, the  $CO_2$  may be absorbed with 0.2 ml. of 5 N NaOH.  $O_2$  and  $N_2$  are sufficiently insoluble in

FIG. 191. USE OF CALCIUM CHLORIDE TUBE RESERVOIR.

FIG. 192. BULB FOR PREPARING AND STORING GAS-FREE SOLUTIONS.

this medium to make deaeration unnecessary. Only slight negative pressure is required to admit it. Air-free 1 N NaOH must be used for whole blood.

After absorption of  $CO_2$  cock *b* is sealed with mercury and the meniscus of the solution in the chamber is lowered a little below the *a* mark. Mercury is readmitted from cock *e* until the solution meniscus is again on the *a* mark. Cock *e* is closed and the reading of the manometer is taken ( $p_2$  mm.). The  $CO_2$  pressure  $P_{CO_2}$  is

$$P_{CO_2} = p_1 - p_2 - c$$

where *c* is the correction discussed on p. 713. This correction is determined in a blank analysis in which *S* ml. of water, made alkaline with 2 or 3 drops of normal NaOH, are extracted in the apparatus,  $p_1$  and  $p_2$  being read before and after addition of the same amount of alkali as used in the determination.

$$c = p_1 - p_2$$

<sup>25</sup> The alkali must be made gas-free and kept in properly protected reservoirs. 25 to 30 ml. of 1 N NaOH are deaerated in the extraction chamber and transferred under oil to a reservoir made from a calcium chloride tube (Fig. 191). This will keep for a day. For larger amounts of solution, the apparatus shown in Fig. 192 is suggested. It consists of two leveling bulbs connected by a rubber tube 1 meter long. One of the bulbs (illustrated) is provided with a glass capillary and stopcock. The bulb is half-filled with absorbent solution and extracted by evacuation and shaking. Solution is delivered into the extraction chamber directly from the capillary of this reservoir.

To minimize error, all solutions must be measured very accurately, so that  $S$  varies within  $\pm 0.05$  ml. Also, sufficient time must elapse for temperature equilibrium to be established. (For other sources of error and refinements of technique, see the original paper.<sup>26</sup>)

CALCULATION. See p. 714.

**Determination of Plasma CO<sub>2</sub> Capacity.** CO<sub>2</sub> capacity, as a clinical measure of acidosis, may be determined by the volumetric method of Van Slyke and Cullen (p. 693). For the manometric determination, admit a drop of caprylic alcohol into the capillary of the cup, followed by 1.5 ml. of 0.1 N lactic acid. One ml. of plasma (previously saturated with alveolar air) is introduced below the acid. The solutions are admitted to the extraction chamber, cock  $b$  sealed, the chamber evacuated and shaken 2 minutes. Then  $p_1$  is read as described above with the gas volume at 2 ml. The gas is ejected, the ejected portion of the solution returned to the chamber, and the pressure reduced so that the gas space is again 2 ml. The value  $p_2$  and the temperature are then read.

CALCULATION. Pressure of extracted air and CO<sub>2</sub> =  $p_1 - p_2$ .

The CO<sub>2</sub> capacity is obtained from this pressure by the use of the nomogram (Fig. 193).

**Determination of Oxygen in Blood.**<sup>27</sup> Oxygen may be determined manometrically on 1-ml. samples of blood with a variation within 0.2 volume per cent.

The special O<sub>2</sub> reagent<sup>28</sup> is emulsified by rotating, and 7.5 ml. are measured into the apparatus and deaerated by shaking in vacuo for three minutes. During the shaking, the mercury should be well in the neck below the bulb, to afford minimum exposure of surface, as mercury reacts with ferricyanide. One ml. of the well-mixed blood is drawn into a pipet, preferably such as described on p. 711. 6 ml. of the extracted reagent are forced into the cup, leaving 1.5 ml. in the chamber. The blood is introduced under the reagent directly into the chamber as described under "Measuring Samples." The pipet is carefully withdrawn and 1 ml. of reagent is permitted to flow into the chamber, rinsing through the blood in the capillary. The cock is sealed with a drop of mercury and the excess reagent discarded. The apparatus is evacuated and shaken for 3 minutes. 1 ml. of air-free 1 N NaOH is placed in the cup and the CO<sub>2</sub> absorbed by admitting 0.5 ml. of the hydroxide into the chamber under diminished pressure as described in CO<sub>2</sub> determination on whole blood.

The solution meniscus is brought to 2 ml. ( $a$ ) and  $p_1$  (pressure of O<sub>2</sub> + N<sub>2</sub>) is read. (For low O<sub>2</sub> values it is preferable to read  $p_1$  with  $a$  at 0.5 ml.) As in the volumetric method, O<sub>2</sub> may now be determined either by making a correction for N<sub>2</sub>, or directly by absorption. In the first case, after  $p_1$  has been

<sup>26</sup> Austin, *J. Biol. Chem.*, 61, 345 (1924), has described a modification of this procedure to be used in CO<sub>2</sub> analyses of serum obtained after ether anesthesia.

<sup>27</sup> Sendroy, *J. Biol. Chem.*, 91, 307 (1931), describes a shorter method for hemoglobin by manometric O<sub>2</sub>-capacity determination.

<sup>28</sup> *Special Oxygen Reagent*.

|                                  |          |
|----------------------------------|----------|
| Potassium ferricyanide . . . . . | 3.0 g.   |
| Saponin (Merck) . . . . .        | 3.0 g.   |
| Caprylic alcohol . . . . .       | 3.0 ml.  |
| Water to . . . . .               | 1000 ml. |

Low results for oxygen may be accounted for by saponin of low hemolytic activity, in which case the amount may be increased.

FIG. 193. NOMOGRAM FOR CALCULATION OF PLASMA  $\text{CO}_2$  CAPACITY.

A straight line connecting the observed points on the pressure and temperature scales cuts the  $\text{CO}_2$  capacity scale at the point indicating the capacity.

read, the gases are ejected from the chamber and  $p_2$  is determined with the solution meniscus at the same  $a$  mark.

The absorption method is resorted to for greater precision or when other gases (e.g.,  $\text{CO}$ ) are present. After  $p_1$  has been read, cock  $e$  is opened, with the leveling bulb in position to produce a gas space of 4 to 5 ml. Cock  $e$  is then closed. Next 1.5 ml. of hydrosulfite solution<sup>29</sup> is introduced into the cup

<sup>29</sup> Grind up 100 g. of sodium hydrosulfite and 10 g. of sodium anthraquinone- $\beta$ -sulfonate (Eastman Kodak Co.) and keep in stoppered bottle. To prepare absorbent solution stir

and by turning cock *b* admitted a drop at a time. As each drop trickles down, it absorbs  $O_2$  and the mercury in the manometer falls. After a few drops have been admitted no further perceptible fall occurs. Cock *e* is then opened and the solution permitted to rise as near the stopcock as it will, with the leveling bulb in the lower ring. The remainder of 1 ml. of hydrosulfite is then added, completing the absorption of traces of  $O_2$ . The gas is brought to the same *a* volume and  $p_2$  is read on the manometer.

$$p_{O_2} = p_1 - p_2 - c_{O_2}$$

To check the completeness of  $O_2$  absorption and the absence of air leakage, expel the  $N_2$  and measure  $p_3$  in the gas-free apparatus. The  $N_2$  should approximate 1.2 volumes per cent in the  $O_2$  content determination, or 1.4 volumes per cent in  $O_2$  capacity.

An alternative absorbent for  $O_2$  is the alkaline pyrogallate reagent (p. 708). This is not so clean or rapid as the hydrosulfite, but is more stable and its use is advised when  $O_2$  determinations are done only occasionally. The gummy precipitate formed with the blood mixture necessitates mixing the solutions in the bulb of the chamber, well below the *a* mark, resulting in a greater negative pressure for the admission of the absorbent. One ml. of alkaline pyrogallate is admitted dropwise over 4 or 5 minutes. The pressure is then allowed to rise to atmospheric so that the upper tube is rinsed by the solution, thus avoiding a reduction of vapor tension due to the strong alkali. Then  $p_2$  is read. The apparatus is cleaned with water after using this absorbent.

The *c* correction, when oxygen is determined by absorption, is due to two factors, the lowering of the mercury meniscus by the absorbent and the trace of  $O_2$  left in the reagent after one extraction. To determine *c*, deaerate 7.5 ml. of the special  $O_2$  reagent for 3 minutes, expel 5 ml., leaving 2.5 in the chamber. Shake again for 3 minutes and then admit 1.5 ml. of air-free 1 N NaOH in the manner described for  $CO_2$ . Read  $p_1$  with *a* at 0.5 and 2.0 ml. Then run in the absorbent as in the analysis and obtain  $p_2$  at both points. Use  $c_{O_2}$  corresponding to *a* in the analysis.

$$c_{O_2} = p_1 - p_2$$

Eject residual  $N_2$  and read  $p_3$ .

$$c_{N_2} = p_2 - p_3$$

If  $O_2$  is determined indirectly by correcting for  $N_2$  instead of by absorption, *c* is obtained in the same way, except that  $p_2$  is measured after ejection of the  $O_2 + N_2$ , without preliminary absorption.

CALCULATIONS. The estimated corrections for dissolved  $O_2$  and  $N_2$  of blood in calculation of total or combined oxygen or oxygen capacity, given in the accompanying table, may vary somewhat with the cell content.

The corrections are subtracted from the volume per cent of gas as determined by the use of the table on p. 712.

---

10 g. of this mixture in 50 ml. of 1 N KOH and quickly filter through cotton. Deaerate the solution and transfer to container under oil as described in the footnote on p. 715. One drop of 10 per cent  $FeCl_3$  still further accelerates the absorption activity. The solubility of  $N_2$  in this medium is negligible.

**Determination of Carbon Monoxide Hemoglobin, of Methemoglobin, and of Hemoglobin by the Carbon Monoxide Capacity Method:**<sup>30</sup> **Principle.** Carbon monoxide is liberated from combination with hemoglobin by treatment with an acid ferricyanide solution. CO<sub>2</sub> and O<sub>2</sub> are absorbed with alkaline pyrogallol solution and CO determined by correcting for N<sub>2</sub> in the residual gas.

For determination of hemoglobin the blood is saturated with CO and the CO capacity determined. Volumes of CO absorbed are identical with those for O<sub>2</sub>. This gives active hemoglobin.

CO without the aid of hydrosulfite does not change methemoglobin to carboxy-hemoglobin. The difference between CO capacity with and without hydrosulfite treatment represents methemoglobin. Hemochromogen behaves like methemoglobin but is rarely present.<sup>31</sup>

**Determination of Hemoglobin (Active) by CO Capacity.** Draw 1 drop of caprylic alcohol into the capillary beneath the cup of the manometric apparatus. Measure 4.75 ml. of water into the cup. With stopcock pipet provided with rubber tip (see p. 711), run 2 ml. of blood directly into the chamber, followed by the 4.75 ml. of water. Place 1 to 2 ml. of mercury in the cup above the chamber. Fill the outlet capillary of a Hempel gas pipet containing CO (see Fig. 194) with mercury. Fit the tip of the pipet into the bottom of the cup as shown in the illustration. Turn the two cocks shown in the illustration so that CO gas<sup>33</sup> can flow from the pipet into the chamber. The flow is regu-

<sup>30</sup> Van Slyke and Hiller: *J. Biol. Chem.*, 78, 807 (1928); 84, 205 (1929). Methods for smaller amounts of blood are also given. For a somewhat more accurate procedure for the determination of carbon monoxide in blood, see Sendroy and Liu: *J. Biol. Chem.*, 89, 133 (1930).

<sup>31</sup> Conant, Scott, and Douglass, *J. Biol. Chem.*, 76, 223 (1928), give a method suitable in the presence of hemochromogen.

<sup>32</sup> The bulbs are of about 50-ml. capacity each. The capillary is of 1-mm. bore. When the pipet is not in use, a little mercury is let into the capillary leading to the CO bulb, to seal the three-way cock and prevent leakage around it. This drop of mercury in the capillary to the right of the cock is shown in the illustration. This pipet may also be used to store air-free solutions. In this case the solution replaces the CO gas shown above, and mercury is used where water is indicated in the above figure. Supplied by the makers of the Van Slyke-Neill apparatus.

<sup>33</sup> *CO Gas.* Connect the lower openings of two 5-liter aspirator bottles with rubber tubing at least 15 mm. wide. Fill one (A) completely with water. A is also fitted with a thistle tube with stopcock and a side tube with stopcock connecting with a large test tube carrying a safety thistle tube containing mercury passing through the stopper only and a

lated by the cock leading to the mercury leveling bulb of the manometric apparatus. With the leveling bulb in mid-position (a little below the bottom of the chamber), open this cock slowly, withdrawing mercury from the chamber until CO enters to the 2-ml. mark. Close the cock of the chamber, seal with a drop of mercury, and evacuate. With the mercury meniscus at the

FIG. 194. HEMPEL PIPET PROVIDED WITH THREE-WAY STOPCOCK<sup>32</sup> (VAN SLYKE AND HILLER).

50-ml. mark, shake until equilibrium is reached (1 minute or longer as determined in blank below). Eject the mixture of gases from the chamber.

Evacuate until blood solution is in lower fourth of chamber. Put about 1 ml. of mercury and 2 to 3 ml. of water in the cup. Through the mercury seal introduce 0.25 ml. of acid ferricyanide<sup>34</sup> solution, using a rubber-tipped buret made by fusing a stopcock onto a pipet graduated in 0.01-ml. divisions. Before the tip of the buret is inserted into the mercury, move it through the water layer to dislodge ferricyanide crystals or air bubbles. Fill the capillary and bore of the cock with mercury but run none into the chamber. Evacuate, lowering the mercury to the 50-ml. mark. Shake slowly for about 5 seconds, and then vigorously for 3 minutes. Admit mercury until gas space is reduced to 5 to 6 ml. Measure 2 ml. of air-free 1 N NaOH<sup>34</sup> into the cup, letting it run in slowly with the tip against the bottom of the

cup. Allow 1 ml. of the NaOH to flow slowly into the chamber. Absorption of CO<sub>2</sub> is complete in less than 1 minute. Bring the volume of gas to 2 ml. Record the manometer reading as  $p_1$ . Eject the gas. Seal the stopcock with a drop of mercury. Lower the fluid meniscus to 2 ml. Read the manometer again ( $p_2$ ).

CALCULATION. The hemoglobin content of the blood in terms of CO- or O<sub>2</sub>-combining power is calculated by the equation:

$$\text{CO or O}_2 \text{ capacity} = (p_1 - p_2 - c)f$$

where  $f$  is a factor obtained from the table on p. 712 and  $c$  is determined by a blank analysis in which the procedure described above is repeated in every detail except that 2 ml. of water are substituted for the 2 ml. of blood. The correction is calculated as  $c = p_1 - p_2$ . The value of  $c$ , once accurately determined, can be used as a constant since it is small and insensitive to ordinary changes in laboratory conditions.

**Determination of Total Hemoglobin and Methemoglobin.** Wash apparatus with three successive portions of 10 to 15 ml. of water, to the first of which

second thistle tube, with stopcock, reaching to the bottom of the test tube. Run into the test tube 3 ml. of anhydrous formic acid, and then, slowly, concentrated H<sub>2</sub>SO<sub>4</sub>, gently warming the mixture with a microburner. When about 300 ml. of CO and air have collected in A, drive this out by opening the thistle tube and lifting B. Continue generation until the CO from all the formic acid is collected in A. Clamp the tube between the two bottles with a screw clamp and detach the test tube. Carry out the entire procedure in a hood or in a free draft of air. Smaller vessels may be used if less CO is desired.

<sup>34</sup> Acid Ferricyanide Solution. To 92 volumes of stock solution, containing 32 g. of K<sub>3</sub>Fe(CN)<sub>6</sub> per 100 ml., add 8 volumes of concentrated lactic acid of sp. gr. 1.2. It may be used for more than 2 months. 1 N NaOH. Rendered air-free as described on p. 715.

a little hydrosulfite solution is added. This is done by evacuating to the 50-ml. mark, running in the water, shaking for 15 to 20 seconds, and ejecting the solution.

Draw 2 drops of caprylic alcohol into the capillary beneath the cup. Measure into the cup 4.3 ml. of water. Using the stopcock pipet with rubber tip, run 2 ml. of blood directly into the chamber, followed by a few drops of the water in the cup to wash blood through the capillary. From a microburet (see above) run 0.4 ml. of the ammoniacal sodium hydrosulfite<sup>35</sup> solution into the chamber, followed by the water remaining in the cup. Put 1 to 2 ml. of mercury in the cup. Lower the mercury in the chamber to the 50-ml. mark. Run in CO from the Hempel pipet until the pressure on the manometer rises about 150 mm., the mercury remaining at the 50-ml. mark. If 100 mm. of CO are run in and then mercury admitted from the leveling bulb to raise the level to the 50-ml. mark, the proper pressure will usually be attained. Shake for 1½ minutes. Eject gases from the chamber. Determine CO exactly as in the method above for active hemoglobin, except that 0.30 ml. instead of 0.25 ml. of the ferricyanide solution is run in. Determine correction *c* by running a blank test on 2 ml. of water (see above). This *c* will be somewhat greater than in the method for active hemoglobin. The calculation is otherwise the same and gives total hemoglobin.

$$\text{Methemoglobin} = \text{total hemoglobin} - \text{active hemoglobin}$$

**Manometric Determination of Other Substances.** See footnote 22, p. 709. Other manometric methods are those for urea using the urease<sup>36</sup> or hypobromite<sup>37</sup> procedures, oxalic acid or calcium,<sup>38</sup> total reducing substances,<sup>39</sup> and fermentable sugars<sup>40</sup> in blood and urine, lactic acid in blood,<sup>41</sup> potassium in serum,<sup>42</sup> gas in fermentation,<sup>43</sup> primary amino nitrogen,<sup>44</sup> cysteine and cystine,<sup>45</sup> gas mixtures,<sup>46</sup> carbon in organic substances,<sup>47</sup> chloride in serum and urine,<sup>48</sup> phosphorus in organic compounds,<sup>49</sup> carboxyl groups in amino acids,<sup>50</sup> inorganic sulfate,<sup>51</sup> magnesium,<sup>52</sup> amino acids in blood,<sup>53</sup> amino acids in urine,<sup>54</sup> arginase,<sup>55</sup> total carbon and its radioactivity.<sup>56</sup> For some of these methods, later references will be found in Chapters 23 and 31.

---

<sup>35</sup> *Ammoniacal Sodium Hydrosulfite.* Pour 50 ml. of diluted (1:50) ammonia solution upon 2.0 g. of pulverized  $\text{Na}_2\text{S}_2\text{O}_4$  contained in a 100-ml. beaker. Cover at once with a layer of paraffin oil. Dissolve by stirring with a rod for a few seconds.

## Energy Metabolism

**Historical.** Combustion in living beings was first described by Lavoisier (1743–1794). This brilliant chemist discovered the true nature of oxygen, and how its union in the body with carbon and hydrogen resulted in the formation of carbon dioxide and water and in the production of heat. In experiments on man he determined that oxidation was increased by food, by a cold environment, and by muscular work. He knew the main constituents of the atmosphere and that nitrogen played no active part in animal respiration. Lavoisier was under the false impression that oxygen decomposed some fluid in the lung, causing the liberation of hydrogen and carbon with the subsequent oxidation of these elements and their excretion as carbon dioxide and water in the expired air. Scientists of a later date abandoned the theory of oxidation in the lungs, and favored the blood as the site of these chemical changes. This belief was strengthened by the discovery of gases in the blood by Magnus in 1837. Later it became known that, for the most part, oxidation occurs in the tissues and that the blood simply carries the gases to and from the lungs.

In 1842 Liebig announced that the substances burned in the body were carbohydrate, fat, and protein, and suggested that the urinary nitrogen would serve as an index of the extent of protein destruction. Ten years later Bidder and Schmidt described protein metabolism, and shortly afterwards Carl Voit measured protein waste by determining the amount of nitrogen in the excreta. Voit made the important discovery that muscular exercise did not increase protein metabolism. During many years of careful work, Rubner, a pupil of Voit, determined the fuel values of the foodstuffs and by means of a respiration calorimeter showed that the heat production as calculated from the respiratory exchange was the same as that obtained by the direct measurement of the heat given off by the body. In 1883, Rubner demonstrated the relationship between the surface area of the body and the heat production, thus providing a basis for comparison of the metabolism of different individuals.

In 1915 DuBois devised the most satisfactory method for estimating the surface area of the body, and later published normal standards of heat production for males and females, the accuracy of which has been fairly well established.

In America, Atwater, Armsby, Benedict, Lusk, DuBois, and their many associates have added valuable contributions to the knowledge of normal metabolism. Benedict and those associated with him in the Carnegie Nutrition Laboratory have in addition perfected various forms of respira-

tion apparatus, and they are chiefly responsible for the extensive use of calorimetry in the clinic.

### Physical and Chemical Bases of Animal Calorimetry.

**GASES.** Gases are compressible fluids. The molecules of which they are composed are in constant motion and tend to disperse. The gas therefore expands and fills all parts of the containing vessel and exerts pressure upon the enclosing walls. Heat increases the tendency to expand and so increases the pressure unless the container permits the gas to assume a larger volume. If the temperature remains constant and pressure is applied to the container, the molecules are forced closer together and the volume is decreased. Therefore, when we speak of a volume of gas, we must also state the temperature and pressure under which it was measured. Regardless of the experimental conditions of measurement, gas volumes are always recorded as the volume at standard temperature ( $0^{\circ}$  Centigrade or  $273^{\circ}$  Absolute) and standard pressure (760 mm. of mercury at  $0^{\circ}$  C.<sup>1</sup>). This is sometimes referred to as *standard conditions* or as N.T.P. (normal temperature and pressure).

If the temperature is kept constant, the volume of a gas varies inversely with the pressure (*Boyle's Law*). Therefore, to express a volume of gas, measured at some other pressure, as its volume at 760 mm., the formula is:

$$\text{Volume} \times \frac{\text{Pressure (corrected)}}{760} = \text{Volume at 760 mm.}$$

If the pressure on a gas remains the same and the temperature changes, the volume of the gas will vary directly  $\frac{1}{273}$  (or 0.00367) of its volume at  $0^{\circ}$  C. for each degree of change in temperature (*Charles' or Gay Lussac's Law*). The coefficient of expansion of nearly all gases is 0.00367.

To convert the volume of a gas at temperature  $t^{\circ}$  C., and at constant pressure, to its volume at  $0^{\circ}$  C., the formula is:

$$\text{Volume} \times \frac{273}{273 + t^{\circ} \text{ C.}} = \text{Volume at } 0^{\circ} \text{ C.}$$

The two conversion equations given may be combined into a single equation as follows:

$$\frac{P \times V}{273 + t} = \frac{760 \times V_0}{273}$$

where  $P$  and  $V$  represent the experimentally determined pressure and volume, corrected if necessary, at the temperature  $t^{\circ}$  C., and  $V_0$  represents the volume under standard conditions.

If a volume of gas is in contact with water, evaporation continues until the tendency of the water to evaporate is equal to the tendency of its vapor to condense, at which time the gas is said to be saturated with water vapor. The total pressure of the saturated gas and water vapor is

---

<sup>1</sup> The reading on a brass-scale barometer is correct for only one temperature and must be corrected by the use of a correction table which gives the height at which the column of mercury would stand if the temperature were  $0^{\circ}$  C. For such a table, refer to a handbook of chemistry or physics. See also p. 697.

equal to the sum of the pressures of the gas and of the water vapor (*Dalton's Law*). These are spoken of as *partial pressures*. The partial pressure of the water vapor increases with temperature. To determine the pressure of the gas in a dry state, the partial pressure of water vapor at the given temperature (see p. 709) must be deducted from the barometric pressure.

*Example.* The expired air of a man has a volume of 100 liters, the temperature in the gasometer is 22° C., and the brass scale barometer reads 767 mm. The pressure of expired air, *dry*, is:

$$767 \text{ mm.} - \underset{\text{Barometric correction}}{2.72} - \underset{\text{Water vapor}}{19.63} = 744.65 \text{ mm.}$$

The volume of dry air at 0° C. and 760 mm. is:

$$100 \times \frac{744.65}{760} \times \frac{273}{273 + 22} = 90.66 \text{ liters}$$

Equal volumes of different gases or vapors under like conditions of temperature and pressure contain the same number of molecules (*Avogadro's Law*). Thus the density or *mass per volume* of any gas or vapor will depend upon the weight of its molecule. The molecular weight in grams of any gas or vapor has a volume of practically 22.4 liters at 0° C. and 760 mm. Hence the density of 1 liter of a gas at 0° C. and 760 mm. is molecular weight ÷ 22.4.

*Density of Gases at 0° C. and 760 mm.*

1 liter of oxygen weighs 1.4292 g.

1 g. of oxygen occupies  $\frac{1}{1.4292} = 0.6997$  liter

1 liter of carbon dioxide weighs 1.9652 g.

1 g. of carbon dioxide occupies  $\frac{1}{1.9652} = 0.5089$  liter

**HEAT.** The heat which we recognize by *temperature* is the energy of molecular motion. This property is imparted to matter by chemical action, electric currents, and mechanical work. In animals the chemical source only need be considered and we may confine our attention to that form of combustion in which the substance finally appears in the completely oxidized form.

In animal calorimetry the unit of heat is the *large Calorie*, abbreviated Cal., which is defined as the amount of heat necessary to raise the temperature of 1 liter of water from 15° C. to 16° C.

*Heat of Combustion in a Calorimeter.*

1 g. of *hydrogen* gas produces 34.5 Cal.

1 g. of *charcoal* produces 8.0 Cal.

1 g. of *starch* produces about 4.2 Cal.

1 g. of *glucose* produces about 3.74 Cal.

1 g. of *sucrose* produces about 3.96 Cal.

*Heat of Combustion in Animals.*

1 g. of average *carbohydrate* produces about 4 Cal.

1 g. of average *fat* produces about 9 Cal.

1 g. of average *protein* produces about 4 Cal.

**Oxidation of Carbohydrates.** Carbohydrates, by the processes of digestion, undergo hydrolytic cleavage if necessary and are absorbed through the intestinal wall into the blood mainly in the form of glucose. Under normal conditions the blood contains 0.1 per cent or less of this sugar in the free state; over 300 g. or more may be stored as glycogen in the body tissues, principally in the muscles and liver. Glycogen is readily reconverted to glucose and it serves as a deposit to be drawn upon in an emergency. Glucose is the favorite body fuel, and is used prodigally when the supply is plentiful and thriftily in periods of starvation.

The oxidation of glucose is represented as follows:

|                                  |                        |   |               |   |                 |
|----------------------------------|------------------------|---|---------------|---|-----------------|
|                                  | $C_6H_{12}O_6$         | + | $6O_2$        | = | $6CO_2 + 6H_2O$ |
| Molecular weights in grams.....  | 180                    |   | 192           |   | 264      108    |
| Heat and volume equivalents..... | 673.2 Cal.             |   | 134.34 liters |   | 134.34 liters   |
| Heat and volume equivalents..... | 5.011 Cal. per 1 liter |   |               |   | 1 liter         |

Carbohydrates contain hydrogen and oxygen in the same proportion as is found in water. When these substances burn, outside oxygen is used to unite with the carbon, forming a volume of carbon dioxide equal to the volume of oxygen absorbed. The ratio of the volume of carbon dioxide produced to the volume of oxygen absorbed is known as the *respiratory quotient* (R.Q.). This has a different value for each of the major food components and serves to determine what substances are being burned. From the above equation it is seen that the respiratory quotient for glucose is

$$\frac{CO_2}{O_2} = 1.0 \text{ and that 1 liter of oxygen represents a liberation of 5.011 Cal.}$$

In animal calorimetry the heat equivalent of 1 liter of oxygen is generally accepted as 5.047 Cal. when carbohydrates are burned in the body.

**Oxidation of Fats.** The fats and oils of our food are largely mixtures of palmitin, stearin, and olein (see Chapter 3). These substances are of similar chemical composition and when they undergo oxidation they yield about the same amount of heat. After absorption, fat passes from the blood to the tissues, where it is either burned or stored for future use. Fats have a high fuel value and they are continually being used by the body for this purpose. In the absence of carbohydrates, fats supply over 80 per cent of the body heat.

Fat combustion is usually represented by the oxidation of palmitin as follows:

|                                  |                        |   |               |   |                    |
|----------------------------------|------------------------|---|---------------|---|--------------------|
|                                  | $2(C_{51}H_{98}O_6)$   | + | $145O_2$      | = | $102CO_2 + 98H_2O$ |
| Molecular weight in grams.....   | 1612                   |   | 4640          |   | 4488      1764     |
| Heat and volume equivalents..... | 15233.4 Cal.           |   | 3246.6 liters |   | 2283.9 liters      |
| Heat and volume equivalents..... | 4.655 Cal. per 1 liter |   |               |   | 0.704 liter        |

From the above equation it is seen that when palmitin is burned the respiratory quotient is 0.704 and that 1 liter of absorbed oxygen liberates

ANALYSIS OF THE OXIDATION OF MIXTURES OF CARBOHYDRATE AND FAT\*  
(Table of Zuntz and Schumburg modified by Lusk)

| R.Q.  | Percentage of Total<br>Oxygen Consumed |        | Percentage of Total<br>Heat Produced |        | Cal. per liter of O <sub>2</sub> |        |                 |

\* The last column has been added to facilitate the expression of oxygen absorbed per minute in terms of Calories per hour. Characteristics are omitted (see last paragraph, p. 741).

4.655 Cal. Zuntz and Schumburg obtained slightly different figures for the oxidation of fat in the body. In their work the respiratory quotient was found to be 0.707 and the heat value for 1 liter of oxygen 4.686 Cal. If only mixtures of carbohydrate and fat were oxidized, the respiratory quotients would vary between 0.707 and 1.00, and from their value it should be possible to determine the proportions of each of these foodstuffs burned. A table analyzing the oxidation of such mixtures on the basis of the so-called *nonprotein respiratory quotient* was prepared by Zuntz and Schumburg and modified by Lusk (see p. 727).

**Protein Metabolism.** Proteins in the diet are completely broken down in the gastrointestinal tract to the form of amino acids, in which form they are absorbed into the blood and pass to the various parts of the body. Here they may be utilized either for incorporation into new tissue protein which is continually being broken down and resynthesized, or they may undergo metabolic reactions leading to the formation of non-protein nitrogenous compounds of importance to the body, such as creatine, thyroxine, adrenaline, etc. Presumably they may also be utilized for the direct production of energy, although under ordinary circumstances protein is not considered to be primarily a fuel. Regardless of the intermediate steps in protein metabolism, which are discussed in detail in Chapter 33, the end products of protein breakdown in the animal body include not only carbon dioxide and water, as for carbohydrates and fats, but also the urea of the urine and certain other nitrogenous constituents of the urine and feces, as well as such compounds as urinary sulfate produced by the oxidation of sulfur-containing amino acids. Hence to evaluate the contribution of protein to the total metabolism, and to distinguish it from the nonprotein metabolism, the analysis of urine and feces is necessary in addition to the measurement of the respiratory gas exchange.

A computation of protein metabolism by Loewy is as follows:

100 g. of meat protein contains:

|            |           |            |            |           |
|------------|-----------|------------|------------|-----------|
| 52.38 g. C | 7.27 g. H | 22.68 g. O | 16.65 g. N | 1.02 g. S |
|------------|-----------|------------|------------|-----------|

of which there are eliminated in the urine:

|            |            |             |            |           |
|------------|------------|-------------|------------|-----------|
| 9.406 g. C | 2.663 g. H | 14.099 g. O | 16.28 g. N | 1.02 g. S |
|------------|------------|-------------|------------|-----------|

in the feces:

|            |            |            |           |
|------------|------------|------------|-----------|
| 1.471 g. C | 0.212 g. H | 0.889 g. O | 0.37 g. N |
|------------|------------|------------|-----------|

leaving a residuum for the respiratory process of:

|           |          |           |
|-----------|----------|-----------|
| 41.5 g. C | 4.4 g. H | 7.69 g. O |
|-----------|----------|-----------|

Deduct intramolecular water:

|            |           |
|------------|-----------|
| 0.961 g. H | 7.69 g. O |
|------------|-----------|

leaving

---

|           |            |                |
|-----------|------------|----------------|
| 41.5 g. C | 3.439 g. H | for oxidation. |
|-----------|------------|----------------|

When CO<sub>2</sub> is formed, 12 g. C unite with 32 g. O

Therefore 41.5 g. C unite with  $\frac{32 \times 41.5}{12} = 110.67 \text{ g. O}$

When H<sub>2</sub>O is formed, 2 g. H unite with 16 g. O

Therefore 3.439 g. H unite with  $\frac{16 \times 3.439}{2} = 27.512 \text{ g. O}$

---

|                                    |                                     |
|------------------------------------|-------------------------------------|
| Total oxygen absorbed.....         | 138.18 g.                           |
| Total carbon dioxide produced..... | 41.5 g. C + 110.67 g. O = 152.17 g. |

In the computation above, 1 g. of urinary nitrogen represents:

$\frac{100 \text{ g. protein}}{16.28} = 6.15 \text{ g. of muscle protein}$   
 $\frac{138.18 \text{ g. O}_2}{16.28} = 8.49 \text{ g. of O}_2 \text{ absorbed}$   
 $\frac{152.17 \text{ g. CO}_2}{16.28} = 9.35 \text{ g. of CO}_2 \text{ produced}$

6.15 g. protein  $\times$  4.25 (Cal.) = 26.14 Cal.  
8.49 g. O<sub>2</sub>  $\times$  0.6997 (liters) = 5.94 liters of O<sub>2</sub> for protein  
9.35 g. CO<sub>2</sub>  $\times$  0.5089 (liters) = 4.76 liters of CO<sub>2</sub> from protein

Respiratory quotient for meat protein =  $\frac{4.76}{5.94} = 0.801$

Based on the analytical figures for the average protein it is estimated that 1 g. of urinary nitrogen represents the metabolism of 6.25 g. of protein, the absorption of 5.91 liters of oxygen, the production of 4.76 liters of carbon dioxide, and the liberation of 26.51 Cal.

An example of the practical application of the above *constants* is as follows:  
A man (aged 38.5 yrs., height 159 cm., weight 90 lb.) was tested 14 hours after the last meal. An analysis of the urine showed an excretion of 0.16 g. of nitrogen per hour. The total respiratory exchange showed an absorption of 12.52 liters of oxygen and the production of 9.3 liters of carbon dioxide per hour.

0.16 g. of urinary nitrogen represents

0.16  $\times$  6.25 = 1 g. of protein metabolized with the absorption of  
0.16  $\times$  5.91 = 0.95 liter of O<sub>2</sub>, the production of  
0.16  $\times$  4.76 = 0.76 liter of CO<sub>2</sub>, and the liberation of  
0.16  $\times$  26.51 = 4.24 Cal.  
Total CO<sub>2</sub> (or O<sub>2</sub>) – protein CO<sub>2</sub> (or O<sub>2</sub>) = nonprotein CO<sub>2</sub> (or O<sub>2</sub>)  
9.3 liters CO<sub>2</sub> – 0.76 liter CO<sub>2</sub> = 8.54 liters CO<sub>2</sub>  
12.52 liters O<sub>2</sub> – 0.95 liter O<sub>2</sub> = 11.57 liters O<sub>2</sub>

$\frac{8.54 \text{ liters CO}_2}{11.57 \text{ liters O}_2} = 0.74 \text{ (nonprotein R.Q.)}$

From Zuntz and Schumburg's table (modified by Lusk, see p. 727), it is seen that when the nonprotein R.Q. is 0.74, 1 liter of O<sub>2</sub> represents the liberation of 4.727 Cal., and 12 per cent of the nonprotein heat comes from carbohydrate and 88 per cent from fat.

11.57 liters O<sub>2</sub>  $\times$  4.727 = 54.69 Cal. (nonprotein)  
12 per cent of 54.69 = 6.56 Cal. from carbohydrate  
88 per cent of 54.69 = 48.13 Cal. from fat  
54.69 + 4.24 (protein Cal.) = total of 58.93 Cal. per hour

In this computation 7 per cent of the body heat was derived from the combustion of protein, 11 per cent from carbohydrate, and 82 per cent from fat.

As Richardson points out, the measured respiratory quotient is not necessarily the metabolic quotient and gives no information concerning the intermediate steps in the conversion of consumed  $O_2$  to  $CO_2$ . Non-oxidative processes which promote  $CO_2$  production, such as acid formation (e.g., diabetes or excessive muscular activity) or acid retention (e.g., nephritis), and conditions which diminish the  $CO_2$  output (e.g., insulin or alkali therapy, etc.) exercise an important influence on the respiratory quotient. Taking these factors into account, however, studies of conditions of abnormal carbohydrate and fat metabolism such as diabetes and ketosis, and of the physiology of food utilization and muscular activity, have been greatly advanced by measurements of the respiratory quotient.

**Respiration.** The ventilation of the lung and the exchange of gases between the alveolar air and the blood are usually referred to as external respiration, as contrasted with the exchange of gases in the tissues, known as internal respiration (see Chapter 12). Any disproportion between external and internal respiration affects the oxygen or carbon dioxide content of the blood. The tension of oxygen in the blood is lowered when the lungs are extensively disordered, as in pneumonia, and during periods of supreme muscular effort; under these conditions the oxygen requirement of the tissues is greater than the oxygenating power of the lung. An unusual increase in the supply of oxygen in the lung has but a very slight effect on the tension of oxygen in the blood, and practically no effect on the rate of combustion in the tissues. Of greater interest is the carbon dioxide tension of the blood, which is nicely regulated by an adjustment of the ventilation of the lung, and of the circulation of the blood, so that these mechanisms parallel the rate of combustion in the tissues.<sup>2</sup>

There is a general parallelism between the heat production, the heart rate, and the ventilation rate. However, the heart rate is not solely determined by the requirements of respiration, and ventilation can be voluntarily controlled. A rapid heart and an increased ventilation rate make one suspect that the metabolism is increased, but the rate of heat production cannot be predicted from these phenomena.

**EXTERNAL RESPIRATION.** Atmospheric air is of very constant composition the world over. Advantage is taken of this fact in computing the respiratory exchange, that is, the amount of oxygen absorbed and the amount of carbon dioxide produced in a given time.

Atmospheric air has the following composition:

|                     |                |
|---------------------|----------------|
| Carbon dioxide..... | 0.03 per cent  |
| Oxygen.....         | 20.94 per cent |
| Nitrogen.....       | 79.03 per cent |

Under ordinary conditions, at each breath a person inspires about 500 ml. of air and of this amount only 350 ml. actually enter the lung and diffuse more or less with the 3000 ml. already there. The expired air includes the 140 ml. of the "dead space" and 350 ml. of partially mixed air

<sup>2</sup> For further discussion of the gas exchange in blood and tissues, see Chapter 24.

from the lung (see Fig. 195). Expired air contains about 16 per cent oxygen, 4 per cent carbon dioxide, and 80 per cent nitrogen.

If we exhale forcibly and collect the last portion, the so-called alveolar air, we find that it contains about 14.5 per cent of oxygen and 5.6 per cent

FIG. 195. INSPIRED AND EXPIRED AIR.

The *tidal air* is that which enters and leaves the body with each normal respiration. The *supplemental air* is that which can be forcibly expired after a normal tidal expiration; this leaves in the lungs the *residual air* which cannot be voluntarily expelled. The *complemental air* is that which can be forcibly drawn into the lungs over and above a normal tidal inspiration. The *vital capacity* is the greatest volume of air which can be expired following a forced inspiration; it includes the tidal, the supplemental, and the complemental volumes.

The *inspired* or atmospheric air is of constant composition. The composition of the *expired air* is not constant; it is determined by the varying factors of combustion in the tissues, the rate of blood flow, and the rate of ventilation in the lung. The *alveolar air* is the last portion of the supplemental air to be expired and represents the composition of the residual air, and its gases are in equilibrium with the arterial blood. The blood in its passage through the lung gives off carbon dioxide and absorbs oxygen.

of carbon dioxide. That is, the air deep in the lung, where it comes in close proximity to the blood, has the greatest concentration of carbon dioxide and the lowest concentration of oxygen. These gases are in equilibrium with the gases in the arterial blood.

Fig. 195 shows that after an ordinary expiration, 1500 ml. of additional air can be forcibly expired; then, if the greatest possible inhalation is made, almost 4 liters of fresh air can be drawn into the lungs. This greatly dilutes the carbon dioxide in the alveolar air and induces a rapid passage of the gas from the blood. If forced breathing is continued, a large amount of carbon dioxide, which is ordinarily stored in the blood, is in this manner "washed out" and may be erroneously regarded as carbon dioxide produced during a period of a metabolism test.

The increased supply of oxygen due to forced ventilation has no effect on metabolism tests; in fact, as has previously been stated, one can breathe pure oxygen without appreciably increasing its absorption. This fact is taken advantage of in the "closed circuit" types of respiration apparatus which require the rebreathing of air rich in oxygen.

Nitrogen plays a passive role in respiration; the amount expired is the same as the amount inspired. As there is a definite proportion between the oxygen and the nitrogen of the atmosphere, it is possible to calculate the amount of oxygen inspired on the basis of the nitrogen in the expired air. The formula is:

$$V = \frac{20.94 \times \text{per cent N}_2 \text{ in expired air}}{79.03}$$

when  $V$  = volume of oxygen in inspired air corresponding to 100 volumes of expired air.

It must be emphasized that in order to measure successfully the carbon dioxide produced during a metabolism test of short duration, *ventilation must be an involuntary act.*

**Energy Requirement.** The energy requirement of the animal body may be divided into two functional classifications, viz., that for basal metabolism and that for active work. Basal metabolism includes the energy expended in respiration, blood circulation, intestinal contractions, activities of various organs, maintenance of muscular tonus, thermal equilibrium, etc. The basal metabolic rate is influenced by the amount of active protoplasmic mass (hence by height, weight, surface area, age, sex, composition of the tissues, etc.) and is governed by endocrine organs, particularly the thyroid and pituitary glands. For a discussion of the clinical aspects of basal metabolism and its measurement, see p. 734.

The energy consumed in work, play, and indeed all forms of voluntary activity, imposes an additional requirement for fuel over the basal, which depends on the nature and extent of the muscular work. Whereas an average man expends about 100 Cal. per hour while sitting at rest, his metabolism may increase to as high as six times this value with extreme physical effort.

Mary Swartz Rose summarized the hourly expenditure of Calories of an average 70-kg. man under various conditions as follows: sleeping 65, awake lying still 77, sitting at rest 100, standing relaxed 105, walking slowly to moderately fast 200–300, running 5.3 miles per hour 570, swimming 500, walking down stairs 364, walking up stairs 1100, "light exercise" 170, "active exercise" 290, "very severe exercise" 600, dishwashing

144, carpentry or painting 240, sawing wood 480. From estimates such as these one may predict the calorific content of the diet necessary to meet individual requirements. An example for a 70-kg. man is given by Sherman as follows:

|                                                |   |           |
|------------------------------------------------|---|-----------|
| 8 hrs. sleep at 65 Cal.                        | = | 520 Cal.  |
| 2 hrs. light exercise <sup>3</sup> at 170 Cal. | = | 340 Cal.  |
| 8 hrs. carpenter work at 240 Cal.              | = | 1920 Cal. |
| 6 hrs. sitting at rest at 100 Cal.             | = | 600 Cal.  |
| <hr/>                                          |   |           |
| Total food requirement for the day,            |   | 3380 Cal. |

The total energy requirement of different types of workers ranges from a minimum of 2000 to 2500 Cal. per day (white-collar workers) to a maximum of 4000 to 6000 (lumbermen, excavators, etc.), of which about 1400 to 1900 Cal. are consumed in basal metabolism and the balance in various forms of activity.

Food calories consumed in excess of an individual's energy requirements are deposited principally in the form of adipose tissue which is drawn on for energy when the dietary intake of calories falls below the expended level. A deficit of approximately 3500 calories is required to deplete the body of one pound of adipose tissue. When the fat depots are exhausted, as in acute inanition, muscle protein is used as a source of energy.

### BASAL METABOLISM

Basal metabolism, or the basal metabolic rate, is an expression of the heat production of the body in complete mental and physical repose, and in the postabsorptive state. For a successful test the subject must be in a "comfortable" environment, if "too hot" or "too cold" the result will be abnormally high. The body temperature must be within the normal limits. DuBois estimates an increase in metabolism of 7.2 per cent for each degree Fahrenheit in fevers. The patient must be quiet and preferably experienced with the test. Mental activity alone has but a slightly elevating effect upon the heat production. Emotional excitation will raise the metabolism 20 per cent or more probably owing to the stimulation of the adrenal glands. The emotional factor constitutes the greatest source of error in basal metabolism determinations. It is not difficult to insure muscular repose and physical comfort, but it requires the utmost sympathy and tact to allay the apprehensions of the patient and insure physiological repose. A common practice is to test the patient repeatedly and to accept the lowest or the last result as the true basal rate; the fallacy of this is obvious when one considers that the number of such tests is usually determined by the endurance of the patient. DuBois conducts three or four tests and takes the average of the two lowest that show fair agreement. Even under favorable conditions it is possible, in unstable individuals, to get variations as high as 6 per cent in as many hours. These variations are physiological, not technical; the technique is more accurate than our ability to recognize or control emotional changes.

---

<sup>3</sup> Going to and from work, for example.

**Clinical Interpretation of Basal Metabolism.** In 1893 the clinical use of calorimetry was presaged by Friedrich Müller, who observed that patients with Graves's disease lost weight and had a marked nitrogenous waste despite the fact that the diet was adequate to maintain a normal state of nutrition. This observation was soon verified by Magnus-Levy, who determined the now well-known action of the thyroid gland in regulating the rate of combustion in the body. It is true that other factors affect the rate of heat production and that certain well-recognized diseases are accompanied by metabolic changes, but *in the majority of cases variations in the basal metabolism can be interpreted as variations in the function of the thyroid gland.*

In an extensive study of basal metabolic rate determinations, Boothby and Sandiford showed that 92.1 per cent of normal individuals have a basal metabolic rate within  $\pm 10$  per cent, and 99.3 per cent within  $\pm 15$  per cent of the DuBois standards. They found that a smaller percentage of these same subjects had basal metabolic rates within the same limits when the Harris and Benedict standards were used. These standards are discussed in the following section.

In clinical cases the basal metabolism may vary from 40 per cent below to 130 per cent above the average normal. In this discussion a tabulation of the findings in various disorders is avoided because, standing alone, the values are misleading. If no other cause can be found for an abnormal heat production, the result may be cautiously attributed to a disordered activity of the thyroid gland. Glands other than the thyroid may affect the rate of cellular combustion, but at the present time we know of only two body substances which change the rate of heat production, namely, thyroxine and adrenaline. The latter has a rapid, but fleeting, stimulating effect; the effect of the former lasts for several weeks. When the activity of the adrenal glands is decreased, as in Addison's disease, the basal metabolism is found to be subnormal. Hyperactivity of these glands may account for the temporary increase in metabolism occasionally found in nervous patients, who also show corresponding variations in pulse rate and in blood pressure.

The basal metabolic rate does not establish a diagnosis of hyperthyroidism. A patient afflicted with hyperthyroidism may be tested during an intermission and the basal metabolism would be within the normal limits despite the persistence of such clinical signs as nervousness, palpitation, tremors, and exophthalmos. Conversely, the test may detect active hyperthyroidism in patients showing few of the classical symptoms of the disease. The test does not tell the surgeon when it is safe to operate upon the patient; it informs him when it is least dangerous. He must base his operative prognosis upon the clinical condition of the patient and not upon the basal metabolic rate.

The onset of hyperthyroidism is accompanied by a progressive increase in heat production which may reach over 100 per cent above the average normal and persist for weeks after the glandular activity has subsided. Therefore, repeated tests are necessary in order to follow the course of the disease; an increasing rate indicates an active state of the gland and

naturally precludes operative intervention; a decreasing rate gives a more hopeful outlook.

The pulse rate is largely dependent upon the rate of metabolism. Clinically, a decreasing pulse rate indicates a subsidence of the hyperthyroidism. Few patients with pulse rates below 50 have a basal metabolic rate above the average normal and few patients with pulse rates below 85 have any considerable increase in their metabolism.

Heat comes from oxidation in the active protoplasmic tissue of the body. The rate of heat production is not determined by surface cooling, as one method of measurement would seem to imply (see footnote 17, p. 738); in reality, heat dissipation is regulated according to heat production. Any rapid change in the relative amount of protoplasmic tissue will cause changes in the basal metabolic rate when expressed in terms of weight or surface area. This partly explains the gradual drop in the basal metabolic rate during the glandular and muscular waste of starvation and in hospital patients during their early confinement to bed. A rapid accumulation of fluid in the body has a similar effect and it is quite common to find nephritics with marked edema having a basal metabolic rate 20 to 30 per cent below the average normal. This must not be interpreted as a sign of hypothyroidism.

Under the basal conditions we measure the heat resulting from activities of the vital organs and from the intracellular chemical changes associated with life, growth, and development. These facts must be borne in mind and due allowance made for any unusual activity before the results are attributed entirely to the thyroid gland. Dyspnea, hypertension, cardiac decompensation, and tremors involve increased muscular activity and so raise the heat production. Certain diseases are characterized by increased cellular activity and in these cases the heat production is increased. The most outstanding of this group is leukemia, in which disease the basal metabolic rate may be as high as in severe Graves's disease. Polycythemia, anemia, and Paget's disease of the bones are other conditions in which the increased heat production probably results from increased cellular activity. In this group possibly belongs the acute stage of acromegaly. In these conditions the basal metabolism is rarely over 25 per cent above the average normal. The possibility of self-administration of drugs such as iodine or thyroid extract must be considered in the interpretation of basal metabolic rate.

From birth to the age of one and a half years the basal metabolism increases at a remarkable rate. This is followed by a gradual decline until full growth and development are attained; constancy characterizes the rate in adult life, with a slight decline as old age advances.<sup>4</sup> Variations in the rate of growth and development in childhood cause abnormal results

---

<sup>4</sup> Of interest in this connection are the observations of Benedict, Sherman, Campbell, and Zmachinsky (*J. Nutrition*, **14**, 179 (1937)) that middle-aged male rats not previously exercised were unable to adjust themselves to vigorous enforced exercise and declined rapidly, whereas female rats were benefited by similar treatment, showing a distinct tendency to lower basal metabolism. Basal metabolism in old age is the subject of a paper by Matson and Hitchcock: *Am. J. Physiol.*, **110**, 329 (1934).

when judged by the age standard. In prematurely developed children the basal metabolic rate is low according to the age standard, but is probably normal for the stage of development if this could be accurately expressed. The difficulty in applying the test to children has resulted in a paucity of normal tests and great variation in the results obtained. The normal biological variations are much greater in children than in adults and may be greater than the pathological changes anticipated by the physician. Fortunately the test is rarely required before the age of puberty and the normal standards beyond that age are fairly well established.

The metabolism of women averages about 12 per cent below that of men, and owing to the menstrual cycle, is more variable. There is usually, though not invariably, a premenstrual rise and a postmenstrual fall in the basal metabolic rate, which should be considered in the interpretation of results.

There is some evidence of lower metabolic rates among certain oriental and tropical races.

STANDARDS OF NORMAL BASAL METABOLISM AND CALCULATIONS.<sup>5</sup> The heat production of normal individuals under basal conditions largely depends upon the factors of age, height, and weight. The normal standards are based upon thousands of determinations in several centers of investigation. A better appreciation of basal conditions and the elimination of a high proportion of first tests has resulted in a tendency toward lower standards in recent years. At the present time there are three different systems of predicting the normal heat production.

1. *Aub and DuBois*<sup>6</sup> determine the heat production in relation to the surface area of the body; the surface area is estimated by the DuBois and DuBois<sup>7</sup> formula which is based on the height and weight:

$$A = Wt^{0.425} \times Ht^{0.725} \times 71.84$$

where  $A$  equals the area in sq. cm.,  $Wt$  the weight in kg., and  $Ht$  the height in cm. In routine work the nomogram of Boothby and Sandiford<sup>8</sup> (Fig. 196) may be used for determining the surface area. Stoner<sup>9</sup> has computed tables of values for this formula in unit cm. and kg. intervals for the height range of 110 to 200 cm. and the weight range of 20 to 110 kg.

The original so-called Sage standards of Aub and DuBois have been modified on the basis of larger numbers of normal controls. Bailey's<sup>10</sup> table covers the ages from 4 to 65 in yearly intervals, while Boothby and Sandiford<sup>11</sup> give values by years from 5 to 19 and in 5-year intervals between 20 and 79 (see also table on p. 738). These standards fail to reflect the modern downward trend, but since they are based on tests on patients, they may be better suited for clinical purposes than lower standards based on trained subjects.

2. *The Harris-Benedict*<sup>12</sup> multiple prediction equations and tables<sup>13</sup> are based on

<sup>5</sup> For prediction tables of normal heat production, reference should be made to books dealing in this subject (see the Bibliography at the end of this chapter).

<sup>8</sup> Boothby and Sandiford: *Boston Med. Surg. J.*, **185**, 337 (1921).

<sup>9</sup> Stoner: *J. Lab. Clin. Med.*, **11**, 355 (1926).

<sup>10</sup> Bailey: *J. Lab. Clin. Med.*, **6**, 657 (1921).

<sup>11</sup> Boothby and Sandiford: *Am. J. Physiol.*, **90**, 290 (1929). See also Krogh's table in DuBois: *Basal Metabolism in Health and Disease*, 3d ed. Philadelphia, Lea & Febiger, 1936.

<sup>12</sup> Harris and Benedict: *Carnegie Inst. Wash., Pub. No. 279*, 1919.

<sup>13</sup> Tables which greatly simplify the use of these formulas may be found in Carpenter: *Carnegie Inst. Wash. Pub. No. 303*, 1921. See also DuBois's book, cited above.

FIG. 196. SURFACE-AREA NOMOGRAM.

A line connecting the height with the weight intersects the middle line at the corresponding surface area.

Copyright 1920 by Boothby and Sandiford.

a statistical study of the available data for the basal metabolism of normal men and women. The equations are,

$$\text{For men, } H = 66.4730 + 13.7516W + 5.0033S - 6.7550A$$

$$\text{For women, } H = 655.0955 + 9.5634W + 1.8496S - 4.6756A$$

in which  $H$  = total heat production per 24 hours,  $W$  = weight in kilograms,  $S$  = stature in centimeters, and  $A$  = age in years. The Harris-Benedict standards average about 3 to 4 per cent lower than the Sage standards, and according to Benedict<sup>14</sup> they should be even lower, especially for women. He recommends lowering the standards for women by 5 per cent. Benedict calls attention to the distinction between "hospital normals" and physiological standards, the use of the former being justified for clinical purposes only.

STANDARD VALUES FOR MEAN ENERGY  
PRODUCTION IN RELATION TO AGE AND SEX\*

| Age at Last<br>Birthday<br>Year | Calories per sq. m. per hr. |         |
|---------------------------------|-----------------------------|---------|
|                                 | Males                       | Females |

| 60                              | 35.8                        | 33.0    |

\* After Boothby, Berkson, and Dunn: *Am. J. Physiol.*, **116**, 468 (1936).

These and other methods have been critically studied by Means and Woodwell,<sup>15</sup> and by Boothby and Sandiford,<sup>16</sup> and by Krogh. The consensus seems to be that the Harris-Benedict predictions are the most reliable for average normal subjects; that the DuBois standards give results in average normal cases about 4 per cent too high; that in all cases, including those of exceptional build and age, the DuBois standards show less deviation than any of the others.<sup>17</sup>

<sup>14</sup> Benedict: *Am. J. Physiol.*, **85**, 607 (1928).

<sup>15</sup> Means and Woodwell: *Arch. Internal Med.*, **27**, 608 (1921).

<sup>16</sup> Boothby and Sandiford: *J. Biol. Chem.*, **54**, 767 (1922); *Physiol. Revs.*, **4**, 69 (1924).

<sup>17</sup> While the DuBois formula indicates that a definite mathematical relationship exists between the surface area and the quantity of energy produced, it has been disputed whether this is a true physiological relation. Benedict, the chief opponent of the surface-area law, suggests, however, that "From the practical standpoint it is perhaps not a matter of importance whether the rate of metabolism is directly proportional to the surface area, whether it is controlled by the heat loss from the body, whether the heat loss is independent of the heat supply, or whether the heat produced is determined by the active mass of protoplasmic tissue and the stimulus to the cells. But it is important to know whether there is a referable basis which can be used intelligently for comparing various individuals." *Lectures on Nutrition*, p. 51, Philadelphia, W. B. Saunders Co., 1925.

The method of predicting the normal heat production, and the normal standards, for infants and children are the subjects of several papers.<sup>18</sup>

THE RESPIRATORY QUOTIENT (R.Q.). This is the ratio of the volume of carbon dioxide produced to the volume of oxygen consumed during the same time interval.

$$\text{R.Q.} = \frac{\text{CO}_2 \text{ produced}}{\text{O}_2 \text{ consumed}} = \frac{\text{volume CO}_2 \text{ in expired air} - \text{volume CO}_2 \text{ in inspired air}}{\text{volume O}_2 \text{ in inspired air} - \text{volume O}_2 \text{ in expired air}}$$

The measurement of the volume of inspired air is attended with technical difficulties. However, the actual volumes of gas disappear from the working formula as demonstrated below. If we let

- $V_e$  and  $V_i$  = volume of expired and inspired air
- $C_e$  and  $C_i$  = per cent  $\text{CO}_2$  in expired and inspired air
- $O_e$  and  $O_i$  = per cent  $\text{O}_2$  in expired and inspired air
- $N_e$  and  $N_i$  = per cent  $\text{N}_2$  in expired and inspired air

we may rewrite the above equation as follows:

$$\text{R.Q.} = \frac{C_e V_e - C_i V_i}{O_i V_i - O_e V_e} \tag{1}$$

Since nitrogen is neither absorbed nor evolved, its volume in inspired and expired air remains unchanged. Therefore its percentage in inspired and expired air is in inverse ratio to their respective volumes. That is

$$N_i:N_e = V_e:V_i$$

or

$$V_i = \frac{N_e V_e}{N_i}$$

Substituting this value in (1) and simplifying, we get

$$\text{R.Q.} = \frac{C_e N_i - C_i N_e}{O_i N_e - O_e N_i} \tag{2}$$

Substituting the values given for the composition of atmospheric air (p. 730) for  $O_i$ ,  $C_i$  and  $N_i$ , we obtain

$$\text{R.Q.} = \frac{79.03 C_e - 0.03 N_e}{20.94 N_e - 79.03 O_e} \tag{3}$$

Simplifying,

$$\text{R.Q.} = \frac{C_e - 0.00038 N_e}{0.265 N_e - O_e}$$

Since  $0.00038 N_e$  never varies significantly from 0.03, we have finally

$$\text{R.Q.} = \frac{C_e - 0.03}{0.265 N_e - O_e} \tag{4}$$

From this equation it is possible to calculate R.Q. simply from the  $\text{CO}_2$  and  $\text{O}_2$  percentages in expired air, since  $N_e$  is obtained by difference.

BASAL METABOLISM OR BASAL METABOLIC RATE (B.M.R.). This may be defined as the percentile variation of the observed from the normal or predicted heat production for an individual of given height, weight, age, and sex in a postabsorptive state and in complete mental and physical repose. The heat production for a given period is

<sup>18</sup> Talbot: *Physiol. Revs.*, **5**, 477 (1925); Stark: *Am. J. Physiol.*, **111**, 630 (1935); Talbot, Wilson, and Worcester: *Am. J. Diseases Child.*, **53**, 273 (1937); Lewis, Kinsman, and Iliff: *Am. J. Diseases Child.*, **53**, 348 (1937).

obtained by multiplying the volume, at normal temperature and pressure, of oxygen consumed during that period by the calorific value for oxygen corresponding to the observed (or assumed) R.Q. Basal heat production may be expressed on an hourly or daily basis. The general formula for basal metabolic rate is therefore

$$\text{B.M.R.} = \frac{273pv}{760t} \times \frac{60(\text{or } 1440)}{m} \times C \times \frac{1}{N} \times 100 - 100 \quad (5)$$

|                                                                        |                                                                       |                                                 |                                                              |                                                       |                                                                                     |
|------------------------------------------------------------------------|-----------------------------------------------------------------------|-------------------------------------------------|--------------------------------------------------------------|-------------------------------------------------------|-------------------------------------------------------------------------------------|
| <i>Corrected volume<br/>of O<sub>2</sub> consumed<br/>in m minutes</i> | <i>Factor for con-<br/>version to<br/>hourly (or daily)<br/>basis</i> | <i>Cal.<br/>per<br/>liter<br/>O<sub>2</sub></i> | <i>Ratio<br/>to<br/>normal<br/>heat<br/>produc-<br/>tion</i> | <i>Conver-<br/>sion to<br/>per<br/>cent<br/>basis</i> | <i>Assuming<br/>normal<br/>heat pro-<br/>duction<br/>to be<br/>100 per<br/>cent</i> |
|------------------------------------------------------------------------|-----------------------------------------------------------------------|-------------------------------------------------|--------------------------------------------------------------|-------------------------------------------------------|-------------------------------------------------------------------------------------|

In this equation,  $p$  is the barometric pressure in mm. of mercury corrected for tension of aqueous vapor;  $v$  the observed volume, in liters, of oxygen consumed during the basal test period;  $m$  the duration of the basal test period in minutes;  $t$  the absolute temperature ( $^{\circ}\text{C} + 273$ );  $C$  the calorific value per liter of oxygen<sup>19</sup> corresponding to the observed (or assumed) respiratory quotient (see the table on p. 727; in the oxygen consumption methods the R.Q. is assumed to be 0.82, which corresponds to a calorific value per liter of oxygen of 4.825); and  $N$ , the normal or predicted basal heat production obtained from one of the various tables of standards.

In the usual form of oxygen consumption apparatus equipped with volumetric scales and CO<sub>2</sub> absorbents,  $v$  in equation (5) is obtained by subtracting the reading at the end from that at the beginning of the test period.

When the gasometric method is employed,

$v$  = volume O<sub>2</sub> in inspired air – volume O<sub>2</sub> in expired air, or

$$v = 0.01O_iV_i - 0.01O_eV_e \quad (6)$$

By substituting the value for  $V_i$  as above, and simplifying,

$$v = 0.01V_e \left( O_i \frac{N_e}{N_i} - O_e \right)$$

in which  $V_e$  is the gasometer reading,  $R$ , multiplied by the gasometer factor,  $f$ , hence the volume of expired air in liters. By further substitution of the values for  $O_i$  and  $N_i$  given above, and simplifying,

$$v = 0.01Rf(0.265N_e - O_e)$$

in which the variables are  $R$ ,  $N_e$ , and  $O_e$ . This expression for  $v$  may be incorporated in equation (5).

The *Aub and DuBois tables* give the normal heat production in Cal. per sq. m. of body surface per hr. ( $A$ ), which when multiplied by the surface area in sq. m. ( $S$ ) gives the predicted *hourly* heat production. Making the proper substitutions in the above equation, and collecting constants, we obtain the following simplified formula:<sup>20</sup>

$$\text{B.M.R.} = \frac{2155pvV}{tmSA} - 100$$

In the *Harris and Benedict tables* for normal heat production, the values are expressed on a 24-hour basis. The coefficient in the equation becomes therefore  $24 \times 2155 = 51720$ , and the equation is

<sup>19</sup> According to Magnus-Levy, the metabolism of protein furnishes on the average 15 per cent of the total calories. This may be taken into account by using figures for the calorific value of 1 liter of oxygen 1 per cent lower than those given in the table on p. 727.

<sup>20</sup> Stoner (*Boston Med. Surg. J.*, 189, 195 (1923); *J. Lab. Clin. Med.*, 12, 884 (1927); 13, 164 (1927)) has described these and other simplifications in the calculations for respiratory exchange, as well as data cards which are very useful in routine practice.

B.M.R. =  $\frac{51720pvC}{tmH}$  - 100

in which *H* represents the predicted 24-hour heat production.

In the oxygen consumption methods R.Q. is assumed to be 0.82. Hence 4.825 is substituted for *C*, in the above equations (see the table on p. 727) and the coefficients become 10,400 and 250,000 respectively. Further simplification is attained in routine

practice by standardizing the basal test period and merging the value for *m* into the coefficient.

The calculations may be performed either on calculating machines or logarithmically, in which case five-place tables are used and the characteristics omitted, since the decimal place may be pointed off in the final result by inspection. A form sheet for logarithmic computation described by Boothby and Sandiford is shown in Fig. 197.

The calculations involved in the interpretation of *kymographic records* of respiratory exchange are described in the legend to Fig. 200.

**HUMAN AND ANIMAL CALORIMETRY.** The rate of combustion may be determined by directly measuring the heat given off by the body. Every animal has an optimum temperature and this temperature is maintained by a nice balance between the heat produced by the life processes and the heat lost by the organism.<sup>21</sup> Gephart and DuBois estimate that in man, 24 per cent of the total heat loss results from the evaporation of water from the lungs and skin. A small amount of heat is lost in warming the ingested food, the urine, the feces, and at times the body itself; the remainder is lost by conduction and by radiation.

Lavoisier and Laplace measured the heat loss by placing a guinea pig in an ice chamber for ten hours and observing the amount of ice melted. Over a period of many years, the elaboration of this simple form of calorimeter has culminated in the construction of the Atwater-Rosa-Benedict Respiration Calorimeter.<sup>22</sup> With this apparatus, the heat of the body is determined indirectly from the respiratory exchange, and directly by a careful computation based on observations of all the known means of heat loss.

The principle of this apparatus was applied by Armsby<sup>23</sup> in the elaboration of a calorimeter for use with farm animals. Benedict<sup>24</sup> and associates also devised a respiration chamber for use with domestic animals. This apparatus was later modified for use in human calorimetry.<sup>25</sup> Respiration calorimeters have provided the means of acquiring most of the present-day knowledge of energy metabolism. They have been extremely valuable in proving the accuracy of indirect calorimetry.

Because of the expense of installation and the technical difficulties of operation of respiration calorimeters, heat production is usually measured indirectly, i.e., from the gaseous exchange. Two types of methods are in use: (1) Open-circuit methods, in which atmospheric air is breathed and expired air collected and analyzed; and (2) closed-circuit methods, in which oxygen-enriched air is breathed and the consumed oxygen measured. The former procedure provides a more complete picture of respiratory exchange since it permits determination of the respiratory quotient. On the other hand, the closed circuit methods are much simpler technically and where only total metabolism must be determined are equally satisfactory. In the closed circuit method an average respiratory quotient of 0.82, corresponding to a calorific value for O<sub>2</sub> of 4.825 Cal. per liter, is assumed.

The various types of respiration apparatus on the market are simplified modifications of Dr. F. G. Benedict's<sup>26</sup> clinical respiration chamber.

Basal metabolism is usually determined in 10- to 15-minute periods using either one of the Benedict closed-circuit methods as developed in the Carnegie Nutrition Laboratory, or a modified Tissot or open-circuit method. Obviously, the determination of urinary nitrogen in such tests is impracticable. It has been the custom to apply the calorific values in the Zuntz and Schumburg table (see p. 727) directly to the respiratory exchange as measured, without computing separately the protein metabolized. DuBois points out that this procedure gives results about 1 per cent too high.

The example described below serves to illustrate the basic principles employed in

<sup>26</sup> Later developments in closed-circuit apparatus and comparison with open-circuit methods are discussed by Benedict: *Boston Med. Surg. J.*, 193, 807 (1925).

FIG. 198. DIAGRAM OF THE BENEDICT-ROTH RESPIRATION APPARATUS.

The patient breathes through a mouthpiece. The nose is clamped. Two tubes connect the mouthpiece with the spirometer. An inspiratory Saddle valve directs the oxygen from the spirometer chamber to the patient; an expiratory valve insures its continuous circulation. The expirations pass through soda lime which removes carbon dioxide. The calibrated spirometer bell is balanced by a counterweight which carries a pointer. The pointer shows the movements of the bell on a millimeter scale. A test is started with the chamber full of oxygen; as oxygen is absorbed by the patient the volume in the chamber decreases. The loss of volume represents oxygen absorbed during the period of the test. Correction is made for any change in chamber temperature during the test.

Slightly modified from Roth: *Boston Med. Surg. J.*, 186, 491 (1922).

the oxygen-consumption type of measurement. Specific directions are furnished with various commercial instruments adapted for office or hospital use.

The *Benedict-Roth respiration apparatus* (Figs. 198, 199) is extensively used in clinics for determining the basal metabolic rate of patients. Roth<sup>27</sup> has dispensed with the

<sup>27</sup> Roth: *Boston Med. Surg. J.*, 186, 457, 491 (1922). This and other types of basal-metabolism apparatus for clinical use are made by Warren E. Collins, Inc., 553H Huntington Ave., Boston, Mass.; Sanborn Co., 39 Osborn St., Cambridge, Mass.; and Jones Metabolic Equipment Co., 1870 Ogden Ave., Chicago, Ill.

electric blower of the Benedict machines, and has inserted two Sudd valves to insure circulation of the oxygen. The spirometer bell is designed to have a volume of 20.73 ml. for every millimeter of height. This greatly simplifies the calculations. The fall of the spirometer bell during a test of 6 minutes represents the volume of oxygen absorbed by the patient. As with other Benedict apparatus, the respiratory quotient is assumed to be 0.82; this gives a heat value for 1 liter of oxygen of 4.825 Cal. "With a bell of this size, *each mm. of the fall of the bell in a six-minute period represents exactly 1 Cal.*

FIG. 199. BENEDICT-ROTH RESPIRATION APPARATUS WITH KYMOGRAPH.

*per hour.* (1 mm. in 6 min. = 20.73 ml. = 0.2073 liter per hour.  $0.2073 \times 4.825 = 1$  Cal. per hour.)"

The form of this apparatus illustrated in Fig. 199 is provided with a kymograph which is self-time-marking in minute periods. A pen attached to the counterweight traces the respiratory excursions and shows the lowering of the spirometer bell due to the absorption of oxygen. Fig. 200 illustrates the method of drawing the "oxygen consumption line," and of measuring the "rise" of this line for any 6-minute period which may be selected on the tracing. If the moisture content of the circulating air is high, as is the case when Wilson soda lime is used as an absorber, a correction must be made for water vapor. Roth<sup>28</sup> gives the factors for reducing the volume of

<sup>28</sup> A table for reducing volumes of 80 per cent saturated air to 0° C. and 760 mm., dry, is given by Roth: *Boston Med. Surg. J.*, 186, 457 (1922).

absorbed oxygen to 0° C., 760 mm., dry (when the vapor tension is 80 per cent of saturation).

**Procedure.** The patient is tested before breakfast and after a 12- to 15-hour fast. A record is made of the sex, age, height, and weight. A rest in a semi-reclining position for half an hour must precede the test. During the rest period, the pulse rate, the respiration rate and the temperature are observed, and the patient is briefly instructed in order to secure his confidence

FIG. 200. GRAPHIC RECORD OF A METABOLISM TEST.

E. H. C., male, aged 38. Height, 176 cm. Weight, 84 kg. Surface area, 2.0 sq. m. Barometric pressure, 745 mm. Average temperature, 24° C. (no increase during test). Rise of O<sub>2</sub> line in 6 minutes, 94 mm. = 94 Cal. per hour. Correction for temperature, pressure, and water vapor  $94 \times 0.879 = 82.63$  Cal. per hour. Divide by surface area  $82.63 \div 2 = 41.3$  Cal. per square meter of surface per hour, which is 5 per cent above the average normal (39.5) for this individual (Roth).

For an example of a simplified data card for taking records of instruments not equipped with kymographs and for making the calculations, see Stoner: *Boston Med. Surg. J.*, 189, 195 (1923).

and cooperation. The apparatus is tested for leaks as follows: a stopper is placed in the opening of the mouthpiece, a 200-g. weight is placed on the bell. The pointer should remain stationary for a minute or more. The weight and stopper are removed and the spirometer is filled with oxygen. The mouthpiece and later the nose clip are applied to the patient, care being taken to avoid leaks. The kymograph<sup>29</sup> is started. The temperature of the spirometer, and the barometric pressure are recorded. The test is continued until a

<sup>29</sup> In the case of spirometers not equipped with kymographs, readings on the scale are made at the beginning and end of the periods. Stoner (*Boston Med. Surg. J.*, 189, 193 (1923)) divides a 10-minute period into five 2-minute periods, taking the average of 10 spirometer readings at the beginning of each period. In this way he is able to select a 4-minute period showing the least oxygen consumption, and also to avoid the error due to wide fluctuations in individual respirations.

satisfactory uninterrupted section of exactly 6 minutes can be selected for subsequent measurement. Before stopping the test, a weight of 50 g. is placed on the bell and operation is continued for a few minutes; if a leak occurs it is shown by a sharp rise in the oxygen consumption line. The temperature of the spirometer is again recorded. Fig. 200 shows a graphic record of a test, and the legend gives the necessary calculations for determining the basal metabolic rate.

Wesson<sup>30</sup> has described an apparatus and procedure for determining the respiratory quotient in small animals. A multiple-chamber respiration apparatus for small animals, based on the oxygen-consumption method, has been described by Benedict.<sup>31</sup>

For research purposes the expired air may be collected in a gasometer or in an impervious rubber or plastic bag and subjected to analytical determination of CO<sub>2</sub> and O<sub>2</sub> content. Methods based on the use of the Haldane-Henderson gas-analysis apparatus are employed. These procedures offer greater flexibility and more information but require more expensive equipment and a high degree of manipulative skill.

## Hormones

The endocrine organs, or glands of internal secretion (see Fig. 201), are tissues whose function it is to secrete certain specific chemical substances known as *hormones* into the blood stream, which distributes them to all parts of the body. Certain tissues respond to their presence in a characteristic way, increasing, decreasing, or modifying their processes of growth or of metabolic or physiological activity. The hormones are therefore chemical messengers serving to integrate the various activities of the

FIG. 201. SCHEMATIC CHART OF ENDOCRINE SYSTEM.

From Barker, *et al.*: *Endocrinology and Metabolism*, New York, Appleton, 1924.

body; they may themselves undergo metabolic transformations, such as partial or complete oxidation, or reduction; and recognizable products of these transformations, or the hormones themselves, may be excreted in the urine and in the bile.

The secretory activity of the endocrine organs varies from time to time. As the chart on p. 750 shows, the morphological structure and the endocrine activity of the gonads, adrenal cortex, and thyroid are largely controlled by hormones produced by the anterior lobe of the pituitary

(anterior hypophysis) which also produces hormones acting directly on the structure and function of nonendocrine tissues. The anterior pituitary in turn is partly controlled (directly or indirectly) by the concentration of hormones produced by the gonads, thyroid, etc., and also by the nervous system directly. Similarly, the posterior pituitary and the adrenal medulla are subject to direct nervous regulation. The control of the endocrine activity of the pancreas, parathyroids, and other possible sources of hormones is not fully understood. It will be noted in the chart that a single organ, or a single metabolic process, may be affected by more than one hormone, and often also by factors not endocrine in nature.

The hormones do not vary significantly in chemical structure from species to species, hence extracts from the endocrine organs of animals may often be used in treating disorders due to insufficient activity of a human gland; synthetic or artificial products, allied to or identical with the natural hormones, may be less costly. Disorders due to excessive activity—for example, when a tumor develops from endocrine cells—are often treated by surgical removal of the abnormal tissue; or, more rarely, by selective inhibitory drugs or by irradiation with x-rays. Chemically, the known hormones may be divided into two main groups. The first may be referred to as nitrogenous, and range in size and complexity from simple bases such as adrenaline to proteins of high molecular weight and undetermined structure. The second group, more homogeneous, may be called the steroid hormones

## THE STEROID HORMONES OF THE GONADS AND ADRENAL CORTEX

**General Chemistry of the Steroids and Steroid Hormones.** The basic saturated carbon ring skeleton of the steroids is illustrated in Formula I.

**Carbon Ring Skeleton of the Steroids (I)**

Depending on the chemical nature of the substituent (R) at C<sub>17</sub>, the steroids may be divided into five classes:

(a) The *sterols*, like cholesterol and ergosterol (see Chapters 11 and 35), where R consists of an eight- or nine-carbon-atom aliphatic side chain.

(b) The *bile acids* (p. 410), where R consists of a five-carbon side chain terminating in a carboxylic acid group.

(c) The *cardiac aglycones*, breakdown products of the heart-stimulating glycosides of *Strophanthus*, *Digitalis*, etc., which are characterized by a lactone ring substituted at C<sub>17</sub>.

(d) The *sapogenins*, derived from plant saponins, where R is comprised of an ethereal ring system.

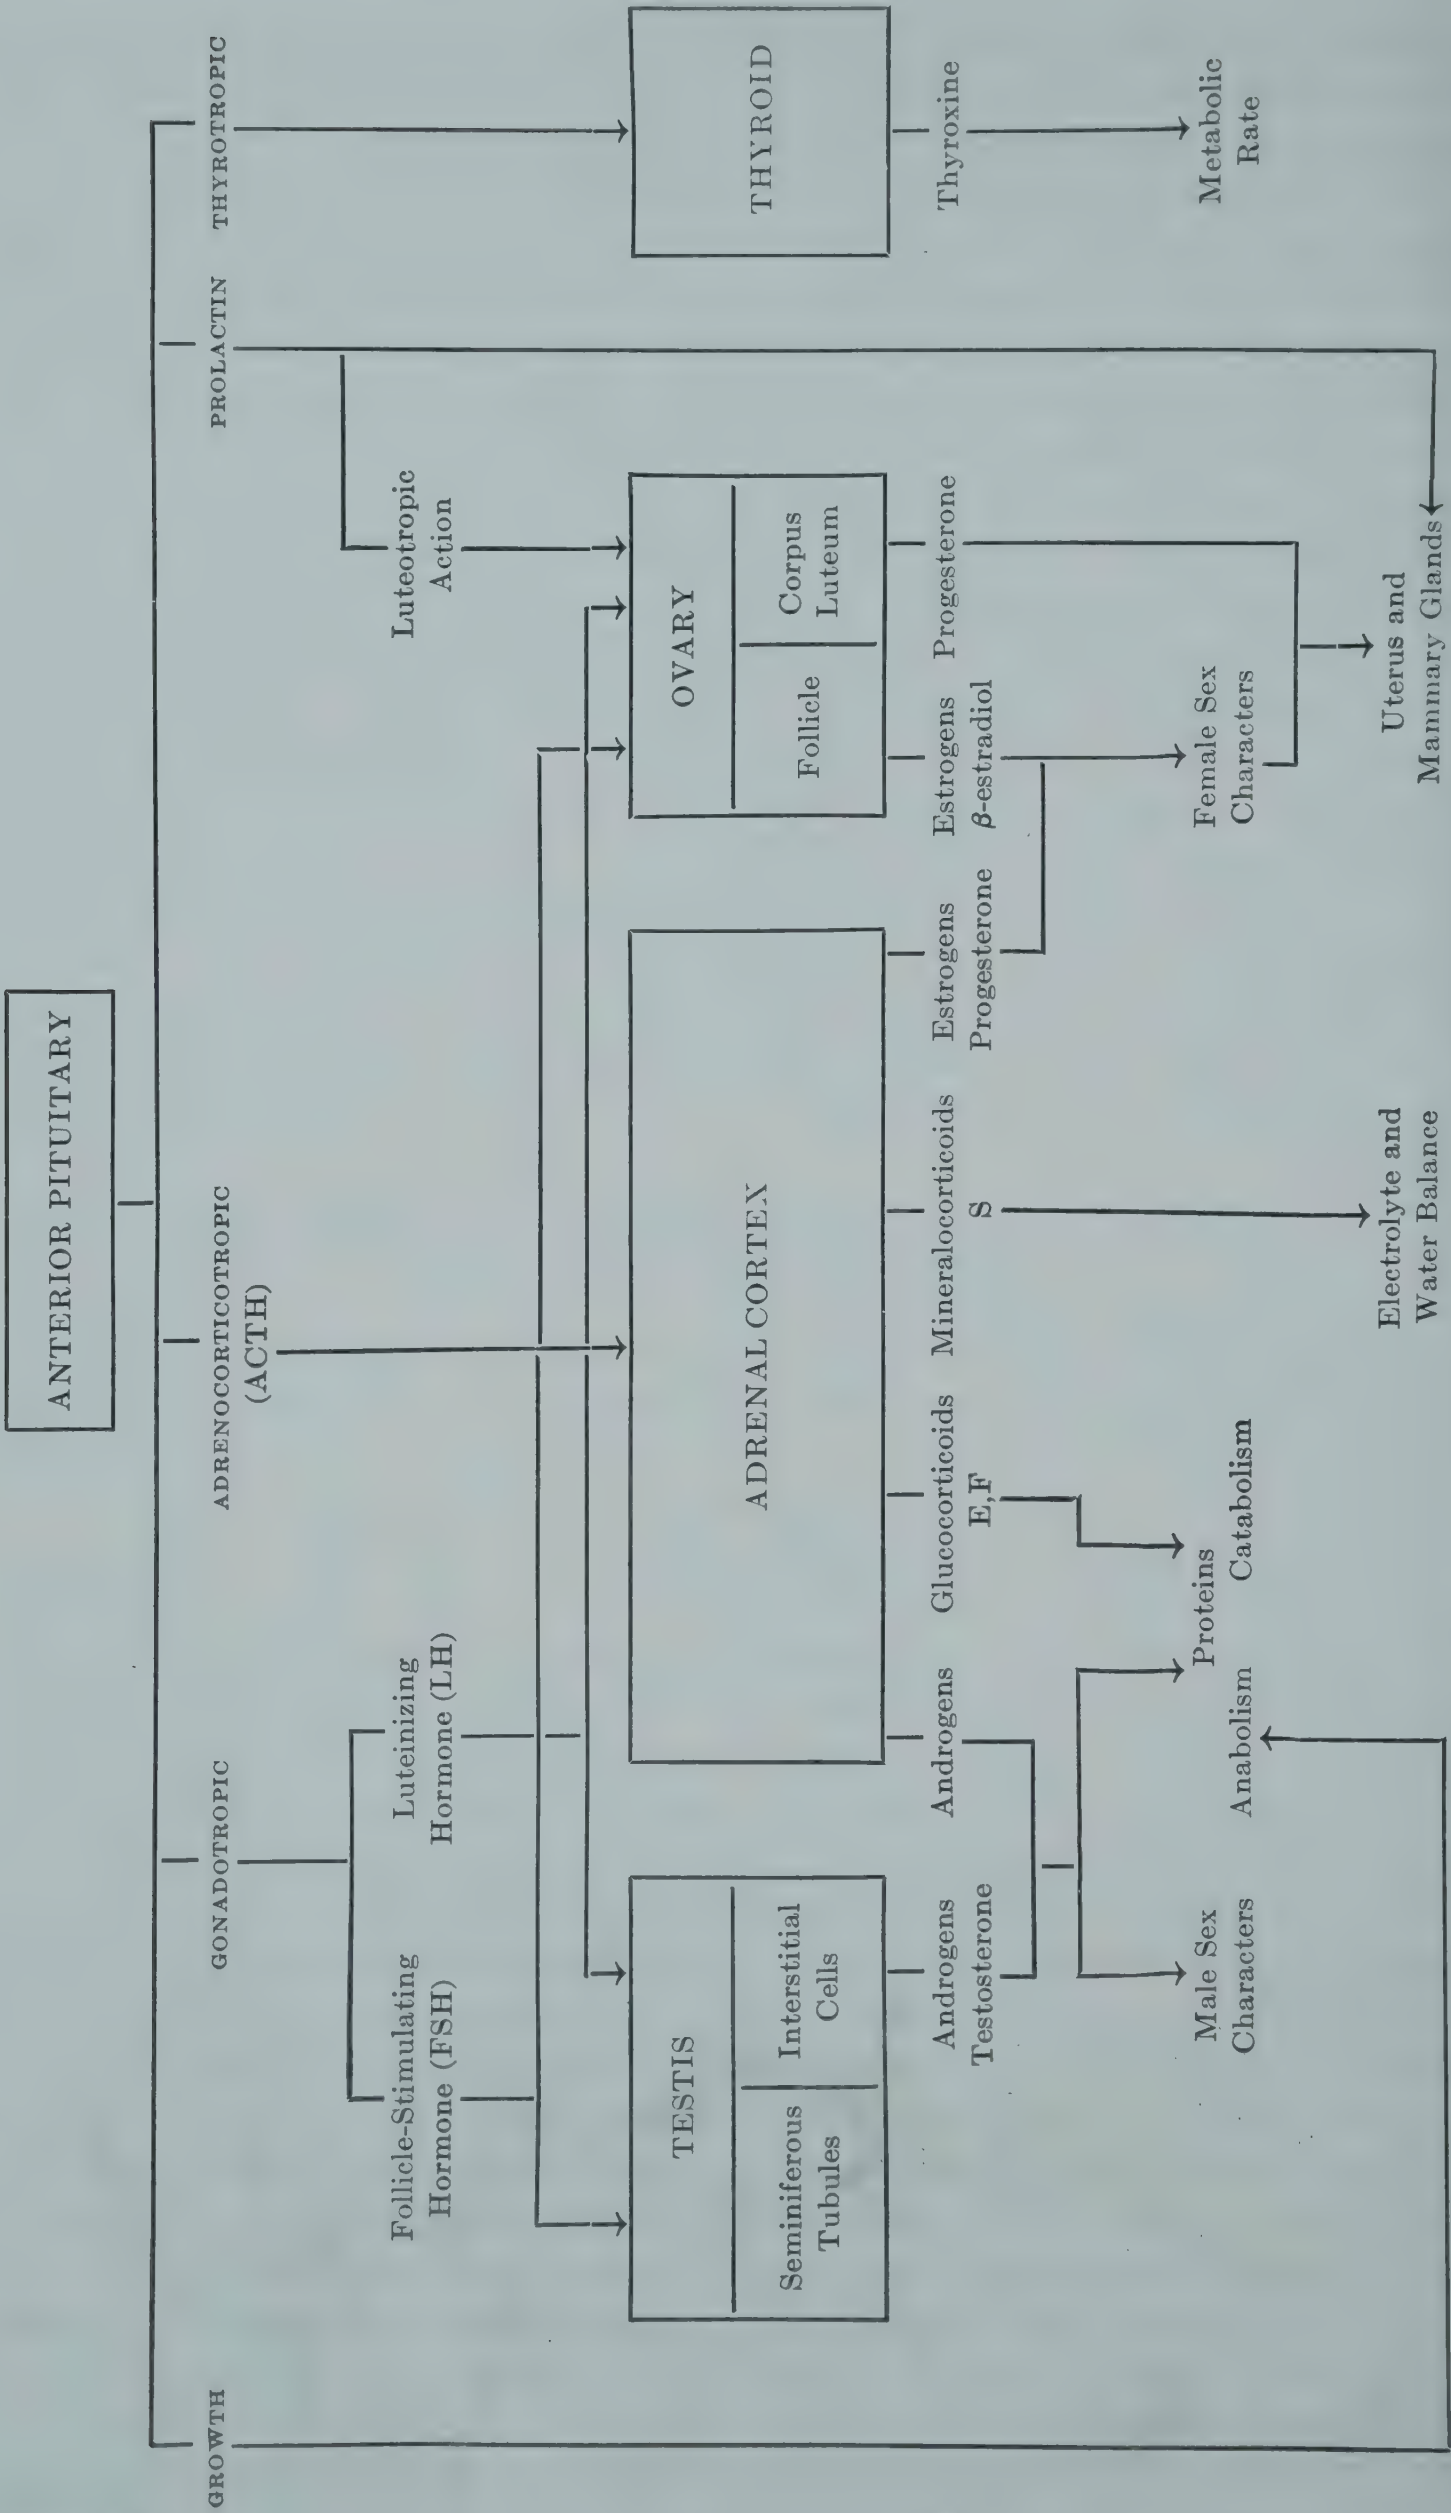

(e) The *steroid hormones*, where C<sub>17</sub> bears a ketonic or hydroxyl group (the androgens and estrogens), or carries a substituted two-carbon side chain (progesterone and the adrenal cortical steroids).

The steroid hormones all carry phenolic or ketonic oxygen on C<sub>3</sub>. The summary on pp. 751–754 formulates the principal steroid hormones, and illustrates, by means of arrows, the metabolic pathways followed in the body in the course of their inactivation and excretion. The ovarian follicular hormones—the estrogens—all possess an aromatic or benzenoid ring A, while the hormones of the testis, corpus luteum, and adrenal cortex are all characterized by the presence in ring A of an  $\alpha$ - $\beta$  unsaturated ketonic grouping, the saturation of which leads to practically complete loss of physiological activity. In the course of this reduction, which is a common mechanism of inactivation *in vivo*, carbon atoms numbers 3 and 5 become asymmetric, and hence four fully reduced geometrical isomers are possible in each instance. The hydroxyl group resulting on hydrogenation of the ketone may be oriented either *cis* or *trans* with respect to the angular methyl group at C<sub>10</sub>. Respectively, the *cis* and *trans* epimers are designated by the suffixes  $\beta$  and  $\alpha$ , and conventionally are differentiated in two-dimensional formulas by the use of a solid and a dotted line. [Compare androsterone (III) and isoandrosterone (IV).] 3( $\beta$ )-Hydroxy-steroids form with digitonin (a saponin from *Digitalis*) sparingly soluble addition compounds, whereas the epimeric 3( $\alpha$ )-compounds do not. Likewise the hydrogen atom introduced at C<sub>5</sub> on saturation of a 4:5 or 5:6 double bond may be *cis* or *trans* oriented in relation to the angular methyl group at C<sub>10</sub>; again, in planar formulation, the solid and dotted lines respectively are used [compare androsterone (III) and etiocholanolone (V)]. Because of this isomerism about C<sub>5</sub>, there are two saturated parent hydrocarbons of the steroid hormones containing 19 carbon atoms, namely androstane (*trans*) and etiocholane (*cis*), and two pertaining to the hormones with 21 carbon atoms, namely pregnane (*cis*) and allopregnane (*trans*).

The total synthesis of steroids has been realized through a long sequence of intricate chemical reactions which, however, are not yet applicable commercially. Steroid hormones are prepared by degradation of naturally occurring plant and animal steroids. Diosgenin, a sapogenin from the Mexican yam, is readily converted to progesterone (XVIII) and deoxycorticosterone (XIV), and from these to testosterone (II) and estrone (VIII). Much less satisfactorily, the same four hormones may be derived from cholesterol. The bile acids, particularly deoxycholic acid, serve as starting material for the part-synthesis of the corticoids bearing an oxygen function at C<sub>11</sub>, namely cortisone (XV), corticosterone (XVI), and Compound F (XVII). Certain microorganisms possess the unique and specific property of introducing a hydroxyl group at C<sub>11</sub>, and they are employed in some commercial procedures for the preparation of cortisone. Isotope studies show that in the body all the steroid hormones and cholesterol can be synthesized from acetate.

In general, all steroid hormones are insoluble in water but soluble in fat solvents such as ether, acetone, alcohol, etc., and in vegetable oils, in which medium they are usually dissolved for administration to the body. They are relatively inactive *per os*, and consequently are given intramus-

cularly or subcutaneously. Esters of the hormones, such as the acetate, propionate, and benzoate, are much more valuable therapeutically than the free steroids, since their physiological action is more protracted owing to the delayed rate of absorption and utilization. The steroid hormones and their catabolites are generally eliminated in the urine in water-soluble form in conjugation with glucuronic or sulfuric acid.

**Formulation of Steroid Hormones and Related Substances.** The chemical name is given in each instance, followed by the commonly used name in parentheses. The arrows indicate metabolic pathways followed in the body.

## THE TESTES

Removal of the testes causes atrophy of the seminal vesicles, prostate, and other accessory organs of the male genital system. The effects are most pronounced if the operation is performed before sexual maturity, and are due to withdrawal of androgenic hormones, such as testosterone (II), secreted by the Leydig or interstitial cells. The androgenic hormones will restore the atrophied tissues in castrated animals, such as rats or mice, and are frequently assayed by their power to cause enlargement of the comb in the capon.

Testosterone (II) is the principal male sex hormone isolated from testis tissue. In the course of its metabolism in man it is reduced to androsterone (III), isoandrosterone (IV) and etiocholanolone (V), all of which are excreted in the urine (see 17-ketosteroids, p. 759). Methyltestosterone (VII), prepared artificially, but not known to occur in nature, finds wide therapeutic application because it is highly active *per os*.

The International Standard male hormone unit is the activity equivalent of 0.1 mg. of pure androsterone. By comparison of comb growth in the capon, testosterone is about six times, and isoandrosterone one-seventh, as potent as androsterone, while etiocholanolone is practically inert. Administered parenterally, methyltestosterone and testosterone show equal activity; orally methyltestosterone is two to four times less active than parenterally, but about 20 times more potent than testosterone given by mouth.

## THE OVARIES

The development of the accessory sex organs in the female is not so dependent on hormonal stimuli as in the male; nevertheless, extirpation of the ovaries causes atrophic change in the uterus, vagina, mammary glands, etc., and in the plumage of poultry. In most mammals, mating occurs only during periods of heat or *estrus*, when the concentration of estrogenic hormones produced by the ovary and in particular by the Graafian follicles becomes maximal. In rodents estrus is accompanied by the appearance of cornified cells in the lumen of the vagina, from the walls of which they have desquamated. This reaction follows the administration of estrogenic substances to castrated animals, and is the basis of biological assay.

After ovulation in mammals, the ruptured Graafian follicle is transformed into the corpus luteum, which produces the hormone progesterone (XVIII) whose chief function is to prepare the mucous membrane of the uterus for the implantation of the embryo. Progesterone is assayed by its power to cause a glandular "progestational" proliferation of this membrane in immature or castrate rabbits previously sensitized with estrogens. Gestation, in its early stages, is interrupted by destruction of the corpora lutea; when implantation and pregnancy occur, the active life of the corpora lutea is prolonged. In the later stages of human pregnancy, estrogens and progesterone are produced by the placenta; they act together in promoting mammary development.

The principal estrogens are  $\beta$ -estradiol (VIII), estrone (IX), and estriol (X); their relative activities are roughly 10:1:1 or less, but wide fluctuation in these proportions is observed by the different methods of testing. Only the first two are known to occur in *liquor folliculi*, where  $\beta$ -estradiol accounts for 90 per cent of the physiological activity, and hence is regarded as the chief ovarian follicular hormone.  $\beta$ -Estradiol and estrone are interconvertible in the animal organism, for the administration of either leads to the excretion of the other. Estriol has been isolated only from human pregnancy urine and from human placenta, and that organ is regarded as the main site of production. In gestation (Fig. 202), the estrogen output rises sharply with the growth of the placenta to a pre-

partum level of 12 to 40 mg. *per diem*; estriol constitutes the chief catabolite (about 90 per cent of the total), but estrone is excreted in appreciable amount together with traces of  $\beta$ -estradiol. The conjugate of estriol in human pregnancy urine has been isolated as the 16- or 17-monoglucuronide. Throughout the normal menstrual cycle, the urine estrogen content is low, of the order of 0.08 mg. *per diem* at the maximum. Biological assay reveals pre- and postovulatory peaks with the minimum output during the period of flow. While the chemical nature of the estrogens excreted in the nonpregnant state has not been established by isolation, partition experiments indicate that all three are eliminated.

FIG. 202. VARIATION IN URINARY OUTPUT OF SEX HORMONES AND METABOLITES WITH PERIOD OF GESTATION.

Throughout gestation in the mare, estrone represents the most abundant excretory product. Estriol is not formed in this species, but considerable amounts of estrogens unsaturated in ring B as well as in ring A are eliminated; *equilenin* (XI) is the most abundant.

Many synthetic derivatives of stilbene possess marked estrogenic potency, although they are nonsteroidal and do not occur in nature. Important among these is *diethyl stilbestrol* (XII) which, like other members of the group, is much more active orally than the free natural estrogens. The water-soluble conjugated estrogens of human and equine pregnancy urine (principally estriol glucuronide and estrone sulfate respectively) are also effective by mouth.

The International Unit is defined as the activity contained in 0.1  $\mu$ g. of estrone. As the different estrogens cannot properly be compared because of variations in the time and period of action, a subsidiary standard

exists for  $\beta$ -estradiol-3-monobenzoate which is the activity equivalent of 0.1  $\mu$ g. of that substance.

Progesterone is produced by the corpus luteum of the ovary during the postovulatory phase of the menstrual cycle, and in much larger amounts throughout gestation by both the corpus luteum and the placenta. Traces are elaborated by the adrenal cortex in both sexes. The chief metabolite of progesterone (XVIII) is the inactive pregnanediol (XIX), which is excreted in the urine in conjugation with glucuronic acid. Estimation of the sodium pregnanediol glucuronidate content of urine thus provides a useful index of luteal function. From 40 to 55 mg. of pregnanediol are eliminated during the normal menstrual cycle, the excretion beginning probably one to two days after ovulation and ceasing one to three days before the onset of uterine bleeding. A significant decrease in total output, or shortening of the period of excretion, indicates that progestation is not sufficiently well developed or is of too brief duration to support implantation. From fertilization to the end of the ovarian phase of pregnancy (ca. three to four lunar months), urine pregnanediol remains at the maximum level associated with the luteal phase of the cycle (ca. 5 to 10 mg. *per diem*), and then rapidly rises with the growth of the placenta to a daily output at parturition of about 60 to 100 mg. (Fig. 202). A significant fall during the first third of gestation indicates corpus luteum deficiency or failure of the placenta to develop at the normal rate, either of which threatens abortion. A residual pregnanediol titer of the order of 0.2 mg. *per diem* remains in the urine of men and of women in the follicular phase of the cycle; presumably this is of adrenal cortical origin. The International Unit is defined as the activity contained in 1 mg. of the pure crystalline progesterone.

### THE ADRENAL CORTEX

The adrenal glands consist of two distinct tissues in close apposition: the *medulla*, producing epinephrine (adrenaline) and norepinephrine (noradrenaline) and derived from the sympathetic nervous system (see p. 766); and the much larger surrounding *cortex*, embryologically related to the gonads. Extirpation or destruction of the cortical tissue is fatal. Before death, the body loses sodium salts in the urine and accumulates potassium, so that the volume of extracellular fluid is reduced, the blood becomes viscous, the circulation sluggish, and renal function seriously impaired; treatment with diets low in potassium and enriched with sodium salts is helpful. Another group of symptoms includes diminished breakdown of tissue proteins to form glycogenic amino acids, so that glycogen stores decrease rapidly on fasting, hypoglycemia develops, and resistance is greatly lessened to extremes of heat and cold, infections, toxic drugs, trauma, fatigue, and stress of all kinds. Addison's disease, in which the cortical tissue is gradually destroyed, is characterized by asthenia, emaciation, low blood pressure, pigmentation of the skin, and often hypoglycemia, although here (as in the adrenalectomized dog) the disturbance of electrolyte metabolism is usually the greatest threat to survival.

About 30 steroids have been isolated in crystalline form from cortical

extracts. Of these 30 steroids, many are physiologically quite inert; others, such as traces of estrone (IX) and progesterone (XVIII) have been discussed above; several, such as androstenedione, adrenosterone, and 17-hydroxyprogesterone, have definite androgenic activity; but the most interesting are six which are active in correcting the specific effects of adrenalectomy and may therefore be called *corticoids* (Selye). All six are derivatives of  $\Delta^4$ -pregnenc-3,20-dione-21-ol. The adrenal contains enzyme systems which promote the introduction of oxygen at positions 11, 17, and 21 of the steroid skeleton; for example, adrenal tissue, in perfusion or incubation experiments, will readily convert progesterone (XVIII) to compounds F (XVII), E (XV) and B (XVI). *Deoxycorticosterone* (XIV) is present in very small amounts, if at all, but as it is readily available commercially, it has been widely used in medicine, especially as its 21-acetate (DCA); it is highly potent in correcting the imbalance in the metabolism of sodium and potassium and hence in maintaining life in the adrenalectomized dog or in patients with Addison's disease, and may be called a *mineralocorticoid*. On the other hand, *cortisone* (17-hydroxy-11-dehydrocorticosterone, Kendall's "compound E") (XV), and *hydrocortisone* (17-hydroxycorticosterone, Kendall's "compound F") (XVII) may be called *glucocorticoids*; they have slight and variable action on sodium and potassium balance but profound influence on protein and carbohydrate metabolism, on which their medical uses depend. *Corticosterone* (XVI) and *11-dehydrocorticosterone* possess both glucocorticoid and mineralocorticoid activity (oxygen at position 11 is essential for the former), but not in any high degree. It must be emphasized that cortical extracts contain mineralocorticoids with life-maintaining activity. These compounds (the "amorphous fraction") have not yet been crystallized or identified and are much more water-soluble than the glucocorticoids. Biological assay procedures for glucocorticoids are based on their power to increase resistance to cold in adrenalectomized rats or to restore liver glycogen levels. Mineralocorticoids are assayed by their life-maintaining power or more specifically by their effect on the metabolism of sodium and potassium.

The structure and secretory activity of the adrenal cortex is controlled by the adrenocorticotrophic hormone (ACTH) of the anterior pituitary. After hypophysectomy, the cortex atrophies, especially the inner layers, and low resistance to stress and impaired glycogen storage indicate that glucocorticoids are not being produced. The injection of a single dose of ACTH, in the rat, leads to rapid depletion of the cholesterol and ascorbic acid of the cortex (this is the basis of the Sayers assay method) with some temporary increase in cortical volume and various evidences of increased manufacture and discharge of corticoids, principally hydroxycorticosterone (compound F). The application of suitable stress, e.g., brief exposure to cold or the injection of a sublethal dose of epinephrine, will produce the same results by causing the pituitary to discharge ACTH. In human subjects the injection or discharge of ACTH or of glucocorticoids is evidenced by (a) a fall in the numbers of circulating eosinophils and lymphocytes, (b) an increased excretion of nitrogenous waste products, notably uric acid, and (c) increased urinary excretion of corticoids as

determined by chemical or biological assay (but representing only a small fraction of the corticoids actually secreted or injected) and of 17-ketosteroids. ACTH and compounds E and F have proved dramatically successful in relieving the symptoms of rheumatoid arthritis and many other diseases; the disappearance of pain and the development of a sense of well-being are particularly remarkable. Prolonged treatment with small daily doses of cortisone appears to be both possible and effective. However excessive doses administered over a long period of time may induce symptoms of *Cushing's syndrome*, with tendencies toward obesity, hypertension, osteoporosis, and psychic disturbances. In patients disposed to diabetes, symptoms of this disease may be aggravated. Large doses are contraindicated in tuberculosis, gastric ulcer, and diabetes. Cushing's syndrome is thus attributed to overproduction of glucocorticoids. The concept of a causal relation between overproduction of mineralocorticoids and the *collagen diseases* (rheumatoid arthritis, periarteritis nodosa, etc.), attributed to Selye, has been questioned by many investigators and is the subject of active study. Overproduction of adrenal androgens, with high 17-ketosteroid excretion, leads to the adrenogenital syndrome (*virilism*, *hirsutism*, or precocious masculinization) with enhanced protein synthesis and muscularity.

### 17-KETOSTEROIDS

Human urines contain steroids carrying ketonic oxygen at C<sub>17</sub>, some of which are phenolic while others are neutral. The latter are commonly called "17-ketosteroids." The principal members of this group are androsterone (III), etiocholanolone (V), isoandrosterone (IV), and dehydroisoandrosterone (VI); the first two of these arise in part from the testis, while all represent the excretion products of some of the steroids of the adrenal cortex. Accordingly, measurement of 17-ketosteroid output provides a biochemical index of testicular and adrenocortical activity.

The normal 17-ketosteroid excretion of men between the ages of 20 and 40 years averages about 15 mg. *per diem*; normal women in the same age group excrete approximately 10 mg. *per diem*. In children under 8 years of age, less than 1 mg. *per diem* is eliminated, but from this age on there is a gradual increase to adult values. Likewise in old age a significant diminution is observed. As gonadectomy in the male decreases the average output from 15 to 10 mg., and is without effect in the female, it is concluded that approximately 10 mg. are derived from the adrenal cortex and 5 mg. from the testis. The human ovary is not a source of neutral 17-ketosteroid.

Disorders of the testis, adrenal cortex, and anterior pituitary may profoundly alter 17-ketosteroid excretion. In eunuchoidism values from normal to that of the surgical castrate (10 mg.) are reported, whereas in the rare cases of masculinizing tumors of the interstitial cells of the testis the output may reach 800 mg. *per diem*. In Addison's disease in the male, excretion falls to 1.2 to 6.4 mg., which represents the testicular output, while in the female practically no 17-ketosteroids are produced. In those cases of Cushing's syndrome not associated with carcinoma of the adrenal cortex, normal or only slightly elevated 17-ketosteroid values are ob-

served (10 to 36 mg.), but when carcinoma of the cortex complicates the condition a much higher excretion is usually encountered (40 to 288 mg.). Similarly, in the adrenogenital syndrome, simple hyperplasia of the cortex leads to only a moderately high 17-ketosteroid output (up to 100 mg. approximately), whereas carcinoma generally gives rise to a more marked increase (ca. 100 to 250 mg.). In both instances, carcinoma may be distinguishable from hyperplasia by the higher excretion, and also by the increased proportion of the 3( $\beta$ )-hydroxy-17-ketosteroids (chiefly dehydroisoandrosterone) to the 3( $\alpha$ ). Normally, and in hyperplasia, the  $\beta$ : $\alpha$  ratio is 1:9, whereas in carcinoma it may rise to about 1:1. In pan-hypopituitarism, a general underproduction of all anterior-lobe hormones, the 17-ketosteroid excretion is low (0 to 3 mg.).

## EXPERIMENTS ON STEROID HORMONES<sup>1</sup>

**1. Partition and Estimation of the Estrogens of Urine: Principle.** The determination comprises (a) hydrolysis of the water-soluble conjugates in urine, (b) extraction of the steroid moieties and their separation by partition between solvents, and (c) estimation of the estrogen content of the various fractions either colorimetrically (see Exp. 3) or by biological assay (see Exp. 4). Colorimetric methods are unsatisfactory when the estrogen output is less than 1.5 mg. per liter approximately, as in normal urine and throughout the first four months of gestation.

**Procedure: Method of Bachman and Pettit.<sup>2</sup>** Acidify 100 ml. of human pregnancy urine to pH 2 (thymol blue) with HCl. Add 5 ml. concentrated HCl, and boil the mixture under reflux for one hour. The hydrolyzed urine is cooled and diluted with 100 ml. of distilled water, and extracted once with 200 and twice with 100 ml. of peroxide-free ether. The combined ether extracts are washed with 8 ml. of 9 per cent NaHCO<sub>3</sub> (anhydrous), which is discarded, and are evaporated to dryness. The residue is dissolved in the minimum volume of ethanol (not over 0.5 ml.), and diluted with 35 ml. of benzene.

Estriol and extraneous phenols and acids are now removed from the benzene solution by extraction once with 35 and twice with 17.5 ml. of 9 per cent Na<sub>2</sub>CO<sub>3</sub> (anhydrous) and once with 3.5 ml. of water; these extracts are combined and acidified to a pH less than 6 with HCl. The estriol fraction is collected with ether (three extractions with 40 ml.), which is washed with 12 ml. of 9 per cent NaHCO<sub>3</sub> and taken to dryness. The residue is again taken into benzene (50 ml.) with the aid of ethanol (0.5 ml.) and further purified by washing with 9 per cent NaHCO<sub>3</sub> (1 ml.) and by transference to water (extraction three times with 50-ml. portions). Evaporation of the combined water extracts to dryness *in vacuo* yields Fraction T, which is more than 50 per cent estriol by weight.

The first benzene solution (35 ml.) contains the estrone and estradiol which, after washing of the benzene solution once with 10 ml. of 45 per cent H<sub>2</sub>SO<sub>4</sub> (by volume) and twice with 20 ml. of water, are removed by extraction with N NaOH (four times with 35-ml. portions). The combined alkaline extracts are acidified with HCl and extracted once with 225 and twice with 125 ml. of benzene. The combined benzene extracts are concentrated to about 50 ml.,

<sup>1</sup> Space does not permit incorporation of the many methods for the estimation of the steroid hormones and their metabolites in urine and blood. For full practical details, reference should be made to *Methods in Medical Research*, Vol. 2, Chicago, Year Book Publishers, 1950; or to Emmens: *Hormone Assay*, New York, Academic Press Inc., 1950.

FIGS. 203-208. VAGINAL SMEARS OF ARTIFICIALLY INDUCED ESTRUS IN SPAYED RAT.

FIG. 203. Diestrous smear: leukocytes in stringy mass ( $\times 40$ ).

FIG. 204. Proestrous smear: chiefly nucleated epithelial cells with an occasional leukocyte ( $\times 40$ ). Present 35 to 40 hours after first injection.

FIG. 205. Estrous smear: nonnucleated cornified epithelial scales ( $\times 40$ ). This type usually appears within 48 hours after the first injection and is a certain criterion of the positive action of an extract.

FIG. 206. Flat, cornified elements of the estrous smear stage ( $\times 250$ ). Eosin stains these cells a brilliant red. Although the site of the former nucleus is apparent, all basophilic staining reaction has been lost.

FIG. 207. Early stage of leukocytic infiltration (metestrum) ( $\times 40$ ). Few nucleated epithelial cells have appeared as yet.

FIG. 208. Late stage of the metestrum ( $\times 40$ ). Enormous numbers of leukocytes, some cornified scales (in center of field), and many nucleated epithelial cells.

From Allen, Doisy, *et al.*: *Am. J. Anat.*, **34**, 169 (1924-1925). Courtesy, Cameron: *Recent Advances in Endocrinology*, 5th ed., Philadelphia, The Blakiston Company, 1945.

washed successively with 12 ml. of 45 per cent  $\text{H}_2\text{SO}_4$ , twice with 25 ml. of 9 per cent  $\text{Na}_2\text{CO}_3$ , and twice with 25 ml. of water, and evaporated to dryness (Fraction OD).

Both Fractions T and OD are purified sufficiently that they may be assayed colorimetrically (see Exp. 3). When a separate estimate of the estradiol and estrone content is required, Fraction OD is divided into ketonic (estrone) and nonketonic (estradiol) fractions by treatment with Girard's reagent<sup>3</sup> prior to assay.

**2. Isolation of Crystalline Estriol from Human Pregnancy Urine.** Fraction T (Exp. 1) from late pregnancy urine readily yields reasonably pure estriol on crystallization from benzene. For this purpose 500 ml. or more of urine may be taken, all quantities of reagents and solvents being increased proportionately.

**3. Kober's Color Reaction for Estrogens.**<sup>4</sup> The sample to be tested is evaporated to dryness in a test tube, to which is added 2 ml. of an equimolecular mixture of sulfuric and (*o* and *p*) phenylsulfonic acids. The test tube is heated for 10 minutes at  $100^\circ\text{C}$ . and at once cooled in ice. A red color gradually develops.

**4. Biological Test for Estrogens.**<sup>5</sup> Young adult female rats or mice are ovariectomized. If the operation is complete, within a week the vaginal smear will contain only leukocytes. The smear may be obtained by washing out the vagina with a drop of saline solution, using a small homemade pipet with a rubber bulb, or by introducing a small pledget of moist cotton wool on a loop of platinum wire, and in either case spreading the fluid on a clean microscope slide. It is not necessary to fix or stain the cells. Inject the animals with three 0.5 ml. doses of a solution of estrin in oil, or in 10 per cent alcohol made slightly alkaline, preferably allowing at least 6 hours to elapse between injections. Examine the vaginal smear on the second, third, and fourth days. The leukocytes will almost disappear, and the smear should come to consist of horny, scale-like squamous cells, and some epithelial cells still retaining their nuclei. The test can be made quantitative only if large numbers of animals are used, and their sensitivity to crystalline estrogens must be established. The response is affected by the strain of the animals, by the degree of subdivision of the dose and the solvent used, by the number of examinations made, and by many other factors. See Figs. 203–208.

**5. Determination of Sodium Pregnanediol Glucuronidate in Urine: Method of Venning.**<sup>6</sup> Urine is collected with four to five drops of tricresol as preservative and kept chilled until extraction to prevent hydrolysis. In the nonpregnant state a 48-hour specimen is required, in early pregnancy, a 24-hour specimen, and in late pregnancy, part thereof.

The urine is extracted 3 times with normal butanol (200, 100, 50 ml. per liter of urine). Gentle shaking (20 to 25 times) prevents formation of excessive emulsion. The combined butanol extracts are shaken vigorously, allowed to stand for 1 hour, when the urine which collects at the bottom is run off and the butanol is evaporated in a distilling flask almost to dryness under reduced

<sup>3</sup>  $(\text{CH}_3)_3\text{NCl}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{NH}_2$ . Girard and Sandulesco: *Helv. chim. acta*, **19**, 1095 (1936).

<sup>4</sup> Kober: *Biochem. Z.*, **239**, 209 (1931).

<sup>5</sup> Marrian and Parkes: *J. Physiol.*, **67**, 389 (1929).

<sup>6</sup> Venning: *J. Biol. Chem.*, **119**, 473 (1937) and **126**, 595 (1938).

pressure. The residue is taken up in 60 ml. of 0.1 N NaOH, again extracted 3 times with butanol (60, 20, and 10 ml.), and the combined butanol extracts are washed twice with 5 ml. of water and evaporated to dryness under reduced pressure. The residue is dissolved in exactly 5 ml. of water and transferred to a 125-ml. flask with several small portions of acetone. Volume is made to 100 ml. with acetone, and, after standing overnight in the refrigerator, pregnanediol glucuronidate precipitates. Most of the supernatant acetone is removed by suction without disturbing the precipitate. The remaining mixture is transferred to a 50-ml. centrifuge tube and centrifuged for 10 minutes. The residual acetone is carefully decanted and the crude ester is dissolved in water for purification by reprecipitation. The amount of water used is dependent upon the weight; 2 ml. for quantities less than 5 mg.; 3 ml. for 5 to 10 mg.; and 5 ml. for more than 10 mg. The water is added to the original flask to dissolve adhering material and then transferred to the 50-ml. centrifuge tube containing the precipitate. The tube is warmed and the contents are filtered back with suction into the original flask. The tube is rinsed twice with small amounts of acetone which are filtered into the flask, and the volume is made to 100 ml. with acetone. After 12 hours in the refrigerator, the acetone is removed as before by suction and centrifugation. The precipitate is dissolved in 10 ml. of hot 95 per cent ethanol and filtered with suction into a tared beaker (30 ml.). The flask, centrifuge tube, and filter paper are washed twice with hot ethanol. After evaporation of the solution to dryness on the bath, the weight of the precipitate is determined.

CALCULATION. The percentage recovery of the ester depends upon the amount present and the volume of water used in the second precipitation; accordingly a correction factor is applied (see the table below). Sodium pregnanediol glucuronidate contains 61.7 per cent pregnanediol.

Mg. pregnanediol excreted *per diem* = 
$$\frac{\text{Wt. of ppt.} \times 0.617 \times 24 \text{ hr. volume} \times 100}{\text{Per cent recovery} \times \text{volume extracted}}$$

The melting point of the final precipitate should always be confirmed; sodium pregnanediol glucuronidate melts at 273° C. with evolution of gas.

| Weight of precipitate in mg. | Per cent recovery      |                        |                        |
|------------------------------|------------------------|------------------------|------------------------|
|                              | 2 ml. H <sub>2</sub> O | 3 ml. H <sub>2</sub> O | 5 ml. H <sub>2</sub> O |
| 2                            | 0-60*                  | ..                     | ..                     |
| 3-4                          | 50-67*                 | ..                     | ..                     |
| 5-8                          | 70-75*                 | 79                     | ..                     |
| 9-10                         | ..                     | 82                     | 75                     |

\* Approximate values.

**6. Preparation of Adrenal Cortex Extract: Method of Cartland and Kuizenga.**<sup>7</sup> Minced whole beef adrenals are thoroughly extracted with 99 per cent acetone (2.5 liters per kg.) and again with 80 per cent acetone. The extracts are combined, filtered, and concentrated under reduced pressure (below 45° C.) till the acetone is removed. The aqueous residue is twice extracted with petroleum ether, which removes inert fats and is discarded, and then twice extracted with ethylene dichloride (400 ml. per kg. gland each time), which extracts the hormone but not adrenaline nor phospholipides. The ethylene dichloride soluble fraction is chilled to -15° C., and ice and precipitated solids are filtered off. The ethylene dichloride is removed under reduced pressure and the residue dissolved in ethyl alcohol. This is mixed with an equal volume of petroleum ether; water is then added to make the alcohol 90 per cent; this causes some of the petroleum ether to separate as an upper layer, which is removed in a separatory funnel and discarded. Two further discarded petroleum ether fractions are obtained by diluting the alcohol further to 80 and finally 70 per cent. The alcohol is now removed under reduced pressure, below 45° C., and the resulting aqueous colloidal solution suitably diluted to give a final preparation of volume 1 ml. per 40 g. gland, with NaCl added to make 0.9 per cent, and containing 10 per cent ethyl alcohol as preservative. This final solution is filtered and sterilized by Berkefeld filtration, and preserved in sterile ampoules in the refrigerator. (For details of this method, see the original paper.)

**7. Chemical Assays of Corticoids: Principles.** Several colorimetric methods have been described all of which depend upon the C<sub>20</sub>-C<sub>21</sub> ketol grouping in the side chain but are independent of the functional groups in the ring structure. These are based upon (a) reduction of phosphomolybdic acid to molybdenum blue, (b) reduction of cupric ion to cuprous ion, and (c) oxidative cleavage with periodic acid of carbon atom 21, which is released as formaldehyde and estimated with chromotropic acid. The methods are applied to the full 24-hour output of urine and lead to titers of "reducing steroids" and "formaldehydogenic steroids." All the methods include in the estimates the active corticoids, plus much larger quantities of inactive metabolites which respond to these reactions but are physiologically inert. Consequently the values determined by chemical assay (about 1 to 2 mg. per day in normal individuals) are considerably higher than the glucocorticoid titer. (See footnote 1, p. 760.)

**8. Biological Assay of Glucocorticoids and Determination of Urinary Cortin by Liver Glycogen Deposition: Method of Venning, Kazmin and Bell.**<sup>8</sup> The method is applicable to crystalline corticoids or to urine extracts. The reference standard is cortisone (XV), the biological activity of 1  $\mu$ g. of which is defined as one glyco-genic unit in the assay of unknown extracts.

**Procedure.** For urines containing a normal or low titer, a 48-hour specimen is required. The urine is adjusted to pH 1 with HCl, and extracted 3-4 times with ethylene dichloride or chloroform. Any emulsions encountered can be broken by centrifuging. The clear extracts are evaporated almost to dryness under reduced pressure (water bath temperature not over 55° C.). The residue is taken up in 30 ml. of chloroform, and the solution is extracted 3 times with

<sup>7</sup> Cartland and Kuizenga: *J. Biol. Chem.*, **116**, 57 (1936). See also Kuizenga, Wick, Ingle, Nelson, and Cartland: *J. Biol. Chem.*, **147**, 561 (1943).

<sup>8</sup> Venning, Kazmin, and Bell: *Endocrinology*, **38**, 79 (1946).

5 ml. of cold 0.1 N NaOH and 3 times with 5 ml. of water. These washings are back-extracted with chloroform, the chloroform extracts combined, and evaporated to 1–2 ml. for transfer to a test tube. Finally they are evaporated to dryness under a stream of nitrogen. The dry residue may be stored until ready for assay.

For the bioassay male white mice weighing 20–25 g. are used. Two days before adrenalectomy the mice are taken off a stock diet of "Purina" chow and put on the McCollum lactation diet,<sup>9</sup> which contains 26 per cent protein and 52 per cent carbohydrate. Removal of the adrenals is effected by the usual lumbar route. Following the operation, the mice are kept in a constant-temperature room or box at 76° F., and maintained on the McCollum diet supplemented with NaCl (0.9 per cent) and glucose (5 per cent) in the drinking water for the first postoperative day. Glucose is withdrawn thereafter; salt is retained in the diet throughout the test. Food is removed at 5 P.M. of the third postoperative day, and the mice starved until the following morning. Drinking water is removed on the fourth postoperative day, and beginning at 9:15 A.M. a total of 7 injections are given at 9:15, 10:00, 10:45, 11:30 A.M., 12:30, 1:30, and 2:30 P.M. The material to be tested is taken into solution containing 5 per cent glucose and 10 per cent alcohol. At each injection 0.20 ml. is given subcutaneously, so that each mouse receives a total of 1.4 ml. of extract containing 70 mg. of glucose. At 3:30 P.M. the mice are weighed and anesthetized with Sodium Amytal (0.2 ml. of 1.8 per cent solution). The livers are quickly removed and plunged into 4 ml. of hot 30 per cent KOH contained in a 15-ml. graduated centrifuge tube. The tubes are heated in a boiling water bath and frequently shaken, until all the tissue is in solution. The glycogen is precipitated by the addition of 1.2 volume of 95 per cent alcohol. The tubes are reheated until the mixture just begins to boil, cooled in an ice bath, and centrifuged. The supernatant liquid is poured off, and the tubes are allowed to drain. The sides of the tubes are washed down with 0.5 ml. of alcohol and again allowed to drain. Final traces of alcohol are expelled by heating the tubes for a few minutes in the hot water bath.

The glycogen is hydrolyzed as follows: After addition of 5 ml. of 1 N H<sub>2</sub>SO<sub>4</sub>, the tubes are placed in an autoclave and heated for 15 minutes at 15 lb. pressure. The glucose is determined by the method of Good *et al.*<sup>10</sup> or colorimetrically by the method of Nelson<sup>11</sup> (see p. 573). The glycogen is expressed in terms of mg. of liver glucose per 100 g. of mouse body weight.

Six to eight mice must be used for each assay. For normal male urine the equivalent of 6 hours of urine is administered to each mouse, whereas for normal female urine expected to be low in glycogenic activity, the equivalent of an 8-hour aliquot of urine is given each animal.

Values found by this method range from 0.04 to 0.085 mg. per 24 hours for normal men, and from 0.025 to 0.065 for women, calculated as cortisone.

**9. Determination of the Neutral 17-Ketosteroids of Urine: Principle.** The steroids of urine are first set free from their water-soluble conjugates by acid hydrolysis and extracted with ether. After removal of phenolic and acidic impurities, the 17-ketosteroid content of the neutral residue is ascertained by quantitative application of the Zimmermann reaction.<sup>12</sup> This comprises coupling of the reactive 17-ketone group

of the compounds with *m*-dinitrobenzene to form colored complexes, the intensity of which in the green region of the spectrum (520  $m\mu$ ) is measured in the photoelectric colorimeter and compared with the color developed by known amounts of a pure crystalline 17-ketosteroid.

Nonspecific chromogens of urine cause some interference, but as these substances are mainly nonketonic and absorb light in the violet (420  $m\mu$ ) as well as the green (520  $m\mu$ ) region of the spectrum, their influence may be eliminated either by carrying out the color determination on the neutral ketonic fraction of urine, or by the application of a correction factor, which, in effect, subtracts the color component due to extraneous chromogens.

**Procedure.**<sup>13</sup> A 24-hour specimen of urine is collected and measured. To a 100-ml. aliquot, 15 ml. of concentrated HCl are added. The mixture is refluxed for exactly 15 minutes, and then immediately chilled and extracted 4 times with 30-ml. portions of freshly redistilled ether. The combined ethers are washed 4 times with 2N NaOH (15-ml. portions) and then twice with water. On evaporation of the ether, the neutral residue is dissolved in 10 ml. ketone-free ethanol. In the development and measurement of the color, matched colorimeter tubes must be used. To the experimental tube are added, in order and with mixing after the addition of each, 0.2 ml. of the urine extract, 0.2 ml. of 2 per cent pure *m*-dinitrobenzene (prepared fresh) in ethanol, and 0.2 ml. of 5N aqueous KOH (purest electrolytic grade). A control tube is made up in the same way containing 0.2 ml. of ethanol in place of the urine extract. Both tubes are incubated in the dark at  $25 \pm 0.5^\circ$  C. for exactly 105 minutes. Then 15 ml. of 80 per cent ethanol are added to each, and, after mixing, the color intensity in each is measured in a suitable photoelectric colorimeter. To correct for the slight color developed by the reagents alone, the control tube is first inserted in the instrument with the 520  $m\mu$  filter in position, and the instrument adjusted to 0 density (100 per cent transmittance). The control is now replaced by the experimental tube, the reading noted and referred to the calibration curve pertaining to pure androsterone to give the equivalent number of mg. of this substance in the sample.

#### CALCULATION.

$$\text{Mg. 17-ketosteroids excreted per diem} = \frac{\text{Mg. observed} \times \text{ml. 24-hour urine volume}}{2}$$

For the application of factors correcting for interfering chromogens, readings are taken at 420  $m\mu$  also. For further details and modifications see footnote 1, p. 760.

When differential estimates of the 3( $\alpha$ )- and 3( $\beta$ )-hydroxy-17-ketosteroids are desired, their separation is effected with digitonin prior to assay.

## NITROGEN-CONTAINING HORMONES

### ADRENAL MEDULLA

This organ, which gives a specific staining reaction with dichromates ("chromaffin cells"), contains the active nitrogenous bases *epinephrine* or *adrenaline* (XX) and *norepinephrine* (*noradrenaline*, *arterenol*) (XXI). Both may also be prepared synthetically; the latter appears to be more abundant in the circulating blood.

<sup>13</sup> Method used in the McGill University Clinic.

XX

Epinephrine

XXI

Norepinephrine

The natural forms are levorotatory and are many times more active than their optical isomers. They are basic substances, insoluble in weak alkalies and in organic solvents, and form water-soluble crystallizable salts with various acids. They are readily destroyed by oxidation in alkaline solutions, eventually giving rise to amorphous, dark-colored melanins. Being attacked both by "amine-oxidase" and by the cytochrome system they are quickly destroyed in the body, so that the effect of an intravenous injection rapidly passes off; they are slowly and incompletely absorbed from subcutaneous or intramuscular injection sites, where they are apt to produce abscesses; they are inactive orally though somewhat toxic. The physiological reaction to these hormones is, in almost all organs, the same as the response to stimulation of the sympathetic nerve supply: the blood pressure rises because of arteriolar constriction; the heart rate increases if the depressor reflex can be excluded; peristalsis is inhibited; the pupils dilate; the bronchial muscles relax; there is outpouring of ACTH and probably other anterior pituitary hormones; blood sugar and blood lactic acid increase at the expense of the glycogen stores; and the metabolic rate is temporarily increased. Norepinephrine shares the stimulatory rather than the inhibitory properties of the better-known epinephrine. Discharge of these hormones occurs only when stimuli reach the adrenal medulla by way of the splanchnic nerve. This happens rapidly when the body is exposed to emergencies such as cold or shock or violent emotion or pain.

## EXPERIMENTS ON THE ADRENAL MEDULLA

**1. Preparation of Epinephrine.** To each 100 g. of ground fresh adrenal tissue add 50 ml. of a 3 per cent solution of acetic acid in 95 per cent ethyl alcohol. Allow to stand for 12 to 24 hours and remove the liquid by straining. Re-extract the residue twice for 6 hours, each time with the same volume of 3 per cent acetic acid in 60 per cent ethyl alcohol as before. After filtering, concentrate the extract in a flask under diminished pressure to about one-tenth of the original volume. The material which has precipitated should be removed by filtration and the filtrate concentrated under diminished pressure to about 2 to 3 ml. per 100 g. of tissue extracted. Transfer the solution to a test tube and add enough strong ammonium hydroxide to leave a strong odor of ammonia. Stopper and set aside in a cool place for several hours. Remove the precipitate by filtration and wash first with ice-cold water which has been

boiled, then with cold alcohol, and finally with ether. Dissolve the precipitate in 10 ml. of 10 per cent hydrochloric acid, reprecipitate, and treat the precipitate as before.

**2. Properties of Epinephrine.** Dissolve 0.1 g. of epinephrine in about 10 ml. of 0.1 per cent HCl and dilute to 100 ml.

a. **VULPIAN REACTION.** Add a few drops of  $\text{FeCl}_3$  solution. A green color will be produced which is a typical catechol reaction.

b. **EWINS REACTION.** Add to 1 ml. of the solution an equal volume of 0.2 per cent potassium persulfate; a reddish color is produced which is specific and may be quantitatively determined.<sup>14</sup>

c. **FLUORESCENCE.** A faintly alkaline solution of epinephrine, even if extremely dilute, shows a bright apple-green fluorescence for some minutes when irradiated in a quartz vessel with ultraviolet light from a mercury vapor lamp.

## THE PANCREAS

Removal of the pancreas in cats and dogs produces symptoms similar to diabetes mellitus in man. Blood sugar increases greatly and glucosuria

FIG. 209. CRYSTALLINE ZINC INSULIN.

Courtesy, Dr. D. A. Scott.

occurs; the glycogen stores of liver and muscle are depleted; the blood is charged with fat, and acetone bodies (acetoacetic acid,  $\beta$ -hydroxybutyric acid, and acetone), accumulate in the blood and are excreted in the urine, to produce acidosis, coma, and death, usually within three weeks. These symptoms do not follow when the digestive pancreatic juice is prevented from reaching the intestine, or even when the acinar cells which secrete this juice degenerate; they are rather due to removal of solid clumps of cells, the islets of Langerhans, which have no connection with the ducts but form a hormone, *insulin*, which is discharged into the blood and regulates carbohydrate metabolism. Diabetic symptoms appear when the islet cells are damaged by administration of alloxan, or in some species by prolonged administration of certain anterior-pituitary extracts which produce hyperglycemia.

The first useful pancreatic extracts were prepared by extracting the pancreas with acid alcohol and increasing the concentration of alcohol in the filtered extracts until insulin was precipitated. Refinements of the method led to the isolation of insulin in crystalline form as a zinc salt (Fig. 209). Insulin is a protein somewhat of the albumin type, but unusually soluble in moderately dilute alcohol and acetone. It is destroyed by digestive enzymes and must be protected from pancreatic trypsin during extraction; hence, also, it is ineffective orally. Insoluble compounds of insulin with basic proteins (protamines or globin) and zinc are used therapeutically, since they are slowly absorbed from the tissues and injections need not be given so frequently. In normal animals, insulin lowers

<sup>14</sup> Barker, Eastland, and Evers: *Biochem. J.*, **26**, 2129 (1932).

the blood sugar, thus eventually producing convulsions unless counteracted by the administration of glucose, or substance yielding glucose. The unit was at one time defined as one-third of the amount which will, in five hours, lower the blood sugar of a fasting rabbit to the convulsive level (45 mg. per 100 ml.), but assay is now conducted by comparing the activity of an unknown sample with that of crystalline insulin, either in lowering the blood sugar of rabbits or in inducing convulsions in mice: crystalline insulin is reckoned at 22 units per mg.

Some consider that insulin is an essential catalyst in the biological oxidation of carbohydrate; for example, that it favors the action of the enzyme hexokinase in forming glucose-6-phosphate as a first step; others believe that insulin checks the new formation of carbohydrate from fat (at least from glycerol) and protein, which in the absence of insulin is supposed to flood the organism with sugar; others again hold that lack of insulin inhibits reactions whereby a large proportion of dietary carbohydrate is converted into fat. The consequences of pancreatectomy are less marked in animals from which the anterior pituitary, or the adrenal cortices, are removed; they are in any case less marked in species other than the cat and dog.

Pancreatic extracts, including most insulin preparations, contain a *hyperglycemic factor* (HGF) which promotes the breakdown of liver glycogen; it has been suggested that this too is a hormone, produced by the  $\alpha$ -cells of the islets, insulin almost certainly arising in the  $\beta$ -cells.

## EXPERIMENTS ON THE PANCREAS

**1. Preparation of Insulin: Method of Jephcott.<sup>15</sup>** To 1 kg. or more of fresh, finely minced beef pancreas, add 4 volumes of extraction liquid, consisting of 750 ml. of ethyl alcohol, 250 ml. of distilled water, and 15 ml. of concentrated hydrochloric acid. Shake or stir for 2 hours at 37° C. and filter through a double layer of cheesecloth; extract the residues as before. Combine the filtrates and add concentrated ammonia till alkaline to litmus; centrifuge, and discard the precipitate. (Insulin may be precipitated quantitatively by adding 1½ volumes of absolute ethyl alcohol and 2½ volumes of ether and allowing to stand in the cold.) A purer preparation is obtainable as follows: After centrifuging, drive off the alcohol with a blast of air at 37° C. and add 40 g. of ammonium sulfate per 100 ml. The precipitate which rises to the top contains the insulin; it is ground with 70 per cent alcohol and filtered. To the filtrate add an equal volume of 95 per cent alcohol, and discard any precipitate which forms; now add 8 volumes of 95 per cent alcohol to precipitate the insulin, which is filtered off and dried, and dissolved in water (1 ml. per 10 g. of pancreas) containing 0.1 per cent tricresol.

**2. Effect of Insulin on Blood Sugar.** Take a 1-ml. sample of blood for a sugar determination from the marginal ear vein of a 2-kg. rabbit which has been starved for 24 hours. Then inject subcutaneously 5 to 10 units of insulin. Observe the rabbit carefully for symptoms of hypoglycemia, such as hyperirritability, palpitation of the heart, convulsions, and coma. Another sample of blood should be drawn as soon as distress is evident and a third when the rabbit is in convulsions. To relieve the induced hypoglycemia, inject 10 ml.

<sup>15</sup> Jephcott: *Tr. Roy. Soc. Canada*, sec. 5, 25, 183 (1931).

of 10 per cent glucose solution intravenously. After recovery, take another blood sample for a sugar determination. Compare the blood sugar values. It is also possible to save the animal by injecting 0.5 ml. of 1:1000 epinephrine (adrenaline) subcutaneously after the first convulsions; or convulsions may be averted by feeding glucose upon a leaf of lettuce, or by giving glucose by stomach tube or intraperitoneally.

## THE THYROID

The thyroid gland consists of a framework of connective tissue enclosing numerous vesicles lined with epithelium, flattened in the resting state and cubical or columnar (almost obliterating the colloid-filled cavity of the vesicle) when highly active. Marked enlargement of the gland

FIG. 210. EFFECT OF THYROXINE ON MYXEDEMA.

The time interval between pictures is three weeks. The total amount of thyroxine used was less than 20 mg.

From Kendall: *Ind. Eng. Chem.*, **17**, 525 (1925).

is known as *goiter*. It may be associated with normal or subnormal activity, in which case it is related to a deficient intake of iodine and is chiefly found in inland regions, for example around the Great Lakes, where the soil, water, and vegetation are iodine-poor. It may also be associated with increased thyroid activity (Graves's disease, exophthalmic goiter). The thyroid is far richer in iodine than any other tissue. The iodine is chiefly built into the characteristic protein *thyroglobulin*, which makes up a large part of the colloid in the vesicles and may be isolated in relatively pure form.<sup>16</sup> Thyroglobulin on hydrolysis yields *thyroxine*,

<sup>16</sup> Heidelberger and Palmer: *J. Biol. Chem.*, **101**, 433 (1933).

or  $\beta$ -[3:5-diiodo-4-(3':5'-diiodo-4'-hydroxy-phenoxy)-phenyl]- $\alpha$ -amino-propionic acid. This is usually obtained in the racemic form, but is originally levorotatory. Triiodothyronine, containing one iodine atom less, is also present and highly active. The administration of thyroxine or of substances containing it produces only in part the picture of Graves's disease: high metabolic rate, increased pulmonary ventilation and circulation rate tending to overwork the heart, extreme nervous restlessness, and sometimes protrusion of the eyeballs (exophthalmos). Deficient thyroid activity produces myxedema (see Fig. 210) with low basal metabolism, mental and physical sluggishness, and formation of a curious puffy tissue under the skin. The extreme form, in which severe deficiency dates from infancy, is known as *cretinism* (see Fig. 211), and is marked by stunting, deformity, and feeble-mindedness. The actual hormone discharged by the gland is thyroxine, which appears to act as a stimulant of all metabolic processes; its effect is slowly developed and long-lasting, and it is not in general possible to discern it by applying thyroxine to isolated tissues or organs. Thyroxine is too insoluble to be given advantageously by mouth; but it is not destroyed during digestion, so that preparations of desiccated thyroid gland, given orally, are cheap and fully active. Methods of biological assay depend chiefly on measurements of the metabolism of myxedema patients, or of small animals; less accurate methods depend on the fact that thyroid substance accelerates the metamorphosis of tadpoles. Thyroxine may also be determined chemically by its iodine content, but it must be remembered that thyro-globulin also contains the more soluble, physiologically inactive amino acid:

**Diiodotyrosine**

FIG. 211. EFFECT OF THYROXINE ON GROWTH OF A CRETIN.

The illustration shows the same child, in the same dress, before and after receiving thyroxine for one year. Increase in height, 6 inches.

From Kendall: *Ind. Eng. Chem.*, 17, 525 (1925).

Experiments with the radioactive isotopes of iodine indicate that the gland, unless previously saturated, takes up iodide from the blood for the synthesis of diiodotyrosine and thence of thyroxine. These reactions can be inhibited by treatment with large doses of sulfa drugs or with thiourea,

thiouracil, and related compounds, which thus gradually produce signs of hypothyroidism accompanied by goiter. Thiouracil is being used experimentally in the treatment of Graves's disease; the administration of iodine also produces a remission, which though often temporary is valuable in preparation for operation, and is due to retention of colloid within the gland.

The uptake of radioactive iodide (in the form of NaI or KI) can be followed by placing "counters" on the skin above the thyroid, and this has been used as a test of thyroid activity. In larger doses radioactive iodides have been used to control thyroid carcinoma and its metastases, since the intensity of radioactivity becomes much higher in the thyroid cells, normal or cancerous, than elsewhere in the body.

## THE PARATHYROIDS

The parathyroid glands are small, compact bodies, usually four in number and closely apposed to or within the thyroid. If they are removed, the level of calcium in the blood serum falls; this in turn causes neuromuscular hyperexcitability, tremors of the skeletal muscle, and panting which produces alkalosis. With calcium deficiency, this leads to violent tonic and clonic convulsions in which the animal sooner or later dies from arrest of respiration, symptoms best seen in the dog. Acid extraction of ox parathyroids yields extracts which maintain parathyroidectomized dogs alive and free from tetany, and which in normal dogs produce an elevation of serum calcium. The (Hanson) unit is  $0.01 \times$  the amount required to raise the serum calcium of normal, 20-kg. dogs by 1 mg. per 100 ml., though larger increases can be more accurately measured. A large single injection may accelerate the renal excretion of phosphates and raise the serum calcium to twice its normal level in 12 to 15 hours, usually without disturbance to the health of the animal; but if the calcium is maintained at a high level by repeated injections, the blood becomes concentrated and the circulation sluggish, kidney function fails, and hemorrhage occurs in the gastrointestinal tract. The calcium mobilized by the parathyroid hormone comes from the skeleton, where it is probable that the hormone stimulates the formation and activity of the osteoclasts. After prolonged treatment or in the presence of a parathyroid tumor, the bones are demineralized and become fibrous and cystic (hyperparathyroidism: osteitis fibrosa). There is some tendency for the body to lose its responsiveness to parathyroid extracts; this is particularly well seen in the rat. The extracts being obtained by rather drastic procedures, there is no certainty that the principle they contain is the unaltered natural hormone; it is of protein nature<sup>17</sup> and destroyed by digestive enzymes.

## EXPERIMENTS ON THE PARATHYROIDS

**1. Preparation of Parathyroid Extract: Method of Collip.** Place the fresh ox parathyroids, from which the visible fat and connective tissue have been removed, in a small flask or test tube, cover with an equal volume of 5 per cent hydrochloric acid, and keep in a boiling water bath for 1 hour. Allow to cool, and remove the congealed fat mechanically. Then make the solu-

<sup>17</sup> Ross and Wood: *J. Biol. Chem.*, **146**, 49 (1943).

tion faintly alkaline with sodium hydroxide and add acid to the point of maximum precipitation of protein, which is just barely acid to litmus. Filter and dissolve the precipitate in weak alkali, and reprecipitate as before. Filter again and combine the filtrates, adding 0.1 per cent tricresol as preservative and keep the combined filtrates, which constitute the desired extract, in an icebox until ready to use.

2. *Effect of Parathyroid Extract.* Draw 8 to 10 ml. of blood from the saphenous or other suitable vein of a dog weighing at least 10 kg. Save this for determination of serum calcium (p. 644). Inject subcutaneously, every 3 hours for the next 9 to 12 hours, 10 Hanson units of commercial parathyroid extract (or a quantity of extract equivalent to 1 ox parathyroid) per kg. of body weight. Draw blood samples after the last injection, and again 12 hours later. Note the occurrence of depression and anorexia, the increased concentration of the blood, and the rise in serum calcium.

## THE ANTERIOR PITUITARY OR HYPOPHYSIS

The anatomy of the pituitary gland, or hypophysis cerebri (Fig. 212) is complex: the *pars nervosa* is a downgrowth from the hypothalamic region

FIG. 212. HYPOPHYSIS OF CAT.

1, Pars anterior; 2, hypophysial cleft; 3, pars intermedia; 4, pars nervosa; 5, infundibular cavity; 6, pars tuberalis; 7, optic chiasm.

From Best and Taylor: *Physiological Basis of Medical Practice*.  
Courtesy, William Wood & Co.

of the brain, and consists of modified nervous and glial cells, while the rest of the organ is derived from Rathke's pouch, an upgrowth from the roof of the mouth. This gives rise to the *pars tuberalis*, which surrounds the stalk of the pars nervosa like a collar and spreads along the base of the brain, to the *pars intermedia*, closely apposed to the anterior surface of the nervosa and usually separated by a cleft (the cavity of the embryonic pouch) from the large, glandular *pars anterior* which lies in front and on either side of it. The gland can be broken in two at the cleft, leaving the *intermedia* and *tuberalis* adherent to the nervosa as a complex called the posterior lobe. The whole organ rests in a more or less fitting cavity in the sphenoid bone, the *sella turcica*.

Removal of the whole organ or of the anterior lobe alone produces the following effects (best seen in the rat): cessation of growth; atrophy of the ovaries or testes, which cease to function in producing germ cells and as

endocrine organs; atrophy of the thyroid, the reduction of thyroid activity lowering the metabolic rate; atrophy of the adrenal cortex, which may be the cause of an increased susceptibility to toxins, infections, etc., and of a tendency toward dissipation of carbohydrate stores and toward hypoglycemia; and cessation of lactation, if in progress. The administration of suitable extracts, or implantation of anterior-lobe tissue, more or less corrects these deficiencies. It is uncertain how many distinct active principles are present in such extracts, but a number are widely recognized and have been separated in pure or nearly pure state. All are of protein or polypeptide nature, are destroyed by digestive enzymes, and are relatively unstable to heat. There may be interspecific differences in chemical composition rather than in physiological properties, and this may explain the observation that animals treated with anterior-lobe extracts over long periods tend to become unresponsive to them. Clinically, overactivity of the anterior lobe is associated with gigantism and acromegaly (often accompanied by symptoms of diabetes and of hyperthyroidism) and congenital underactivity with dwarfism and infantilism. In Simmonds' disease the gland is almost wholly destroyed.

The hormones generally recognized as separate entities are: (1) the *growth (somatotropic) hormone*, capable of producing accelerated growth in young animals, especially growth in length, and active in metabolism in a "contra-insulin" sense, so as to cause severe hyperglycemia in susceptible animals and sufficient damage to the islets of Langerhans to produce a permanent "metahypophyseal" diabetic state; (2) the *thyrotropic hormone*, stimulating the thyroid gland to activity (reflected in increased height of the epithelial cells, discharge of iodine-containing thyroxine, and hence raised metabolic rate) and producing exophthalmos; (3) the *adrenocorticotropic hormone* (ACTH), stimulating the secretion of glucocorticoids (see p. 758); (4) *prolactin*, the "lactogenic" hormone, which stimulates milk secretion in fully developed mammary glands, and the glandular development of the crop seen in pigeons of both sexes while rearing their young, and which also has the *luteotropic* action of maintaining the structure and endocrine function of the corpora lutea; finally, there are the *gonadotropic hormones*, differentiated as (5) "follicle-stimulating" (FSH) and (6) "luteinizing" or "interstitial-cell-stimulating" (LH or ICSH), which together incite the sex glands to both germinal and endocrine activity (for example, they produce, when injected into immature female rats and mice, premature ripening of follicles, ovulation, formation of corpora lutea, and discharge of ovarian hormones which secondarily affect the uterus and vagina). A substance similar to the luteinizing hormone is produced by the human placenta during pregnancy and is termed *chorionic gonadotropin* (CG) or *prolan*; it is excreted in the urine, and the Aschheim-Zondek, Friedman, and other similar tests, based on this fact, are the most accurate means now available for diagnosing pregnancy in its early stages. These tests also serve for the diagnosis of chorioepithelioma and hydatidiform mole, in which extremely large amounts of gonadotropin are excreted. The serum of pregnant mares (PMS) contains yet another gonadotropin, which though of chorionic origin has a closer resemblance to FSH; it is not excreted in the urine.

## THE POSTERIOR PITUITARY

[illegible]

affect the intestinal and bronchial musculature, and cause squeezing-out of milk from the ducts of the mammary gland.

The total synthesis of an octapeptide amide having the hormonal activity of oxytocin by du Vigneaud and associates<sup>18</sup> has established a landmark since it is the first polypeptide hormone to have been produced in the laboratory. Its molecular weight is approximately 1000; the molecule consists of eight amino acid equivalents (leucine, isoleucine, tyrosine, proline, glutamic acid, aspartic acid, glycine, and cystine) and three equivalents of ammonia, the structure being in part cyclic. (See p. 775.)

The synthesis of the vasopressor-antidiuretic hormone of the posterior pituitary by the Cornell investigators appears imminent.<sup>19</sup>

If the posterior lobe is extirpated, or if the nerve fibers which run into it from the nucleus supraopticus are severed, there is a permanent increase in urine flow and in water consumption (diabetes insipidus). The posterior lobe principles arise in the pars nervosa and are polypeptides; they are unstable in alkaline solution and inactive by mouth. There is evidence that, as ordinarily obtained, they may be breakdown products of a much larger molecule possessing both pressor and oxytocic activity. The pars intermedia, which is embryologically part of the anterior lobe, produces a substance (*intermedin*) which causes expansion of pigment masses in certain cells (melanophores, erythrophores) in the skin of lower vertebrates. A frog from which the pituitary is removed is rendered permanently pale in color by contraction of the melanophores. It is uncertain whether this substance has any function in mammals.

## EXPERIMENTS ON THE PITUITARY

**1. Preparation of Anterior Lobe Extract: Method of Evans.**<sup>20</sup> Bovine anterior lobes, as fresh as possible, are ground in a mortar with twice their weight of sand; 2 ml. of water are added for every g. of gland. The volume of the mixture is measured and three-eighths of this quantity of 0.2 N NaOH is added; the material is kept for 12 hours in the icebox; the supernatant fluid is decanted off and neutralized to phenol-red with 0.2 N acetic acid. Crude extracts of this type contain maximal amounts of the several hormones, except that positive stimulation of the sex glands is not very readily obtainable with bovine material. It is, however, still easier to dehydrate dissected anterior lobes in the lyophilizing apparatus; when dry the tissue crumbles to a light, relatively stable powder, from which uniform suspensions are easily prepared. It may be advantageous to add small amounts of penicillin and streptomycin, so as to lessen the risk of abscesses forming at the site of injection of the suspension.

**2. Preparation of Chorionic Gonadotropin: Method of Katzman and Doisy.**<sup>21</sup> Human pregnancy urine (preserved with a little chloroform and kept at 1 to 5° C.) is made acid to methyl red-methylene blue (pH 4-5) with glacial acetic acid and filtered; 50 ml. of a saturated solution of benzoic acid in acetone are added to each liter of urine, with vigorous stirring, and the mixture

<sup>18</sup> du Vigneaud, Ressler, Swan, Roberts, Katsoyannis, and Gordon: *J. Am. Chem. Soc.*, **75**, 4879 (1953).

<sup>19</sup> du Vigneaud, Lawler, and Popenoe: *J. Am. Chem. Soc.*, **75**, 4880 (1953).

<sup>20</sup> Evans and Simpson: *Am. J. Physiol.*, **98**, 511 (1931).

<sup>21</sup> Katzman and Doisy: *J. Biol. Chem.*, **98**, 739 (1931).

is allowed to stand overnight. The precipitated benzoic acid, upon which the active material is adsorbed, is filtered off with suction and dissolved in a volume of acetone equal to the amount originally added. A small flocculent precipitate of acetone-insoluble material contains the active principle and is separated by decantation and centrifuging and thoroughly washed with acetone. Small additional quantities may be obtained by repeating the benzoic acid adsorption on the urine filtrate. The active principle is extracted from the combined precipitates by three treatments with distilled water, centrifuging after each extraction, and using not more than 25 ml. of water per liter of urine. The water-insoluble residue is discarded. Other useful methods involve adsorption upon Lloyd's reagent<sup>22</sup> or precipitation with tungstic acid.<sup>23</sup> All these methods may be used to concentrate the activity in urines other than those of pregnancy, when the gonadotropic substance is too dilute to be determined by direct biological assay of the urine.

3. *Detection of Chorionic Gonadotropin (Prolan): Pregnancy Test of Aschheim and Zondek.*<sup>24</sup> Five baby female mice, 6 to 8 g. in weight and 3 to 4 weeks old, are injected with the urine to be tested. This should be taken from the first sample passed in the morning, and toxic substances may be removed from it by shaking with ether. Each mouse is given 6 injections of 0.5 ml. of this urine, 3 doses on the first day and 3 on the second, and the animals are killed 96 hours after the beginning of the test. The reaction sought consists of three parts: (I) Formation of large ovarian follicles and precocious appearance of estrus; (II) hemorrhagic follicles, easily seen under a lens as deep clear red spots; (III) formation of corpora lutea, visible under a lens. Reaction I by itself is insufficient to establish a diagnosis of pregnancy. The dependability of the reaction is at least 98 per cent. It usually becomes positive a few days after the first missed menstrual period; in the ensuing month, the concentration of the active principle rises to a well-marked maximum. Very high concentrations occur in the presence of tumors of placental tissue (hydatid mole or chorionepithelioma).

4. *Friedman Pregnancy Test.*<sup>25</sup> This test is more rapidly completed, is equally accurate, and probably more convenient where tests are made only occasionally. It is based on the fact that rabbits ovulate only when their ovaries are specifically stimulated, as they are after mating. A mature female rabbit, which must have been isolated in a cage by itself for at least three weeks previously, is given 10 ml. of urine to be tested by injection into the marginal ear vein. The ovaries are examined 24 hours later; a positive reaction is marked by reddish protrusions or by recent hemorrhage in the follicles. The abdomen may be opened and the ovaries inspected under anesthesia, so that the rabbit may be used again some weeks later, when the corpora lutea formed have disappeared.

## THE KIDNEY

When the kidneys or the arteries supplying them are compressed, there follows a sustained rise in systemic blood pressure, resembling the clinical entity of essential hypertension; the phenomenon is independent of nervous connections and of changes in excretory function. It is ascribed

<sup>22</sup> Davy and Sevringhaus: *Proc. Soc. Exptl. Biol. Med.*, **30**, 1422 (1933).

<sup>23</sup> Katzman and Doisy: *Proc. Soc. Exptl. Biol. Med.*, **31**, 188 (1938).

<sup>24</sup> Aschheim: *J. Am. Med. Assoc.*, **104**, 1324 (1935).

<sup>25</sup> Friedman and Lapham: *Am. J. Obstet. Gynecol.*, **21**, 405 (1931).

to the secretion into the blood of a globulin *renin*, which appears to be a proteolytic enzyme and to vary in composition from species to species. The substrate for renin is a fraction (*hypertensinogen* or "activator") of the serum globulins, and the product of the reaction a heat-stable, dialyzable vasoconstrictor, probably a polypeptide, called *hypertensin* or *angiotonin*; this in turn is slowly destroyed by a substance ("inhibitor," *angiotonase*, or *hypertensinase*) present in normal blood and tissues.

## THE THYMUS AND PINEAL

Endocrine function has frequently been ascribed to these organs, but has not been established; extirpation, even in very young animals, has no specific systemic effects.

## OTHER HORMONES

The first hormone whose function was clearly established (by Bayliss and Starling in 1903) was *secretin*. This is a substance which is liberated from the walls of the duodenum when acid chyme enters the lumen; it is carried by the blood to the pancreas, where it stimulates the secretion of pancreatic juice. Tests on the most highly purified secretin show it to be a polypeptide. See also p. 393.

Less well established are *cholecystokinin*, believed to arise in the same source and to stimulate contraction of the gallbladder; *enterogastrone*, believed to inhibit the secretory and motor activity of the stomach when fat is present in the intestine; and *gastrin*, which physiologically resembles histamine, and may evoke secretion of hydrochloric acid by the fundus of the stomach when the pyloric region is stimulated by the presence of partially digested food.

## Urine: General Characteristics of Normal and Pathological Urine

**Secretion of Urine.** The problem of the mechanism of the formation of urine by the kidney has occupied the attention of investigators for many years, and has produced many conflicting theories. The filtration-reabsorption theory of Cushny has been the basis of the modern theory, and the work of Starling, Marshall, Richards, and their collaborators and of other investigators has led to a more satisfactory conception of the processes involved.

Marshall has summarized the known facts relating to the formation of urine by the mammalian kidney in the following working hypothesis: "All of the non-colloid constituents of the plasma are eliminated by filtration through the glomerulus; water, chloride, bicarbonate, potassium (possibly phosphate, uric acid, and other bodies) are reabsorbed during the passage of the filtrate along the tubules; urea and sulfates are also reabsorbed to some extent under certain conditions but not as actively as chloride; ammonia, hippuric acid, and possibly other bodies are formed in the renal cells and secreted, while certain foreign substances when present in the organism (phenol red) and possibly substances occurring in small amounts in the organism are secreted after a preliminary concentration in the tubule cells. The amount of glomerular filtrate on this hypothesis is considered sufficient to account for all of the sulfate and urea eliminated but not sufficient to account for ammonia, certain dyes (phenol red, etc.) and other bodies which are concentrated to a much greater extent than sulfate by the kidney."

By direct catheterization of the glomerular urine of the frog and comparison of its composition with simultaneously collected bladder urine, Wearn and Richards formulated a hypothesis illustrated diagrammatically in Fig. 213. It will be noted that the chief difference from Marshall's conception is in the site of dye secretion, these workers having found small amounts of dye in the glomerular filtrate although they admit much of the neutral red excretion is carried out by the tubules. They also found the polysaccharide inulin to be excreted by the glomerulus, indicating the presence of pores of considerable size in the membrane.

Reabsorption of water, which may be as high as 97 per cent, appears to occur in both the proximal and distal tubules. Chloride is absorbed preferentially in the distal tubule, where also takes place the reabsorption of bicarbonate and acidification of the urine, probably through excretion of

hydrogen ions.<sup>1</sup> Reabsorption of glucose occurs in the proximal tubule, chiefly through esterification with phosphate. The substance phlorizin prevents this esterification and hence permits glucose to pass into the urine ("phlorizin diabetes"). Nitrogenous waste products appear in the urine either through failure of reabsorption from the glomerular filtrate or through actual secretion by the tubular cells or both. Ammonia appears definitely to be secreted by the tubular cells, some urea may arise in this manner, and there is evidence for the tubular secretion of creatinine by man and *Necturus* but not by the frog. Thus species differences must be considered in interpreting kidney action.

**Volume.** The volume of urine excreted by normal individuals during any definite period fluctuates within very wide limits. The total volume of glomerular filtrate produced by normal adult kidneys may be 75 to 150 liters in 24 hours. However, after tubular reabsorption the average normal

FIG. 213. DIAGRAM ILLUSTRATING THE FORMATION OF URINE.

excretion of urine falls within the range of 1000 to 2000 ml. The volume excretion is influenced greatly by the diet, particularly by the ingestion of fluids, and by the ambient temperature, which affects not only fluid intake but also loss of water through perspiration. Strenuous physical exercise causes a diminished output of urine.

Certain pathological conditions cause the output of urine for any definite period to depart very decidedly from the normal output. If the output is increased the condition is termed *polyuria*, whereas a diminished excretion is termed *oliguria*. Among the pathological conditions in which the volume of urine is *increased* above normal are the following: diabetes mellitus, diabetes insipidus, certain diseases of the nervous system, contracted kidney, amyloid degeneration of the kidney, and in convalescence from acute diseases in general. Many drugs such as calomel, digitalis, acetates, and salicylates also increase the volume of the urine excreted. A *decrease* from the normal is observed in the following pathological conditions: acute nephritis, diseases of the heart and lungs, fevers, diarrhea, and vomiting.

**Color.** Normal urine ordinarily possesses an amber yellow tint, the depth of the color being dependent in part upon the density of the fluid.

<sup>1</sup> Pitts and Alexander: *Am. J. Physiol.*, 144, 239 (1945).

The color of normal urine is due principally to a pigment called urochrome. Traces are generally present of *uroerythrin*, a red pigment possibly derived from the melanins, *coproporphyrins*, and *uroporphyrin*, iron-free reddish pigments resulting from the metabolism of heme. In *porphyria*, a disorder of porphyrin metabolism, the porphyrin content is increased. In certain other pathological urines a chromogen (indoleacetic acid) may be present. This yields urorosein, a reddish pigment, when the urine is strongly acidified (see p. 852). Urochrome is said to be a compound of urobilin and urobilinogen with a peptide substance. The amount excreted per day by an adult man has been estimated at 7.3 mg., being very constant for a given individual. Under pathological conditions or after the administration of various drugs or antiseptics, the color of the urine may vary in intensity from an extremely light yellow to a very dark brown or black or may even assume the color of the drugs or their degradation products. Vogel has constructed a color chart which is of some value for purposes of comparison. The nature and origin of the chief variations in the urinary color are set forth in tabular form on p. 783.

**Turbid Urine.** Normal urine is ordinarily perfectly clear and transparent when voided. On standing for a variable time, however, a cloud (nubecula) consisting principally of nucleoprotein or mucoid (see p. 810) and epithelial cells forms. A turbidity due to the precipitation of phosphates is normally noted in urine passed after a hearty meal. The urine obtained two to three hours after a meal or later is ordinarily free from turbidity. Permanently turbid urines ordinarily arise from pathological conditions.

**Odor.** The odor of normal urine is of a faint, aromatic type. The substances to which this odor is due are not well known, but it is claimed by some investigators to be due, at least in part, to the presence of minute amounts of certain volatile organic acids. When the urine undergoes decomposition, e.g., in alkaline fermentation, a very unpleasant ammoniacal odor is evolved. All urines are subject to such decomposition if allowed to stand for a sufficiently long time. Under normal conditions the urine very often possesses a peculiar odor due to the ingestion of some certain drug or vegetable. For instance, cubebs, copaiba, myrtol, saffron, tolu, and turpentine each impart a somewhat specific odor to the urine. After the ingestion of asparagus, the urine also possesses a typical odor attributed to methyl mercaptan ( $\text{CH}_3\cdot\text{SH}$ ) which may, however, exist in urine only as a precursor which yields the mercaptan on heating in acid solution.

**Frequency of Urination.** The frequency of urination varies greatly in different individuals, but in general is dependent upon the amount of fluid in the bladder. In pathological conditions an inflammatory affection of the urinary tract or any disturbance of the innervation of the bladder will influence the frequency. Affections of the spinal cord which lead to an increased irritability of the bladder or a weakening of the sphincter, or any condition lowering the residual capacity of the bladder, will result in increasing the frequency of urination. It often aids in diagnosis.

**Reaction.** The mixed 24-hour urinary excretion of a normal individual ordinarily possesses an acid reaction to litmus. The actual hydrogen-ion

| <i>Color</i>                                                       | <i>Cause of Coloration</i>                                                                          | <i>Pathological Condition</i>                                     |

|                                                                    | Hydroquinol and catechol                                                                            | Phenol poisoning                                                  |
| Greenish yellow, greenish brown, approaching black                 | Bile pigments                                                                                       | Jaundice                                                          |
| Dirty green* or blue.....                                          | A dark blue scum on the surface, with a blue deposit, due to an excess of indigo-forming substances | Cholera, typhus; seen especially when the urine is putrefying     |
| Brown yellow to red brown, becoming blood red upon adding alkalis. | Substances contained in senna, rhubarb, and chelidonium which are introduced into the system        |                                                                   |

\* This dirty green or blue color also occurs after the use of methylene blue in the organism.

concentration varies over a wide range (pH 4.8 to 8.0), the mean being about pH 6. The reaction of the urine represents an equilibrium among a large number of acid and basic constituents, both organic and inorganic, which it contains. Although organic acids and bases play a part in producing the normal reaction, this reaction is probably, in the main, dependent upon the relative amounts of the mono- and dibasic sodium and potassium phosphates present. The monobasic sodium phosphate ( $\text{NaH}_2\text{PO}_4$ ) is acid in reaction, while the dibasic phosphate ( $\text{Na}_2\text{HPO}_4$ ) is alkaline in reaction. The excretion of acid or alkaline phosphate by the kidneys is one of the factors in the regulation of the neutrality of the blood and of the organism in general. The acidity of the urine, as determined by titration, runs in general parallel with the hydrogen-ion concentration and seems to be dependent upon the same factors, and in more acid urines mainly on the phosphate content. Van Slyke and Palmer have shown that normal men excrete organic acids equivalent to only about 6 ml. of 0.1 N acid per kilo in 24 hours. Strenuous physical exercise produces an increase in hydrogen-ion concentration and in acid and ammonia output. (For further discussion of acidity, see Chapter 31.)

The mean acidity in cardiorenal diseases is high—about pH 5.3 as compared with pH 6, the normal mean. In general the acidity tends to be increased in the greater number of pathological disorders.

The composition of the food is perhaps the most important factor in determining the reaction of the urine (see Chapter 34, "Inorganic Metabolism," for the influence of base-forming and acid-forming foods). The reaction ordinarily varies considerably according to the time of day the urine is passed. For instance, for a variable length of time after a meal the urine may be neutral or even alkaline in reaction to litmus, owing to the claim of the gastric juice upon the acidic radicals to further the formation of hydrochloric acid for use in carrying out the digestive secretory function. This hypothesis has been verified experimentally. This change in reaction is known as the *alkaline tide* and is common to perfectly healthy individuals. The urine may also become temporarily alkaline in reaction as the result of ingesting alkaline carbonates or certain salts of tartaric and citric acids which ultimately yield bicarbonate within the organism. Ingestion of acid fruits (oranges, lemons, peaches, etc.) causes the formation of alkaline urine. This is due to the fact that the ash of such fruits is alkaline and when the fruits are combusted in the body bicarbonate is formed. On the other hand, bread, cereals, meats, etc., yield an acid ash and an acid urine. Certain acid fruits, like cranberries, plums, and prunes, increase urinary acidity. This is due to the fact that these fruits contain considerable quantities of *quinic acid*. Instead of being oxidized, this is converted into hippuric acid, which renders the urine acid in reaction.

Normal urine upon standing for some time becomes alkaline owing to the inception of alkaline or ammoniacal fermentation through the agency of microorganisms. This fermentation has no especial diagnostic value except in cases where the urine has undergone this change *within the organism* and is voided in the decomposed state. Ammoniacal fermentation is ordinarily due to cystitis or occurs as the result of infection in the

process of catheterization. A microscopical examination of such urine (Fig. 214) shows the presence of ammonium magnesium phosphate crystals, amorphous phosphates, and not infrequently ammonium urate.

Occasionally a urine which possesses a normal acidity when voided will upon standing, instead of undergoing ammoniacal fermentation as above described, become more strongly acid in reaction. Such a phenomenon is termed *acid fermentation*. Accompanying this increased acidity there is ordinarily a deepening of the tint of the urinary color. Such urines may contain acid urates, uric acid, fungi, and calcium oxalate (Fig. 215). On standing for a sufficiently long time any urine which exhibits acid fermentation will ultimately change in reaction owing to the inception of alkaline fermentation, and will show the microscopic deposits characteristic of such a urine.

**Specific Gravity.** The specific gravity of the urine of normal individuals varies ordinarily between 1.015 and 1.025. This value is subject to

FIG. 214. DEPOSIT IN AMMONIACAL FERMENTATION.

*a*, Acid ammonium urate; *b*, ammonium magnesium phosphate; *c*, bacteria.

FIG. 215. DEPOSIT IN ACID FERMENTATION.

*a*, Fungus; *b*, amorphous sodium urate; *c*, uric acid; *d*, calcium oxalate.

wide fluctuations under various conditions. For instance, following copious water- or beer-drinking the specific gravity may fall to 1.003 or lower, whereas in cases of excessive perspiration it may rise as high as 1.040 or even higher. Where a very accurate determination of the specific gravity is desired, use is commonly made of the pycnometer or of the Westphal hydrostatic balance. These instruments, however, are not

suited for clinical use. The clinical method of determining the specific gravity is by means of a urinometer (Fig. 216). This affords a very rapid method and at the same time is sufficiently accurate for clinical purposes. The urinometer is always calibrated for use at a specific temperature and

FIG. 216. URINOMETER AND CYLINDER.

the observations made at any other temperature must be subjected to a certain correction to obtain the true specific gravity. In making this correction one unit in the third decimal place is added to the observed specific gravity for every three degrees centigrade above the normal temperature and subtracted for every three degrees below the normal temperature. For instance, if in using a urinometer calibrated for 15° C. the specific gravity of a urine having a temperature of 21° C. is determined as 1.018, it is necessary to add to the observed specific gravity  $2 \times 0.001$  to obtain the real specific gravity of the urine. Therefore the specific gravity at 15° C. of a urine having a specific gravity of 1.018 at 21° C., would be  $1.018 + 0.002 = 1.020$ .

Pathologically, the specific gravity may be subjected to very wide variations. This is especially true in diseases of the kidneys. In acute nephritis ordinarily the urine is concentrated and of a high specific gravity, whereas in chronic nephritis the reverse conditions are more apt to prevail. In fact, under most conditions, whether physiological or pathological, the specific gravity of the urine is inversely proportional to the volume excreted. This is not true of diabetes mellitus, however, in which the volume of urine is large and the specific gravity also is high, owing to the sugar contained in the urine.

The total solids normally excreted in the urine may be roughly calculated by means of Long's coefficient, i.e., 2.6. The solids content of 1000 ml. of urine is obtained by multiplying the last two figures of the specific gravity observed at 25° C. by 2.6. To determine the amount of solids excreted in 24 hours if the volume was 1120 ml. and the specific gravity was 1.018, the calculation would be as follows:

$$(a) \quad 18 \times 2.6 = 46.8 \text{ g. of solid matter in 1000 ml. of urine}$$

$$(b) \quad \frac{46.8 \times 1120}{1000} = 52.4 \text{ g. of solid matter in 1120 ml. of urine}$$

**Collection and Preservation of the Urine Sample.** If any dependable data are desired regarding the quantitative composition of the urine, the examination of the mixed excretion for 24 hours is absolutely necessary. In collecting the urine the bladder may be emptied at a given hour, say 8 A.M., the urine discarded, and all the urine from that hour up to and including that passed the next day at 8 A.M., saved, thoroughly mixed, and a sample taken for analysis.

Toluene is a very satisfactory preservative for urine. In using this preservative simply overlay the urine with a thin layer of the toluene. Formaldehyde (2 drops per 50 ml. of urine) or a bit of camphor or thymol are also satisfactory urine preservatives which do not interfere with the tests for the major urinary constituents.

Another satisfactory preservative consists of a 3:2 mixture of hexamethylenetetramine (urotropin) and salicylic acid, which is used in the proportion of 50 mg. per 10 ml. of urine. These substances produce formaldehyde in solution and, it is claimed, do not interfere with any of the usual tests.

In certain pathological conditions it is desirable to collect the urine passed during the day separately from that passed during the night. When this is done, the urine voided between 8 A.M. and 8 P.M. may be taken as the day sample and that voided between 8 P.M. and 8 A.M. as the night sample.

The qualitative testing of urine samples collected at random, except in a few specific instances, is of no particular value so far as giving us any accurate knowledge as to the exact urinary characteristics of the individual is concerned. In the great majority of cases the qualitative as well as the quantitative tests should be made upon the mixed excretion for a 24-hour period as well as upon a night sample as above described.

ORGANIC PHYSIOLOGICAL CONSTITUENTS

UREA

<sup>1</sup> It is impossible to make an absolute distinction between physiological and pathological constituents of the urine. A substance may be present in urine in small amount physiologically and be sufficiently increased under certain conditions to be termed a pathological constituent. Therefore it depends, in some instances, upon the quantity of a constituent present whether it may be correctly termed a physiological or a pathological constituent.

Urea is the principal end product of the metabolism of protein substances in mammals, amphibia, and elasmobranch fishes. About 80 to 90 per cent of the total nitrogen of human urine is present as urea. The distribution of the nitrogen of the urine among urea and the other nitrogen-containing compounds present depends upon the absolute amount of the total nitrogen excreted. A decrease in the total nitrogen excretion is always accompanied by a decrease in the percentage of the total nitrogen excreted as urea. By so reducing the protein content of the diet of a normal person as to cause the excretion of total nitrogen to be reduced to 3 to 4 g. in 24 hours, *only about 60 per cent of this nitrogen appears in the urine as urea*. Urea is the only one of the nitrogenous excretions which is decreased, relatively as well as absolutely, as a result of decreasing the amount of protein metabolized. Folin reported a hospital case in which only 14.7 per cent of the total nitrogen was present as urea and about 40 per cent was present as ammonia. Mörner had previously reported a case in which but 4.4 per cent of the total nitrogen of the urine was present as urea, and 26.7 per cent was present as ammonia.

Urea occurs most abundantly in the urine of man and carnivora and in somewhat smaller amount in the urine of herbivora; the urine of fishes, amphibians, and certain birds also contains a small amount of the substance. Urea is also found in nearly all the fluids and in many of the tissues and organs of mammals. The amount excreted under normal conditions by an adult man in 24 hours is about 30 g. The excretion is greatest in amount on a diet of meat, and least in amount on a diet consisting of nonnitrogenous foods; this is due to the fact that the urea output is regulated by the protein metabolism. A low-protein diet has a tendency to decrease the metabolism of the tissue proteins and thus the output of urea under these conditions may fall below that observed during starvation. The output of urea is also increased after copious water- or beer-drinking. The increase is probably due primarily to the washing out of the tissues of the urea previously formed, but which had not been removed in the normal processes, and secondarily to a stimulation of protein catabolism.

The formation of urea appears to be a property of the liver exclusively. This has been demonstrated by experiments in which there was complete cessation of urea formation after extirpation of the liver. Studies with isolated tissues, incubated in thin slices under physiological conditions, have also shown that only liver tissue is capable of synthesizing urea.

The mechanism of urea formation by the liver is still uncertain. Early views included formation from free  $\text{NH}_3$ , presumably liberated from amino acids by oxidative deamination, through the intermediate formation of ammonium carbonate,  $(\text{NH}_4)_2\text{CO}_3$ , or ammonium carbamate,  $\text{NH}_4\cdot\text{O}\cdot\text{CO}\cdot\text{NH}_2$ . Attention has shifted to the role of certain amino acids in urea formation because of the studies of Krebs and Henseleit. These investigators, working with liver slices, showed that the liver could synthesize urea from ammonia and postulated the existence of a cyclic mechanism including ammonia, carbon dioxide, and the amino acids arginine, ornithine, and citrulline. The steps in the process, according to the *ornithine cycle* theory, are as follows:

Thus the primary source of urea according to this theory is the action of the enzyme *arginase* on the amino acid arginine, to produce urea and ornithine. The ornithine acts as a catalyst, being converted back to arginine by the reactions shown, taking up ammonia and carbon dioxide

in the process which ultimately appear as urea. This theory, while attractive, is not universally accepted (see Chapter 33). Points in its favor include the well-known and powerful arginase activity of liver, and the fact that citrulline, first isolated from watermelon juice, is found in small amount in the blood, and its synthesis by liver tissue can be demonstrated. Opposed to it is the fact that the experimental demonstration of the ornithine cycle with liver slices requires the presence of free ammonia in far higher concentration than is ever encountered in living

FIG. 217. UREA.

tissue; even moderate amounts of free ammonia are not acted on at all by liver slices. Thus, if the theory is correct, the nitrogen would appear to enter the cycle in some other way than as free ammonia. Further evidence on the subject is clearly required.

Urea crystallizes in long, colorless, four- or six-sided, anhydrous, rhombic prisms (Fig. 217), which melt at 132° C. and are soluble in water or alcohol and insoluble in ether or chloroform. If urea is heated in a test tube, it melts and decomposes with the liberation of ammonia and the formation of biuret and cyanuric acid. According to the Werner hypothesis the changes are as follows:

The biuret may be dissolved in water and a reddish-violet color obtained by treating the aqueous solution with copper sulfate and potassium hydroxide (see "Biuret Test," p. 171). Certain hypochlorites or hypobromites in alkaline solution decompose urea into nitrogen, carbon dioxide, and water. Sodium hypobromite brings about this decomposition as follows:

According to the Werner hypothesis, the urea is momentarily brominated and the resultant compound hydrolyzed by the alkali and oxidized by hypobromite. Sodium cyanate, sodium nitrate, hydrazine, and CO are formed as by-products, thus accounting for the low nitrogen values obtained in the clinical application of this method.

Soybeans, jack beans, and watermelon seeds contain an enzyme called urease which has the power to decompose urea with the liberation of ammonia. This fact is made use of in the quantitative determination of urea (see Chapter 23). Urease action appears to involve the intermediate formation of ammonium carbamate and not of cyanate.

Urea forms crystalline compounds with certain acids; urea nitrate and urea oxalate are the most important. Urea nitrate,  $\text{CO}(\text{NH}_2)_2 \cdot \text{HNO}_3$ , crystallizes in colorless rhombic or six-sided tiles (Fig. 218), which are easily soluble in water. Urea oxalate,  $(\text{CO}(\text{NH}_2)_2)_2 \cdot \text{H}_2\text{C}_2\text{O}_4$ , crystallizes in the form of rhombic or six-sided prisms or plates (Fig. 219): the oxalate differs from the nitrate in being somewhat less soluble in water.

A decrease in the excretion of urea is observed in many diseases in which the diet is much reduced, in diseases associated with impaired liver function, in some disorders as a result of alterations in metabolism, e.g., myxedema, but most frequently as a result of diminished excretion, as in

FIG. 218. UREA NITRATE.

severe and advanced kidney disease. In fact, the determination of the ability of the kidneys to excrete urea (the "urea clearance" test, see Chapter 31) is perhaps the most valuable single clinical index of renal function. A pathological increase may result from tissue catabolism in

FIG. 219. UREA OXALATE.

febrile or wasting conditions. In marked acidosis it may be considerably decreased relative to the total nitrogen (see "Ammonia," p. 814).

Strong solutions of urea have a remarkable solvent effect upon proteins, such as coagulated protein, and upon starch and other substances.

## EXPERIMENTS ON UREA

1. *Isolation from the Urine.* Evaporate 200 ml. of urine in a casserole or evaporating dish over a free flame until the volume is reduced to about 25 ml. Transfer the container to a steam or water bath and continue the evaporation until the residue is semisolid, spreading the material over the sides of the dish to aid in removing as much water as possible. Add 50 ml. of acetone to the residue and stir thoroughly while the acetone is kept gently boiling on a previously heated water bath (with the flame turned out) or steam bath. Do not allow more than one-quarter of the acetone to boil off. Because of the inflammable and poisonous nature of acetone vapor, this and further operations should be conducted in the hood and in the absence of a free flame. Filter the hot extract quickly through a small dry filter into a dry 100-ml. beaker. Repeat the extraction of the residue once more with acetone, adding the filtrate to the first portion. Concentrate the combined extracts to a volume of 25 ml. on the steam bath or by placing the beaker in hot water. Chill the concentrated solution with cold water, cover, and allow to stand until crystallization occurs. Filter off the urea crystals, wash them with a little acetone, and allow to dry in air. Examine the crystals under the microscope and compare them with those shown in Fig. 217.

2. *Melting Point.* Determine the melting point of some urea crystals as follows: Into an ordinary melting-point tube, sealed at one end, introduce powdered urea. Fasten the tube to the bulb of a thermometer and suspend the bulb and its attached tube in a small beaker containing concentrated sulfuric acid. Gently raise the temperature of the acid by means of a low flame, stirring the fluid continually, and note the temperature at which the urea begins to melt.

3. *Crystalline Form.* Dissolve a crystal of pure urea in a few drops of 95 per cent alcohol and place 1 to 2 drops of the alcoholic solution on a microscopical slide. Allow the alcohol to evaporate spontaneously, examine the crystals under the microscope, and compare them with those reproduced in Fig. 217. Recrystallize a little urea from water in the same way and compare the crystals with those obtained from the alcoholic solution.

4. *Formation of Biuret.* Place a small amount of urea in a dry test tube and heat carefully in a low flame. The urea melts at  $132^{\circ}$  C. and liberates ammonia. Continue heating until the fused mass begins to solidify. Cool the tube, dissolve the residue in dilute sodium hydroxide solution, and add very dilute copper sulfate solution (see p. 171). The purplish-violet color is due to the presence of biuret which has been formed from the urea through the application of heat as indicated. The chemistry of this reaction is shown on p. 791.

5. *Urea Nitrate.* Prepare a concentrated solution of urea by dissolving a little of the substance in a few drops of water. Place a drop of this solution on a microscopical slide, add a drop of concentrated nitric acid, and examine under the microscope. Compare the crystals with those reproduced in Fig. 218.

6. *Urea Oxalate.* To a drop of a concentrated solution of urea, prepared as described in Exp. 5, add a drop of a saturated solution of oxalic acid. Examine under the microscope and compare the crystals with those shown in Fig. 219,

**7. Decomposition by Sodium Hypobromite.** Into a mixture of 3 ml. of concentrated sodium hydroxide solution and 2 ml. of bromine water in a test tube introduce a crystal of urea or a small amount of concentrated solution of urea. Through the influence of the sodium hypobromite, NaOBr, the urea is decomposed and carbon dioxide and nitrogen are liberated. The carbon dioxide is absorbed by the excess of sodium hydroxide, while the nitrogen is evolved and causes the marked effervescence observed. This property forms the basis for one of the methods in common use for the quantitative determination of urea. Write the equation showing the decomposition of urea by sodium hypobromite.

It is claimed that all ammonium compounds and all compounds containing the amino [ $-\text{NH}_2$ ] group yield nitrogen when treated with hypobromite as in this test.

**8. Decomposition by Urease.** To 5 ml. of urea solution in a test tube add 1 ml. of urease solution or a little soybean or jack-bean powder. Allow the tube to stand for 10 minutes, heat the contents to boiling, holding moist red and blue litmus papers at the mouth of the tube. What do you observe? Note the odor. Explain.

### URIC ACID

Uric acid is found in the urine normally to the extent of about 0.5 to 1.0 g. per 24 hours, but this amount is subject to wide variations, particularly under certain dietary and pathological conditions. On a purine-free diet the uric acid output may be 0.1–0.5 g. per day, whereas a high purine diet may yield a daily output of 2 g. Uric acid acts as a weak dibasic acid and forms two classes of salts, neutral and acid. The neutral potassium and lithium urates are the most easily soluble of the alkali salts; the ammonium urate is difficultly soluble. The acid salts are more insoluble and form the major portion of the sediment which separates upon cooling the concentrated urine; the alkaline earth urates are very insoluble. Ordinarily uric acid occurs in the urine in the form of urates and upon acidifying the liquid the uric acid is liberated and deposits in crystalline form.

Uric acid is closely related to the purine bases as may be seen from a comparison of its structural formula with those of the purine bases given on p. 202. According to the purine nomenclature, it is designated 2,6,8-trioxypurine. Uric acid forms the principal end product of the nitrogenous metabolism of birds and scaly reptiles; in the human organism it occupies a position quantitatively inferior to urea, ammonia, and creatinine.

In man, uric acid probably results principally from the destruction of nuclear or other purine material, ingested as food or from the disintegrating cellular matter of the organism. The uric acid resulting from the diet

PLATE III

URIC ACID CRYSTALS, NORMAL COLORS.  
(From Purdy, after Peyer.)

was formerly said to be of *exogenous* origin, whereas the product of cellular catabolism was said to be of *endogenous* origin. It is now known that metabolic activities cannot be properly explained on such a simple basis. However, the terms endogenous and exogenous are nevertheless frequently employed. Folin demonstrated that, following a pronounced decrease in the amount of protein metabolized, the absolute quantity of uric acid is decreased, but that this decrease is relatively smaller than the decrease in the total nitrogen excretion and that the percentage of the uric acid nitrogen, in terms of the total nitrogen, is therefore decidedly increased.

The enzymatic conversion of the purines adenine and guanine to the intermediates hypoxanthine and xanthine, and of the latter to uric acid by means of xanthine oxidase, is discussed in Chapter 7, "Nucleic Acids and Nucleoproteins." With the exception of man, the higher apes, and the Dalmatian dog, mammalia carry the conversion one step farther; i.e., to allantoin, through the action of the enzyme uricase. Despite the absence of a typical uricase from human tissues, there is no question but that the human organism has considerable ability to destroy uric acid, by mechanisms not known. Thus uric acid excretion represents a balance between the rate of production and the rate of destruction. From experiments on dogs, Mann and associates drew the conclusion that the destruction of uric acid depends on the presence of the liver. The extirpation of the liver causes an accumulation of uric acid in the blood and tissues or an increased elimination in the urine if renal activity is maintained. These experiments also indicate that the liver is of considerable importance in the general metabolism of the purines.

Using the isotope technique it has been shown<sup>2</sup> that orally administered uric acid is "extensively degraded" to urea, whereas intravenously administered uric acid is excreted essentially unchanged. This latter finding is in agreement with the reported absence of uricase in human tissues.

In birds the formation of uric acid is analogous to the formation of urea in man. In these organisms it is derived principally from the protein material of the tissues and the food and is formed through a process of synthesis which occurs for the most part in the liver; a comparatively small fraction of the total uric acid excretion of birds may result from nuclear material.

When pure, uric acid may be obtained as a white, odorless, and tasteless powder, which is composed principally of small, transparent, crystalline rhombic plates. Uric acid as it separates from the urine is invariably pigmented, and crystallizes in a large variety of characteristic forms, e.g., dumbbells, wedges, rhombic prisms, irregular rectangular or hexagonal plates, whetstones, prismatic rosettes, etc. Uric acid is insoluble in alcohol and ether, soluble with difficulty in boiling water (1:1800) and practically insoluble in cold water (1:39,480, at 18° C.). It is soluble in alkalies, alkali carbonates, boiling glycerol, concentrated sulfuric acid, and in certain organic bases such as ethylamine and piperidine. It is claimed that the uric acid is held in solution in the urine by the urea and disodium hydro-

---

<sup>2</sup> Geren, Bendich, Bodansky, and Brown: *J. Biol. Chem.*, **183**, 21 (1950).

gen phosphate present. Uric acid possesses the power of reducing cupric hydroxide in alkaline solution and may thus lead to an erroneous conclusion in testing for sugar in the urine by means of Fehling's or Trommer's test. A white precipitate of cuprous urate is formed if only a small amount of cupric hydroxide is present, but if enough of the copper salt is present the characteristic red or brownish-red precipitate of cuprous oxide is obtained. Uric acid does not possess the power of reducing bismuth in alkaline solution and therefore does not interfere in testing for sugar in the urine by means of Boettger's or Nylander's tests.

In addition to being a constant urinary constituent uric acid is present in small amounts in normal human blood as well as in the blood of birds. It is also normally present in the brain, heart, liver, lungs, pancreas, and spleen.

Pathologically, the excretion of uric acid is subject to wide variations, but the experimental findings are rather contradictory. It may be stated with certainty, however, that in leukemia, because of the destruction of nuclear material, the uric acid output is increased absolutely as well as relatively to the urea output; under these conditions the ratio between the uric acid and urea may be as low as 1:9, whereas the normal ratio, as we have seen, is 1:50 or higher. An actual output of 12 g. of uric acid per day has been reported in leukemia.

In gout the kidney is said to lose the power of properly eliminating uric acid and it collects in the blood in abnormally high concentration. This is accompanied by the deposition of uric acid in the joint cartilages and especially in the joint of the big toe. Tests have been reported<sup>3</sup> which "minimize the role of dietary purine in the production of overt gout."

The uric acid content of the urine is of importance in relation to the formation of uric acid calculi. The administration of alkali carbonates and citrates, or the feeding of base-forming foods, by decreasing the acidity of the urine, increases its solvent power for uric acid and decreases the liability of formation of this type of calculus.

## EXPERIMENTS ON URIC ACID

**1. Isolation from the Urine.** Place about 200 ml. of filtered urine in a beaker, render it acid with 2 to 10 ml. of concentrated hydrochloric acid, stir thoroughly, and stand the vessel in a cold place for 24 hours. Examine the pigmented crystals of uric acid under the microscope and compare them with those shown in Fig. 220 and Plate III.

**2. Crystalline Form of Pure Uric Acid.** Place about 100 ml. of water in a small beaker, render it distinctly alkaline with potassium hydroxide solution, and add a small amount of pure uric acid, stirring continuously. Cool the solution, render it distinctly acid with hydrochloric acid, and allow it to stand in a cool place for crystallization. Examine the crystals under the microscope and compare them with those reproduced in Fig. 220.

**3. Murexide Test.** To a small amount of pure uric acid in a small evaporating dish add 2 to 3 drops of concentrated nitric acid. Carefully evaporate to dryness on a water bath or over a very low flame. A red or yellow residue

<sup>3</sup> Stetten: *Bull. N. Y. Acad. Med.*, 28, 664 (1952).

remains which turns purplish-red after the dish has been cooled and a drop of very dilute ammonium hydroxide has been added. The color is due to the formation of murexide. If potassium hydroxide is used instead of ammonium hydroxide, a purplish-violet color due to the production of the potassium salt is obtained. The color disappears upon warming; with certain related compounds (purine bases) the color persists under these conditions. This is a valuable test for the detection of uric acid calculi.

In this reaction the uric acid is oxidized to dialuric acid and alloxan. These two substances condense to form alloxantin. This alloxantin reacts with ammonium hydroxide to form purpuric acid. The purple color is due to the formation of ammonium purpurate or murexide.

FIG. 220. PURE URIC ACID.

4. *Phosphotungstic Acid Reaction (Folin)*. To 20 ml. of saturated sodium carbonate solution in a small beaker add a small amount of uric acid. Stir the solution until the uric acid has dissolved, then add 1 ml. of Folin's uric acid reagent (see p. 560). A blue color results.

5. *Silver Reduction Test (Schiff)*. Dissolve a small amount of pure uric acid in sodium carbonate solution and transfer a drop of the resulting mixture to a strip of filter paper saturated with silver nitrate solution. A yellowish-brown or black coloration due to the formation of reduced silver is produced. It is claimed that chlorides interfere with this test.

#### CREATININE

#### CREATINE

**Creatinine.** Creatinine is the anhydride of creatine (methylguanidinoacetic acid) and is a constant constituent of normal human urine. Under normal conditions about 1 to 1.8 g. of creatinine are excreted by an adult man in 24 hours. The exact amount of creatinine excreted under ordinary

circumstances depends in part upon the nature of the diet, since any creatinine in the diet is excreted unchanged in the urine. Foods such as meat and fish contain significant amounts of performed creatinine, particularly after cooking. Creatinine excretion decreases somewhat in starvation. The absolute amount of creatinine eliminated in the urine on a creatinine-free diet is practically a constant quantity for a given individual and is independent of quantitative changes in the total amount of nitrogen eliminated under these conditions. The "creatinine coefficient," which is the daily excretion of creatinine in mg. per kg. of body weight,<sup>4</sup> is an index of this constancy of creatinine elimination. Endogenous creatinine is apparently the result of some special process of normal metabolism which takes place at a constant rate and almost certainly involves body creatine, since creatine can be converted in the body to creatinine. For example, when animals are given tagged creatine the isotopic ratios of tissue creatine and urine creatinine are similar. The conversion of creatinine to creatine in the body does not occur.

Very little that is important is known regarding the excretion of creatinine under pathological conditions. The creatinine content of the urine is said to be increased in conditions associated with increased tissue catabolism, such as fever. The output of creatinine is decreased in disorders associated with muscular atrophy and muscular weakness.

FIG. 221. CREATININE.

The greater part of the data relating to the variation of the creatinine excretion under pathological conditions are not of much value since in nearly every instance the diet was not sufficiently controlled to permit the collection of reliable data.

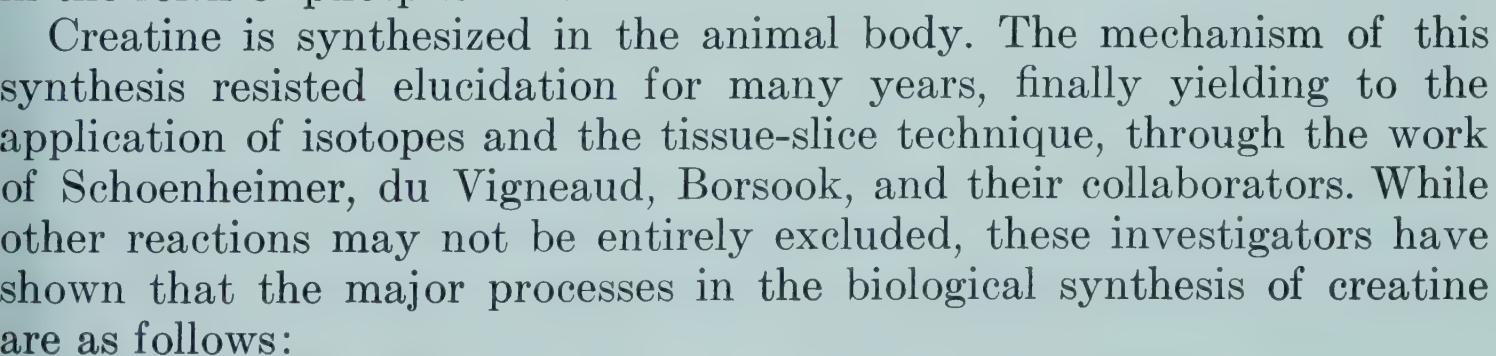

According to Mann and associates the changes in the blood creatinine after removal of the liver depend entirely on the kidneys. If the kidneys are active the blood creatinine does not change. If the kidneys are removed as well, or the animal becomes anuric, the creatinine increases in the blood at the same rate as when only the kidneys are removed. The creatine behaves in a similar manner. The liver would therefore appear to take no specific part in the creatinine-creatine relationship.

Creatinine crystallizes in colorless, glistening, monoclinic prisms (Fig. 221) which are soluble in about 12 parts of cold water; they are more soluble in warm water and in warm alcohol. It forms salts only with strong mineral acids. One of the most important and interesting of the compounds of creatinine is creatinine-zinc chloride,  $(C_4H_7N_3O)_2ZnCl_2$ ,

Creatinine crystallizes in colorless, glistening, monoclinic prisms (Fig. 221) which are soluble in about 12 parts of cold water; they are more soluble in warm water and in warm alcohol. It forms salts only with strong mineral acids. One of the most important and interesting of the compounds of creatinine is creatinine-zinc chloride,  $(C_4H_7N_3O)_2ZnCl_2$ ,

<sup>4</sup> Shaffer designates as the "creatinine coefficient" the excretion of creatinine *nitrogen* in mg. per kg. of body weight.

Thus the synthesis involves the amino acids glycine and arginine in the reaction of transamidination, and a source of labile methyl groups in the transmethylation reaction; the latter may involve either the amino acid methionine or the substance choline. In this connection it is of interest that while glycine is readily synthesized by man, it cannot be synthesized by the chick and is ordinarily required in the diet but may be replaced there by creatine. Of interest also is the clinical observation that in myasthenia gravis the feeding of glycine leads to an increased excretion of creatine. The intermediate compound guanidinoacetic acid is found in normal urine to the extent of about 20 mg. per day.

Creatine is fairly soluble in water but the aqueous solution is unstable, the creatine being gradually transformed to its anhydride creatinine by ring closure after the splitting off of water. This process is accelerated by heat and acid, and this is the basis of the usual procedures for the detection or determination of creatine, the creatine being converted into creatinine and tested for as the latter compound. There is no satisfactory direct test reaction for creatine itself.

## EXPERIMENTS ON CREATININE AND CREATINE

**1. Preparation of Pure Creatinine from Urine (Folin-Benedict).** To 10 liters of undecomposed urine in a large precipitating jar add with stirring a hot solution of 180 g. of picric acid in 450 ml. of boiling alcohol. Allow to stand overnight and syphon off the supernatant fluid. Pour the residue upon a large Buchner funnel, drain with suction, wash once or twice with cold saturated picric acid, and suck dry. Treat the dry or nearly dry picrate in a large mortar or evaporating dish with enough concentrated HCl to form a moderately thin paste (about 60 ml. of acid for each 100 g. of picrate) and stir the mixture thoroughly with the pestle for 3 to 5 minutes. Filter with suction on a hardened paper, and wash the residue twice with enough water to cover it, sucking as nearly dry as possible each time. Transfer the filtrate to a large flask and neutralize with an excess of solid magnesium oxide (the "heavy" variety is best). Add this oxide in small portions with cooling of the flask under running water between the additions. Neutralization of the acid will be indicated by a bright yellow color of the mixture, or litmus paper may be used to test it. Filter with suction. Wash the residue twice with water. Immediately add a few ml. of glacial acetic acid to the filtrate to make it strongly acid. Neglecting any precipitate that may form, dilute the solution with about 4 volumes of 95 per cent alcohol. After 15 minutes filter off the slight precipitate which forms. Treat the final filtrate with 30 to 40 ml. of 30 per cent zinc chloride. Stir and let stand overnight in a cool place. Pour off the supernatant liquid and collect the creatinine zinc chloride on a Buchner funnel, wash once with water, then thoroughly with 50 per cent alcohol, finally with 95 per cent alcohol and dry. A nearly white, light crystalline powder should be obtained. The yield should be 90 to 95 per cent of the original creatinine (usually about 1.5 to 1.8 g. of creatinine zinc chloride per liter of urine).

Recrystallize the creatinine zinc chloride by treating 10 g. with 100 ml. of water and about 60 ml. of normal sulfuric acid, heating the mixture until a clear solution is obtained. Add about 4 g. of purified animal charcoal, continue boiling for about a minute, filter with suction through a small Buchner funnel, pouring the filtrate back on the filter 3 or 4 times until it runs through perfectly colorless. Wash the residue with hot water and

transfer the total filtrate to a beaker and while hot treat with a little strong zinc chloride solution (3 ml.) and with about 7 g. of potassium acetate dissolved in a little water. After 10 minutes dilute with an equal volume of alcohol, and allow to stand in a cold place for some hours. Filter off the crystalline product and examine under a microscope (see Fig. 222). To remove the small amount of potassium sulfate which it contains stir up with its weight of water, filter, wash with a little water and then with alcohol. The preparation should be snow white. Yield, 85 to 90 per cent.

For the decomposition of the creatinine zinc chloride Gaebler suggests the following modification of the original procedure. Place 32 g. creatinine zinc chloride in a pressure bottle (a citrate of magnesia bottle will serve) and add 225 to 250 ml. of concentrated ammonia. Close the bottle and heat in a water bath at 70 to 80° C., shaking to effect solution. Cool quite rapidly to room temperature and then in a salt-ice bath. Pure creatinine crystallizes out. Filter. Wash with ice-cold ammonia, then with acetone, and dry. The yield should be 75 per cent (15 g. of creatinine). The product is perfectly pure and can be used as a standard in the quantitative determination of creatine and creatinine. See the chapters on quantitative analysis of urine and blood.

FIG. 222. CREATININE ZINC CHLORIDE (SALKOWSKI).

2. *Nitroprusside Test (Weyl)*. Take 5 ml. of urine in a test tube, add a few drops of sodium nitroprusside, and render the solution alkaline with NaOH solution. A ruby-red color results which soon turns yellow. See Legal's test for acetone, Chapter 29.

3. *Nitroprusside-Acetic Acid Test (Salkowski)*. To the yellow solution obtained in Weyl's test above, add an excess of acetic acid and apply heat. A green color results and is in turn displaced by a blue color. A precipitate of prussian blue may form.

4. *Picric Acid Reaction (Jaffé)*. Place 5 ml. of urine in a test tube, add an aqueous solution of picric acid, and render the mixture alkaline with NaOH solution. A red color is produced which turns yellow if the solution be acidified. Glucose gives a similar red color but only upon the application of heat. This color reaction observed when creatinine in alkaline solution is treated with picric acid is the basic principle of Folin's colorimetric method for the quantitative determination of creatinine (see Chapter 31) and is due to the formation of a red tautomer of creatinine picrate. The production of this tautomer is "dependent upon the formation of a salt, a keto-enol change within the creatinine molecule, and a change in the picric acid molecule involving the hydrogens in the meta positions and, probably, all three nitro groups."

5. *Preparation of Creatine*. Creatine may be prepared from creatinine zinc chloride by decomposition with calcium hydrate, the process being one of hydrolysis (Benedict).

100 g. of creatinine zinc chloride are treated with about 700 ml. of water in a large casserole and the mixture heated to boiling; 150 g. of pure powdered calcium hydrate are then added, with stirring, and the mixture boiled gently for 20 minutes (with occasional stirring). The hot mixture is then filtered with suction, the residue being washed with hot water. The filtrate is then treated with hydrogen sulfide gas for a few minutes and poured through a folded filter to remove the zinc. The filtrate is acidified by the addition of about 5 ml. of glacial acetic acid and boiled down rapidly to a volume of about 200 ml. This solution is allowed to stand overnight, preferably in a cool place. The next day the crystallized creatine is filtered off with suction, washed with a very little cold water, and then thoroughly washed with alcohol and dried. This product is then recrystallized by dissolving in about 7 times its weight of boiling water and allowing the solution to cool slowly and stand for some hours. This product should be perfectly pure creatine. If necessary it can be recrystallized with very little loss. The crystallized product should be filtered off, washed with alcohol and ether, and dried in air for about half an hour. Thus obtained, the creatine contains water of crystallization which it loses very readily upon exposure to air. To prepare creatine which can be weighed with absolute exactness it is necessary to dehydrate this product by heating for some hours at about 95° C.

The yield in this process is about 18 g. of recrystallized creatine, and about 55 g. of creatinine zinc chloride recovered. Longer boiling with lime does not bring about a greater yield, for after the 20-minute point creatine is decomposed almost exactly as fast as it is formed.

Examine the crystals of creatine under the microscope and compare with illustration in Chapter 10, "Muscular Tissue," in which may be found other creatine tests.

## ETHEREAL SULFATES

The most common ethereal sulfates found in the urine are phenol-sulfuric acid, *p*-cresolsulfuric acid, indoxylsulfuric acid, and skatoxyl-sulfuric acid. Pyrocatecholsulfuric acid also occurs in traces in human urine. The total output of ethereal sulfuric acid (as S) varies ordinarily from 0.04 to 0.1 g. for 24 hours and comprises 5 to 15 per cent of the total sulfur. In health the ratio of ethereal plus neutral sulfate to inorganic sulfate is about 1:10. These ethereal sulfuric acids originate in part from the phenol, cresol, indole, and skatole formed in the putrefaction of protein material in the intestine. The phenol passes to the liver where part of it is conjugated to form phenol potassium sulfate and appears in this form in the urine, whereas the indole and skatole undergo a preliminary oxidation to form indoxyl and skatoxyl respectively before their conjugation and elimination. (See Chapter 20.)

It was formerly generally considered that each of the ethereal sulfuric acids was formed principally in the putrefaction of protein material in the intestine and that therefore a determination of the total ethereal sulfuric acid content of the urine was an index of the extent to which these putrefactive processes were proceeding within the organism. Folin, however, showed that the ethereal sulfuric acid content of the urine did *not* afford an index of the extent of intestinal putrefaction, since these compounds arise only in part from putrefactive processes. He claimed

that the ethereal sulfuric acid excretion represented a form of sulfur metabolism which is more in evidence when the diet contained little or no protein. The ethereal sulfuric acid content of the urine diminishes as the total sulfur content diminishes, but the percentage decrease is much less. Therefore, relative to the total sulfuric acid content, the ethereal sulfuric acid content is increased, although the total sulfuric acid content is diminished. The indoxylsulfuric acid (indican) content of the urine does not originate to any degree from the tissue catabolism of protein material but arises in great part from the action of intestinal putrefactive organisms on tryptophan (see Chapter 20). The excretion of indoxylsulfuric acid

which occurs in the urine as the potassium salt

may *alone* be taken as a rough index of the extent of putrefactive processes within the intestine and is clinically the most important of the ethereal sulfuric acids. Under normal conditions, from 10 to 20 mg. of indican are excreted per day. The variations are due mainly to diet, a high meat diet causing an increase and a carbohydrate diet a decrease. Pathologically, the greatest increases are found in disorders involving increased putrefaction and stagnation of intestinal contents. Bacterial decomposition of body protein as in gangrene, putrid pus formation, etc., gives rise to an increased indican excretion.

Phenols are excreted chiefly in the conjugated form. The phenol output tends to vary directly but not proportionally with the protein ingestion. The total phenol excretion of normal men on an ordinary mixed diet averages around 0.2 g. per day.

## TESTS FOR INDICAN<sup>5</sup>

**1. Jaffé's Test.** Nearly fill a test tube with a mixture composed of equal volumes of concentrated HCl and the urine under examination. Add 2 to 3 ml. of chloroform and a few drops of a calcium hypochlorite solution, place the thumb over the end of the test tube and rock the tube back and forth, inverting at least 10 times. The chloroform is more or less colored, according to the amount of indican present. Ordinarily a blue color due to the forma-

<sup>5</sup> The urine should always be examined fresh if this is possible. In any event formaldehyde should never be used as a preservative for urines which are to be examined for indican by means of any test involving hypochlorite or potassium permanganate. The formaldehyde through its reducing power lowers the oxidizing efficiency of the mixture. The formation of formic acid from the aldehyde may also interfere.

tion of indigo blue is produced; less frequently a red color due to indigo red may be noted.

Repeat this test on some of this same urine to which formaldehyde has been added. Is there any variation in the reaction from what you previously obtained?

The following represents the reaction:

**2. Obermayer's Test.** Nearly fill a test tube with a mixture composed of equal volumes of Obermayer's reagent<sup>6</sup> and the urine under examination. Add 2 to 3 ml. of chloroform, place the thumb over the end of the test tube, and rock the tube back and forth, inverting at least 10 times. How does this compare with Jaffé's test?

### HIPPURIC ACID

This acid occurs normally in the urine of both carnivora and herbivora, but it is much more abundant in the urine of the latter. It is formed by the union of benzoic acid with glycine according to the following reaction:

In the dog this conjugation takes place exclusively in the kidneys, but in man and in the rabbit it is probable that the liver is the main site of this synthesis. Clinically the ability of an individual to synthesize hippuric acid after administration of a test dose of benzoate is used as an index of liver function. Glycine is readily produced by the body from the hydrolysis of dietary or tissue protein, or may be synthesized from certain other amino acids, e.g., serine. Benzoic acid originates ordinarily either from intestinal putrefaction, i.e., from the abnormal metabolism of tyrosine and phenylalanine, or from the food. Many vegetables, fruits, and grasses contain small quantities of preformed benzoic acid and larger amounts of quinic acid and other compounds which in the body are converted to benzoic acid. It has been found that approximately 2 g. of benzoic acid are excreted as hippuric acid after eating 250 g. of prunes. The average

<sup>6</sup> See Appendix.

excretion of hippuric acid by an adult man for 24 hours under normal conditions is about 0.7 g. Hippuric acid crystallizes in needles or rhombic prisms (see Fig. 223), the particular form depending upon the rapidity of crystallization. Pure hippuric acid melts at 187° C. It is easily soluble in alcohol or hot water. It is sufficiently soluble in ether to allow its extrac-

FIG. 223. HIPPURIC ACID.

tion from aqueous solution with this solvent. (For the quantitative determination of hippuric acid, see Chapter 31.)

## EXPERIMENTS ON HIPPURIC ACID

1. *Separation from the Urine.* (See Chapter 31.)

2. *Melting Point.* Determine the melting point of the hippuric acid prepared in the above experiment (see p. 793).

3. *Formation of Nitrobenzene (Lücke's Reaction).* To a little hippuric acid in a small porcelain dish add 1 to 2 ml. of concentrated  $\text{HNO}_3$  and evaporate to dryness on a water bath. Transfer the residue to a dry test tube, apply heat, and note the odor of nitrobenzene (resembling that of oil of bitter almonds).

4. *Sublimation.* Place a few crystals of hippuric acid in a dry test tube and apply heat. The crystals are reduced to an oily fluid which solidifies in a crystalline mass upon cooling. When stronger heat is applied the liquid assumes a red color and finally yields a sublimate of benzoic acid and the odor of hydrocyanic acid.

## OXALIC ACID

Oxalic acid is a constituent of normal urine, about 15 to 20 mg. being eliminated in 24 hours. It separates out from neutral or alkaline urine

as the insoluble crystalline *calcium oxalate*, in the form of either dumbbells or octahedra, usually the latter (see Fig. 230). Many urinary calculi consist largely of calcium oxalate. When ingested oxalic acid is eliminated, at least in part, unchanged. Since many common articles of diet, e.g., asparagus, apples, cabbage, grapes, lettuce, rhubarb, spinach, tomatoes, etc., contain oxalates (or precursors) it seems probable that they are responsible for most of the oxalic acid found in the urine. The ingestion of rhubarb leaves has caused oxalic acid poisoning. They contain about 1.2 per cent of the acid. Spinach contains 0.8 to 0.9 per cent. The eating of these vegetables tends to lessen the supply of calcium in the body. Other green vegetables such as lettuce, celery, endive, asparagus, broccoli, Brussels sprouts, and cabbage contain very small amounts of oxalic acid—generally less than 0.1 per cent. There is also experimental evidence that part of the oxalic acid of the urine is formed within the organism in the course of protein and fat metabolism. It has also been suggested that oxalic acid may arise from an incomplete combustion of carbohydrates, especially under certain abnormal conditions. In this connection it is of interest that oxalic acid is one of the end products of *in vitro* oxidation of ascorbic acid. Pathologically, urinary oxalic acid is increased in diabetes mellitus, in organic diseases of the liver, and in various other conditions which are accompanied by a derangement of the oxidative mechanism. An abnormal increase in oxalic acid excretion is termed oxaluria and may be unaccompanied by any other apparent symptom.

Oxaluric acid ( $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{CO}\cdot\text{COOH}$ ) is occasionally found in traces in normal human urine. On hydrolysis it yields oxalic acid and urea.

## EXPERIMENT ON OXALIC ACID

**Precipitation of Calcium Oxalate.** Place 200 to 250 ml. of urine in a beaker, add 5 ml. of a saturated solution of calcium chloride, make the urine slightly acid with acetic acid, and stand the beaker in a cool place for 24 hours. Examine the sediment under the microscope and compare the crystalline forms with those shown in Fig. 230, p. 855.

### CITRIC ACID

Citric acid is a normal urinary constituent, the 24-hour excretion ranging from about 300 to 1500 mg. Several factors have been noted to influence the excretion rate. It is enhanced in alkaline urine,<sup>7</sup> by estrogens,<sup>8</sup> and with increased urinary excretion of calcium.<sup>9</sup> Urinary citric acid excretion is reduced in acid urine and by androgens. The effect of endogenous estrogens in augmenting urinary citric acid excretion is seen in

<sup>7</sup> Ostberg: *Skand. Arch. Physiol.*, **62**, 81 (1931).

<sup>8</sup> Shorr, Bernheim, and Taussky: *Science*, **95**, 606 (1942).

<sup>9</sup> Shorr: *J. Urology*, **53**, 507 (1945).

the characteristic curve of the normal menstrual cycle, with the lowest excretion during menstruation followed by a mid-menstrual peak and plateau and a return to the lower menstrual levels just before the next menstrual period. Since the citrate ion forms a soluble weakly ionized complex with calcium, an effort has been made to apply this augmenting effect of estrogens to the management of renal stones containing calcium. This application of estrogens is liable to be ineffective owing to the frequent association of urinary infections with organisms which destroy citric acid and is further limited in usefulness by its interference with menstrual cycles and with libido in the male. An enzyme, citrogenase, found in the kidney, heart, and liver can form citric acid by condensation of pyruvic and oxalacetic acids. A marked increase in urinary citric acid following hepatectomy suggests that the liver has a function in its intermediary metabolism.

### NEUTRAL SULFUR COMPOUNDS

Under this head may be classed such substances as cystine, methyl mercaptan, ethyl sulfide, thiocyanates, taurine derivatives, etc. The sulfur content of the compounds just enumerated is generally termed unoxidized or neutral sulfur in order that it may not be confused with the acid or oxidized sulfur which occurs in the inorganic sulfuric acid and ethereal sulfuric acid forms, although this distinction is admittedly inexact. Ordinarily the neutral sulfur content of normal human urine is 5 to 25 per cent of the total sulfur content (see "Partition of Urinary Nitrogen and Sulfur," Chapter 31). The actual amount excreted may be 0.08 to 0.16 g. per day, calculated as S. Its origin is mainly endogenous. The excretion is fairly constant for any given individual in spite of dietary changes. In cystinuria, or in certain degenerative diseases, the amount is increased. (See p. 168 for test for cystine and cysteine sulfur.)

### ALLANTOIN

Allantoin is found in the urine of practically all mammals including man. In human urine it occurs in very small amounts (5 to 15 mg. per day) whereas in all other mammals except anthropoid apes, and the Dalmatian coach dog, it is the principal end product of purine metabolism and may constitute 90 per cent or over of the total purine output. Allantoin is formed upon oxidation of uric acid by the enzyme uricase and the output is increased by the feeding of thymus or pancreas to lower animals. In the dog, according to Mann and associates, the liver is the sole seat of uric acid destruction, since after hepatectomy the uric acid excretion is equivalent to the allantoin output of the normal animal. When pure, allantoin crystallizes in prisms (Fig. 224), and when impure in granules and knobs.

## EXPERIMENTS ON ALLANTOIN

**1. Separation from the Urine:**<sup>10</sup> *Meissner's Method.* Precipitate the urine with baryta water. Neutralize the filtrate carefully with dilute sulfuric acid, filter immediately, and evaporate the filtrate to incipient crystallization. Completely precipitate this warm fluid with 95 per cent alcohol (reserve the

precipitate). Decant or filter and precipitate the solution by ether. Combine the ether and alcohol precipitates, and extract with cold water or hot alcohol; allantoin remains undissolved. Bring the allantoin into solution in hot water and recrystallize.

FIG. 224. ALLANTOIN, FROM CAT'S URINE.

*a, b,* Forms in which it crystallized from the urine; *c,* recrystallized allantoin.

**2. Preparation from Uric Acid.** Dissolve 4 g. of uric acid in 100 ml. of water rendered alkaline with potassium hydroxide. Cool and carefully add 3 g. of potassium permanganate. Filter, immediately acidulate the filtrate with acetic acid, and allow it to stand in a cool place overnight. Filter off the crystals and wash them with water. Save the wash water and filtrate, unite them, and after concentra-

ting to a small volume stand away for crystallization. Now combine all the crystals and recrystallize them from hot water. Use these crystals in the experiments which follow.

**3. Microscopical Examination.** Examine the crystals made in Exp. 2 and compare them with those shown in Fig. 224.

**4. Furfural Test (Schiff).** Place a few crystals of allantoin on a test tablet or in a porcelain dish and add 1 to 2 drops of a concentrated aqueous solution of furfural and 1 to 2 drops of concentrated hydrochloric acid. Observe the formation of a yellow color, which turns to a light purple if allowed to stand. This test is given by urea but not by uric acid.

**5. Murexide Test.** Try this test according to the directions given on p. 796. Note that allantoin fails to respond.

## AMINO ACIDS

Certain of these acids are always present in normal urine. The excretion of total amino acid nitrogen by a normal adult averages 0.4 to 1.0 g. per day or about 2 to 6 per cent of the total nitrogen. Free amino acid nitrogen (for methods of estimation, see Chapter 31) is considerably less than this, and ordinarily constitutes 0.5 to 1 per cent of the total nitrogen. The

<sup>10</sup> The urine of the dog after thymus, pancreas, or uric acid feeding may be employed

amount may be largely increased in disorders associated with tissue waste, e.g., typhoid, acidosis, pronounced atrophy of the liver, etc. After extirpation of the liver, urea formation ceases and amino acids accumulate in the blood or are excreted in the urine if renal activity is maintained. For tests on amino acids, see Chapter 4.

The availability of microbiological assay (see p. 1061) and paper chromatography (see p. 14) has made possible the detection and estimation of the individual amino acids present in normal and pathological urine. In one study on 18 normal male and female subjects on a normal diet, Woodson, *et al.*<sup>10a</sup> found most of the common amino acids present in the urine, in either the free state or in a combined form or both. The mean 24-hour excretion of free amino acids ranged from approximately 1 mg. for aspartic acid to 188 mg. for histidine; for the combined form, from 2 mg. for methionine to 315 mg. for glutamic acid. Those amino acids excreted predominantly in the combined form included aspartic acid, glutamic acid, proline, valine, and isoleucine. The nature of the combined form is not known; either peptides or conjugates are possibilities. No correlation could be established between the excretion of the various amino acids and differences in urine volume, total nitrogen, uric acid, creatinine, or ammonia content of the urines examined.

Dent has made extensive studies of urinary excretion of amino acids, using the techniques of paper chromatography to which he has made valuable contributions.<sup>10b</sup> Investigations have been reported on the general aminoaciduria characteristic of Fanconi's syndrome; on the excessive excretion of cystine, lysine, and arginine in cystinuria; and on other anomalies of amino acid metabolism.

## AROMATIC OXYACIDS

Two of the most important of the oxyacids are *p*-hydroxyphenylacetic acid, and *p*-hydroxyphenylpropionic acid. They are products of the putrefaction of protein material and tyrosine is an intermediate stage in their formation. Both these acids for the most part pass unchanged into the urine, where they occur normally in very small amount. The content may be increased in the same manner as the phenol content, in particular by acute phosphorus poisoning. A fraction of the total aromatic oxyacid content of the urine is in combination with sulfuric acid, but the greater part is present in the form of salts of sodium and potassium.

Levine<sup>11</sup> has shown that the urine of premature infants fed cow's milk regularly contains certain aromatic oxyacids, such as *p*-hydroxyphenylpyruvic acid, the product of the deamination of tyrosine. Administration of vitamin C abolishes this defect. A similar observation has been noted by Sealock in the case of scorbutic guinea pigs (see discussion, p. 1043).

<sup>10b</sup> Dent: *Biochem. J.*, **41**, 240 (1947); **43**, 169 (1948); *Biochem. Soc. Symposia*, **3** (*Partition Chromatography*), 34 (1950); Dent and Rose: *Quart. J. Med.*, **20**, 205 (1951).

<sup>11</sup> Levine: *Science*, **90**, 620 (1939); *J. Clin. Invest.*, **22**, 551 (1943). See also Woolf and Edmunds: *Biochem. J.*, **47**, 630 (1950).

*Homogentisic acid* or 2,5-dihydroxyphenylacetic acid,

is another important oxyacid sometimes present in the urine. Under the name *glycosuric acid* it was first isolated from the urine by Marshall; subsequently Baumann isolated it and determined its chemical constitution. It occurs in cases of alcaptonuria (a so-called "inborn error of metabolism") and has also been found in the urine of the scorbutic guinea pig. A urine containing this oxyacid turns greenish-brown from the surface downward when treated with a little sodium hydroxide or ammonia. If the solution be stirred the color very soon becomes dark brown or even black. Homogentisic acid reduces alkaline copper solutions but not alkaline bismuth solutions.

*Kynurenic acid* or  $\gamma$ -hydroxy- $\beta$ -quinoline carboxylic acid is a product of the metabolism of tryptophan but it appears to be excreted only after the ingestion of this amino acid in excess of normal requirements (see p. 1040).

Its presence after tryptophan administration in the urine of the dog, rat, rabbit, hyena, coyote, wolf, etc., and absence from that of the civet, cheetah, bear, raccoon, etc. (Jackson) may have significance in the zoological classification of species.

## EXPERIMENT ON KYNURENIC ACID

**Isolation of Kynurenic Acid.** Acidify the urine with hydrochloric acid in the proportion 1:25. From this acid fluid both the uric acid and the kynurenic acid separate in the course of 24 to 48 hours. Filter off the combined crystalline deposit of the two acids, dissolve the kynurenic acid in dilute ammonia (uric acid is insoluble), and reprecipitate it with hydrochloric acid. If a solution containing kynurenic acid be evaporated to dryness with hydrochloric acid and potassium chlorate, a reddish residue is obtained which becomes first brownish green and then emerald green on adding ammonia (Jaffé).

Kynurenic acid may be quantitatively determined by Capaldi's method.<sup>12</sup>

## PROTEIN

The nubecula of normal urine has been shown by one investigator to consist of a mucoid containing 12.7 per cent of nitrogen and 2.3 per cent of

<sup>12</sup> Capaldi: *Z. physiol. Chem.*, **23**, 92 (1897); Berg: *J. Biol. Chem.*, **91**, 513 (1931).

sulfur. This substance evidently originates in the urinary passages. It is probably slightly soluble in the urine. Some investigators believe that the material forming the nubecula of normal urine is nucleoprotein and not a mucin or mucoid. A discussion of nucleoprotein and related substances occurring in the urine under pathological conditions will be found in Chapter 29.

Normal urine contains a small amount of soluble protein—albumin, various enzymes (see below), etc.; the amount is too slight to be detected by any but the most delicate procedures. The significance of pathological proteinuria is discussed in Chapter 29.

## CARBOHYDRATES

Normal human urine contains total reducing substances equivalent to about 0.05 to 0.15 per cent of glucose. Fermentable sugars make up about one-tenth of this or about 0.01 per cent. Whether all of the fermentable sugar is glucose is uncertain. Most of the sugar of normal urine is at any rate not glucose. The other sugars may include pentose, lactose, and altered carbohydrates formed by the baking of foods or through the action of bacteria in the intestinal tract. That glucose is not ordinarily excreted in more than traces is further indicated by the failure of glucose ingestion up to 1 g. per kg. of body weight to increase the fermentable urine sugar. In various types of nephritis the excretion of fermentable sugar is increased somewhat. Lactose may be found in the urine of pregnant women in appreciable amounts. In the rare conditions known as *pentosuria* and *fructosuria* these respective sugars may be present in readily detectable amount. Otherwise sugars are not normally found in sufficient amounts to give the ordinary sugar tests. Pathological glucosuria is discussed in Chapter 29.

## ENZYMES

Various types of enzymes produced within the organism are excreted in both the feces and the urine. In this connection it is interesting to note that pepsin, trypsin, lipase, and an amylase have been positively identified in the urine. The amylase may be much increased in pancreatic disease.<sup>13</sup>

## VITAMINS

The normal path of elimination of the fat-soluble vitamins is the intestinal tract. The water-soluble vitamins thiamine, riboflavin, ascorbic acid, and others, are excreted in the urine under normal conditions of vitamin nutrition, the amounts of these vitamins in the 24-hour excretion being directly proportional to the intake. Nicotinamide is normally eliminated in the form of the metabolite N<sup>1</sup>-methylnicotinamide. The urinary output of the water-soluble vitamins under controlled conditions forms the basis of clinical tests for vitamin deficiencies, since in such states the tissues are unsaturated and tend to retain the test doses of vitamins.

In a study on seven healthy males on a normal dietary regime<sup>14</sup> the following ranges of values were found for daily vitamin intake and output:

<sup>13</sup> Dodds: *Brit. J. Exptl. Path.*, **3**, 133 (1922).

<sup>14</sup> Denko, *et al.*: *Arch. Biochem.*, **10**, 33 (1946); **11**, 109 (1946).

| <i>Vitamin</i>                          | <i>Intake</i> | <i>Output</i> |              | <i>Average Excretion*</i> |
|-----------------------------------------|---------------|---------------|--------------|---------------------------|
|                                         |               | <i>Urine</i>  | <i>Feces</i> | <i>Per Cent</i>           |
| Thiamine, mg.                           | 1.24– 1.63    | 0.144– 0.323  | 0.109–0.895  | 57                        |

| Folic acid, $\mu$ g.                    | 43–86         | 2.94 – 4.99   | 222–393      | 542                       |
| Biotin, $\mu$ g.                        | 37–54         | 27.8 –35.6    | 114–201      | 378                       |
| p-Aminobenzoic acid, $\mu$ g.           | 97–220        | 131–198       | 183–361      | 230                       |

\* Per cent excretion = 100 (Urinary + Fecal output)/Intake.

The high excretion rates of the last three vitamins (particularly via the fecal route), is a reflection of the extent of synthesis by intestinal flora. The figures in this table do not represent the entire excretion of nicotinic acid and pyridoxine since their metabolites, N<sup>1</sup>-methylnicotinamide and 4-pyridoxic acid, respectively, were not included.

### VOLATILE FATTY ACIDS

Acetic, butyric, and formic acids have been found under normal conditions in the urine of man and of certain carnivora as well as in the urine of herbivora. Normally they arise principally from the fermentation of carbohydrates and the putrefaction of proteins. The acids containing the fewest carbon atoms (formic and acetic) are found to be present in larger percentage than those which contain a larger number of such atoms. The volatile fatty acids occur in normal urine in traces, the total output for 24 hours according to older investigators varying from 0.008 g. to 0.05 g. Formic acid excretion is increased in methyl alcohol poisoning.

### LACTIC ACID

Lactic acid is supposed to pass into the urine when the supply of oxygen in the organism is diminished through any cause, e.g., in pneumonia, eclampsia, acute yellow atrophy of the liver, carbon monoxide poisoning, acute phosphorus poisoning, or epileptic attacks. This acid has also been found in the urine of healthy persons following the physical exercise incident to prolonged marching. Liljestrand and Wilson found the output of lactic acid to vary from 140 mg. to 1370 mg. after a few minutes of strenuous physical exercise e.g., stair running. (See experiment, Chapter 33.) Lactic acid has been detected in the urine of birds after the removal of the liver.

### PHOSPHORYLATED COMPOUNDS

Phosphorus in organic combination has been found in the urine in such substances as glycerophosphoric acid, which may arise from the decomposition of lecithin, and phosphocarnic acid. It is claimed that on the

average about 2.5 per cent of the total phosphorus elimination is in organic combination.

## PIGMENTS

There are several pigments normally present in human urine, of which the most important is urochrome. Small amounts of urobilin, uroerythrin, and certain porphyrins (uroporphyrin and coproporphyrin) are also present.

**Urochrome.** Urochrome is the principal pigment of normal urine. Its chemical nature is not definitely established. It may be a compound of urobilin and urobilinogen with a peptide substance. It is a product of endogenous metabolism and is fairly constant in amount from day to day in the urine of normal individuals.

**Urobilin.** Urobilin is normally present in too small amount to give any appreciable color to the urine. It exists chiefly in the reduced form as the colorless urobilinogen which upon oxidation gives urobilin. (See Chapter 18.) It is derived from bile pigment by bacterial action in the bowel and most of it is excreted in the feces where the corresponding and probably identical compounds are known as stercobilinogen and stercobilin, respectively. Of the small amount absorbed the larger part is excreted in the bile.

## PURINE BASES

The purine bases found in human urine are adenine, epiguanine (7-methylguanine), guanine, xanthine, heteroxanthine (7-methylxanthine), hypoxanthine, paraxanthine (1,7-dimethylxanthine), and 1-methylxanthine. The main bulk of the purine base content of the urine is made up of 7-methylxanthine, 1,7-dimethylxanthine, and 1-methylxanthine, which are derived for the most part from the caffeine, theobromine, and theophylline of the food. The total purine base content is made up of the products of two distinct forms of metabolism, i.e., metabolism of ingested nucleoproteins and purines and metabolism of tissue nuclear material. Purine bases resulting from the first form of metabolism are said to be of *exogenous* origin, whereas those resulting from the second form of metabolism are said to be of *endogenous* origin. The daily output of purine bases by the urine is extremely small and varies greatly with the individual (16 to 60 mg.). The output is increased after the ingestion of nuclear material as well as after the increased destruction of leukocytes. A well-marked increase accompanies leukemia. The output of purine bases by the urine is increased as a result of x-ray treatment. The purine bases form a higher percentage of the total purine excretion in the case of the monkey, sheep, and goat than in man.

## EXPERIMENT ON PURINE BASES

**Formation of the Silver Salts.** Add an excess of magnesia mixture<sup>15</sup> to 25 ml. of urine. Filter off the precipitate and add ammoniacal silver solution to the filtrate. A precipitate composed of the silver salts of the various purine bases is produced. The purine bases may be determined quantitatively by Kruger and Schmidt's method or Welker's method (see Chapter 31).

---

<sup>15</sup> See Appendix.

## INORGANIC PHYSIOLOGICAL CONSTITUENTS

## AMMONIA

Next to urea, ammonia is quantitatively the most important of the nitrogenous end products of protein metabolism. Ordinarily about 2.5 to 4.5 per cent of the total nitrogen of the urine is eliminated as ammonia, and on the average this would be about 0.7 g. per day. The significance of the ammonia content of the urine appears to be primarily if not entirely concerned with the mechanisms of acid-base balance in the body (see Chapter 24). If ammonia is fed in the form of oxidizable organic salts, such as ammonium acetate, ammonium lactate, etc., no extra ammonia appears in the urine. The organic portion of the salt is oxidized, and the ammonia portion is converted into urea and excreted in this form. If, however, a nonoxidizable salt such as ammonium chloride is administered, while the ammonia portion is probably also converted into urea for excretion (since there is no reason to suppose that the metabolism of the ammonium ion differs with different salts) the excretion of the extra chloride ions requires the simultaneous excretion of an equivalent amount of base. This base must be either sodium, potassium, or ammonium ions themselves, since these are the only forms of base available to the kidney. In the presence of abundant sodium or potassium (fixed base), the extra chloride is excreted largely as the sodium or potassium salt and no disturbance of acid-base balance results. If, however, the supply of fixed base is limited, its excretion results in the development of an acidosis due to the depletion of body base; in fact, the administration of a large dose of ammonium chloride is used clinically for the production of an acidosis. The kidney therefore *synthesizes* ammonia (volatile base) to the limit of its capacity under these conditions to conserve body base, the extra ammonia is excreted in the urine, and the urinary ammonia content rises. Excretion of acid phosphate also occurs here (see p. 818). That the ingested ammonia of the ammonium chloride plays no important part in the increased excretion of ammonia is shown by the fact that exactly the same condition occurs if hydrochloric acid is administered instead of ammonium chloride; there is a rise of urinary ammonia accompanying the increased excretion of chloride. Acid-forming foods (see Chapter 34) also increase the ammonia output, whereas the administration of alkalies or of base-forming foods decreases the excretion of ammonia. Copious water drinking increases the ammonia output. This fact has been interpreted as indicating a stimulation of the gastric secretion.

The acids formed during the process of protein destruction within the body (i.e., sulfuric acid formed by oxidation of the sulfur of methionine and cystine) have an influence upon the excretion of ammonia similar to that exerted by acids which have been administered. Therefore a pathological increase in the output of ammonia is observed in such diseases as are accompanied by an increased and imperfect protein metabolism. Likewise in diabetes mellitus, where the excretion of excessive amounts of acetoacetic acid and  $\beta$ -hydroxybutyric acid as their salts also tends to deprive the body of fixed base, increased excretion of ammonia occurs.

The kidney is the source of urinary ammonia. This is indicated by the fact that following extirpation of the kidneys the blood ammonia does not increase. On removal of the liver blood ammonia increases but not urinary ammonia. This indicates that the two have not the same origin. The blood ammonia appears to arise from the tissues, especially the muscles (probably from the deamination of adenylic acid) and to be converted so readily to urea that the blood ammonia remains too low to account for any appreciable part of the urinary ammonia. Ammonia is apparently formed by the cells of the tubules of the kidney. The precursor is believed to be an amide-nitrogen compound, probably *glutamine*, in blood plasma (Van Slyke) from which the enzyme *glutaminase* forms ammonia and glutamic acid. Deamination of amino acids by kidney tissue may also account for a small portion, possibly through the intermediate formation of glutamine. A decrease in the pH of the blood or of the kidney tissue seems to speed up the ammonia-producing mechanism.

The quantitative determination of ammonia must be made upon fresh or properly preserved urine, since upon standing normal urine will undergo ammoniacal fermentation (see p. 784).

## EXPERIMENT ON AMMONIA

(See Exp. 2 under "Experiments on Phosphates," p. 819.)

## SULFATES

Sulfur in combination is excreted in two forms in the urine: first, as unoxidized, loosely combined or neutral sulfur, and second, as oxidized or acid sulfur. The excretion of neutral sulfur has already been discussed (p. 807). The oxidized sulfur is eliminated chiefly in the form of the inorganic sulfate ion; a relatively small amount occurs in the form of ethereal sulfate, i.e., salts of sulfuric acid in combination with such aromatic substances as phenol, indole, skatole, cresol, pyrocatechol, and hydroquinol. This latter form of sulfuric acid is sometimes called conjugate sulfuric acid. The greater part of the total sulfur is eliminated in the oxidized form, but the absolute percentage of sulfur excreted in the various forms depends upon the total quantity of sulfur present; i.e., there is no definite ratio between the three forms of sulfur which will apply under all conditions. The preformed or inorganic sulfuric acid may be precipitated directly from acidified urine with  $\text{BaCl}_2$ , whereas the ethereal sulfuric acid must undergo a preliminary hydrolysis before it can be so precipitated.

The sulfuric acid excreted in the urine arises principally from the oxidation of the sulfur of protein within the body; a relatively small amount is due to ingested sulfates. Under normal conditions about 1.0 g. of total S is eliminated daily, about 75 to 95 per cent of this being in the form of sulfates. About 90 per cent of this sulfate excretion is in the form of inorganic sulfate and 10 per cent as ethereal sulfates and neutral sulfur.

The sulfate ion is excreted with greater difficulty than any other inorganic radical ordinarily present in normal blood. A retention of 30 times the normal blood value (0.9 to 1.1 mg. of S per 100 ml. of whole blood)

has been observed. Sulfate ions are not readily absorbed by the tissues even when present in high concentration in the blood.

## EXPERIMENTS ON SULFATES

**1. Detection of Inorganic Sulfuric Acid.** Place about 10 ml. of urine in a test tube, acidify with acetic acid, and add some barium chloride solution. A white precipitate of barium sulfate forms.

**2. Detection of Ethereal Sulfuric Acid.** Filter off the barium sulfate precipitate formed in the above experiment, add 1 ml. of hydrochloric acid and a little barium chloride solution to the filtrate and heat the mixture to boiling for 1 to 2 minutes. Note the appearance of a turbidity due to the presence of sulfuric acid which has been hydrolyzed from the ethereal sulfates and has reacted with  $\text{BaCl}_2$  to form  $\text{BaSO}_4$ .

**3. Detection of Unoxidized or Neutral Sulfur.** Place about 10 ml. of urine in a test tube, introduce a small piece of zinc, add sufficient hydrochloric acid to cause a gentle evolution of hydrogen, and over the mouth of the tube place a filter paper saturated with lead acetate solution. In a short time the portion of the paper in contact with the vapors within the test tube becomes blackened due to the formation of lead sulfide. The nascent hydrogen has

reacted with the loosely combined or neutral sulfur to form hydrogen sulfide, and this gas coming in contact with the lead acetate paper has caused the production of the black lead sulfide. Sulfur in the form of inorganic or ethereal sulfuric acid does not respond to this test. (For discussion of neutral sulfur compounds, see p. 807.)

FIG. 225. CALCIUM SULFATE (HENSEL AND WEIL).

**4. Calcium Sulfate Crystals.** Place 10 ml. of urine in a test tube, add 10 drops of calcium chloride solution, and allow the tube to stand until crystals form. Examine the calcium sulfate crystals under the

microscope and compare them with those shown in Fig. 225.

## CHLORIDES

Next to urea, the various chlorides constitute the chief solid constituent of the urine. The excretion of chloride is dependent, in great part, upon the nature of the diet, but, on the average, the daily output is about 10 to 15 g. expressed as sodium chloride. Conditions which favor excessive perspiration, such as strenuous athletic or occupational activity, especially in a hot environment, cause a diminution in urinary output of chlorides, the chloride leaving the body by other channels. Muscular cramps may result when there is an excessive loss of sodium chloride from the body. To obviate this condition, workers in a high-temperature environment or persons indulging in very fatiguing muscular efforts, such as athletes in prolonged competition, make use of salt tablets. Because of their solubility, chlorides are never found in the urinary sediment.

The amount of chlorides excreted in the urine is related primarily to the chloride content of the food ingested. In cases of actual fasting the

chloride content of the urine may be decreased to a slight trace which is derived from the body fluids and tissues. Under these conditions, however, an examination of the blood of the fasting subject will show the content of chloride in this fluid to be approximately normal. This forms a very striking example of the care nature takes to maintain the normal composition of the blood. There is a limit to the power of the body to maintain this equilibrium, however, and if the fasting organism be subjected to the influence of diuretics for a time, a point is reached where the normal composition of the blood can no longer be maintained and a gradual decrease in its chloride content occurs which finally results in death. Since the excreted chloride must carry base (e.g., sodium) along with it, death results not so much from the loss of chloride alone as from the inability of the organism to maintain a normal osmotic pressure in its body fluids, which is a major function of the sodium and chloride ions. Potassium cannot take the place of sodium in this respect, thus the administration of potassium chloride under these conditions is of no value whatever.

Pathologically, the excretion of chlorides may be decreased in some fevers, chronic nephritis, fasting, diarrhea, certain stomach disorders, and after extensive burns. Any condition accompanied by the formation of an exudate (e.g., pneumonia) will cause a diminished chloride output. In convalescence and with resolution of the exudate the chloride excretion rises again.

## EXPERIMENTS ON CHLORIDES

**Detection of Chlorides in Urine.** Place about 5 ml. of urine in a test tube, render it acid with nitric acid, and add a few drops of a solution of silver nitrate. A white precipitate, due to the formation of silver chloride, is produced. This precipitate is soluble in ammonium hydroxide.

## PHOSPHATES

Of the various inorganic anions of urine, phosphate is ordinarily second only to chloride in amount present. The excretion of phosphate is extremely variable, depending in large measure upon the diet, but on the average the total output for 24 hours is about 1.1 g. expressed as P. The bulk of this is in the form of inorganic phosphate, the organic phosphorus of the urine constituting only about 1 to 4 per cent of the total phosphorus content. The greater part of the inorganic phosphate arises from the ingested food, either from phosphate already present as such or more especially from the metabolism of compounds containing phosphorus in organic combination, such as *phosphoproteins*, *nucleoproteins* and *nucleotides*, and *phospholipides*. The various phosphorus-containing compounds of the body also contribute to the total output of this element. The phosphate content of the urine also depends to a considerable extent on conditions within the intestinal lumen; an increased alkalinity together with the presence of substances like calcium and magnesium which form insoluble phosphates tends to increase the proportion of phosphate excreted in the feces at the expense of the urinary phosphate content.

The phosphate ion is found in the urine in two forms, the acid phosphate or monobasic ion,  $\text{H}_2\text{PO}_4^-$ , and the dibasic ion,  $\text{HPO}_4^-$ . The ratio of

these two ions determines in large measure the pH of the urine, since they constitute the major buffer system ordinarily present. In blood and in the glomerular ultrafiltrate of the kidney, these ions are present in a ratio corresponding to about 80 per cent basic phosphate and 20 per cent acid phosphate. If this ratio prevails in the urine, it will have the same pH as the blood, or approximately 7.4. Increased acidity of the urine is due to an increase in the amount of the acid phosphate relative to basic phosphate; at pH 6.6, which is approximately the pH of average urine, about 60 per cent of the total inorganic phosphate is in the acid form and 40 per cent appears as basic phosphate. The best available evidence indicates that the ability of the kidney to excrete a varying fraction of its total phosphate in either the acid or basic forms is an important part of the mechanism for the regulation of acid-base balance in the body; actually, the excretion of one equivalent of acid phosphate instead of basic phosphate corresponds to the excretion of one equivalent of hydrogen ion itself, and the simultaneous retention of one equivalent of base, as inspection of the formulas of these two salts will show. In combating acidosis, this mechanism appears to be of importance second only to the ability of the kidneys to replace sodium or potassium by ammonium. Available evidence indicates that the change from acid to basic phosphate and *vice versa* is brought about in the renal tubules, possibly by secretion of hydrogen ions (Pitts), since the total phosphate excretion does not vary with changes in the relative amounts of the acid and basic forms excreted.

If urine containing phosphate is rendered sufficiently alkaline, the so-called "alkaline earth" elements calcium and magnesium will precipitate, to the extent of their presence, as insoluble calcium and magnesium phosphates. This fraction of the total phosphate of urine was formerly called the "earthy phosphate" fraction as contrasted to the "alkaline phosphate" fraction composed of the soluble phosphates of sodium, potassium, and ammonium. It is doubtful whether this fractionation has any significance other than to indicate the amount of calcium and magnesium present relative to the total phosphate, and it should be abandoned.

The so-called "phosphaturia," the appearance of a copious crystalline precipitate which on examination proves to be magnesium ammonium phosphate ("triple phosphate"), ordinarily represents a decreased acidity of the urine and not an increased phosphate content. Such conditions may, however, be of significance in connection with a possible tendency to the formation of phosphate calculi. Measures designed to acidify the urine, and to decrease its phosphate content, have been of value in the treatment of this condition.

Pathologically the excretion of phosphoric acid is increased in such diseases of the bones as diffuse periostosis, osteomalacia, and rickets; according to some investigators, in the early stages of pulmonary tuberculosis, in acute yellow atrophy of the liver, in diseases which are accompanied by an extensive decomposition of nervous tissue, and after sleep induced by potassium bromide or chloral hydrate (Mendel). It is also increased after copious water drinking. A decrease in the excretion of phosphates is at times noted in febrile affections, such as the acute infec-

tious diseases, in pregnancy, in the period during which the fetal bones are forming, and in diseases of the kidneys, because of nonelimination.

## EXPERIMENTS ON PHOSPHATES

**1. Formation of "Triple Phosphate."** Place some urine in a beaker, render it slightly alkaline with ammonium hydroxide, add a small amount of magnesium sulfate solution, and allow the beaker to stand in a cool place overnight. Crystals of ammonium magnesium phosphate, "triple phosphate," form under these conditions. Examine the crystalline sediment under the microscope and compare the forms of the crystals with those shown in Fig. 226. If possible, examine the crystals from a freshly passed specimen of cloudy urine, or from a sample of urine which on standing for a short while after

FIG. 226. TRIPLE PHOSPHATE (OGDEN).

voiding has become cloudy. How do they compare with those obtained in this experiment?

**2. Ammoniacal Fermentation.** Stand some urine aside in a beaker for several days. Ammoniacal fermentation will develop and "triple phosphate" crystals will form.

*a.* Examine the sediment under the microscope and compare the crystals with those shown in Fig. 226.

*b.* Hold a glass rod dipped in concentrated hydrochloric acid near the surface of the urine. Note the fumes of ammonium chloride.

*c.* Insert a strip of red litmus paper in the urine. Permit the paper to dry. Note the gradual restoration of red color, due to volatilization of ammonia (volatile alkali). Run a control test using 0.5 per cent  $\text{Na}_2\text{CO}_3$  (fixed alkali).

## SODIUM AND POTASSIUM

Sodium and potassium ions are always present in the urine. The amount of potassium excreted in 24 hours by an adult, subsisting upon a mixed diet, is on the average 1 to 3 g., whereas the amount of sodium under the same conditions is ordinarily 3 to 5 g. The ratio of K to Na is generally about 3:5. The absolute quantity of these elements excreted depends, of course, in large measure upon the nature of the diet. Because of the noningestion of NaCl and the accompanying destruction of potas-

sium-containing body tissues, during fasting the urine contains more potassium than sodium.

Pathologically the output of potassium, in its relation to sodium, may be increased during fever; following the crisis, however, the output of this element may be decreased. It may also be increased in conditions associated with acidosis. In Addison's disease there is usually a relative retention of potassium and an increased excretion of sodium; the administration of cortical hormone preparations restores the normal relationship.

CALCIUM AND MAGNESIUM

The daily output of calcium in the urine, which depends principally upon the nature of the diet, is on the average about 0.1 to 0.3 g. per day. The percentage of calcium present in the urine at any one time (10 to 40 per cent of total calcium output) forms no dependable index as to the absorption of this element, since it may be again excreted into the intestine after absorption. Furthermore, as with phosphate (p. 817), the acidity or alkalinity of the intestinal lumen, and the presence of substances such as phosphate and fatty acids which form insoluble calcium salts, may determine to a considerable extent the relative output of calcium in the feces and the urine. Acidity promotes calcium absorption, alkalinity retards it. It is therefore impossible to draw any satisfactory conclusions regarding the excretion of calcium unless accurate analytical data from both the feces and the urine are obtained.

Myers and Fine<sup>16</sup> have reported data showing a comparison of the kidney and intestine as excretory routes for various inorganic constituents. Their findings in this connection are summarized in the following table:

| Number of Cases | Moisture Content of Feces (Per Cent) | Fecal Output in Per Cent of Total in Urine and Feces |    |    |    |    |    |    |    |
|-----------------|--------------------------------------|------------------------------------------------------|----|----|----|----|----|----|----|
|                 |                                      | H <sub>2</sub> O                                     | N  | S  | Cl | P  | Ca | Mg | K  |
| 5               | 76                                   | 6                                                    | 10 | 10 | 3  | 36 | 90 | 72 | 18 |
| 9               | 84                                   | 16                                                   | 15 | 19 | 9  | 33 | 89 | 68 | 27 |

The average findings in five cases with well-formed stools, 74 to 79 per cent moisture, and those with diarrheal stools, 79 to 89 per cent moisture, have been grouped separately in the table. It is not believed that the findings differed especially from the normal, except in that group of cases which suffered from intestinal diarrhea.

Very little is known positively regarding the actual course of the excretion of calcium under pathological conditions. An excess is found in some diseases of the bones, e.g., osteomalacia. In others, as in rickets, the urinary excretion may be very low.

The daily excretion of magnesium by way of the urine usually amounts to between 0.05 and 0.2 g. The amount depends mainly on the diet. About 65 per cent or more of the excreted magnesium is usually eliminated by

<sup>16</sup> Myers and Fine: *Proc. Soc. Exptl. Biol. Med.*, **16**, 73 (1919).

the feces; the remainder passes out in the kidneys. There may be a retention of magnesium in certain bone disorders accompanying a loss of calcium, for example, in osteomalacia. Thus the excretion of calcium and magnesium do not necessarily run parallel.

## EXPERIMENT ON CALCIUM

**Sulkowitch Test.** This is a qualitative test for calcium in the urine. It has applications in parathyroid derangement, urinary calculi, infantile tetany, severe nephritis, etc.

**Procedure.** Place the patient on a diet containing sufficient calcium for his needs, and collect a 24-hour specimen of urine. To 5 ml. of the mixed urine sample add 2 ml. of the Sulkowitch reagent<sup>17</sup> dropwise. If no precipitate forms immediately, mix the contents of the tube thoroughly and allow to stand.

**INTERPRETATION.** In case there is *no precipitate* there is of course no calcium in the urine. From this finding it is concluded that the blood serum probably contains not more than 5 to 7.5 mg. per 100 ml. If the precipitate forms as a fine white cloud, the calcium content of the serum is considered to fall within the *normal range* of 9 to 11 mg. per 100 ml. However if a heavy, milklike precipitate forms, there is danger of *hypercalcemia*. In routine examinations, the precipitates may be graded 1, 2, 3 or 4.

## CARBONATES

Carbonate, in the form of the bicarbonate ion,  $\text{HCO}_3^-$ , generally occurs in small amount in the neutral or alkaline urine of man and carnivora, whereas much larger quantities are ordinarily present in the consistently alkaline urine of herbivora. The alkaline reaction of the urine of herbivora is due in great measure to the presence of bicarbonate. The carbonates of the alkaline earths are sometimes found in amorphous urinary sediments from quite alkaline urine.

## IRON

Iron is present in small amount in normal urine. It probably occurs partly in inorganic and partly in organic combination. The iron contained in urinary pigments or chromogens is in organic combination. According to different investigators the iron content of normal urine probably averages not more than 1 to 2 mg. per day. Mitchell and Hamilton<sup>18</sup> report that sweat contains 1–2 mg. of iron per liter. After splenectomy there is an increased loss of iron from the body particularly by way of the feces.

## EXPERIMENT ON IRON

**Detection of Iron in Urine.** Evaporate a convenient volume (10 to 15 ml.) of urine to dryness. Incinerate and dissolve the residue in a few drops of iron-free hydrochloric acid and dilute the acid solution with 5 ml. of water. Divide the acid solution into two parts and make the following tests: (a) To the first part add a solution of ammonium thiocyanate; a red color indicates

<sup>17</sup> 2.5 g. of oxalic acid, 2.5 g. of ammonium oxalate and 5 ml. of glacial acetic acid, made up to 150 ml. with distilled water.

<sup>18</sup> Mitchell and Hamilton: *J. Biol. Chem.*, **178**, 345 (1950).

the presence of iron. (b) To the second part of the solution add a little potassium ferrocyanide solution; a precipitate of prussian blue forms upon standing.

## FLUORIDES, NITRATES, AND SILICATES

These substances are all found in traces in human urine under normal conditions. Nitrates are undoubtedly introduced into the organism in the water and ingested food. The average excretion of nitrates is about 0.5 g. per day, the output being the largest upon a vegetable diet and smallest upon a meat diet. Nitrites are found only in urine which is undergoing decomposition and are formed from nitrates in the course of ammoniacal fermentation.

## Urine: Pathological Constituents

Many of the substances considered in this chapter as pathological constituents of urine are present in small amount in normal urine. Hence their pathological significance may be more a question of the amount present than of their actual presence in or absence from urine. It is generally true, however, that the usual qualitative tests for these substances are of such sensitivity as to yield an essentially negative result when applied to normal urine, but to respond readily when unusual amounts are present. In this connection it is well to remember that a single specimen of urine may be sufficiently concentrated or otherwise influenced by dietary or other factors as to yield a positive result with a particular test, the significance of which disappears, however, when considered in the light of the total 24-hour excretion. Whenever possible, therefore, unless it is desired otherwise for special purposes, it is recommended that urine tests be carried out on a portion of the well-mixed and properly preserved 24-hour urine before interpreting results; if this is not feasible, the overnight sample collected before breakfast should be used.

### GLUCOSE

Traces of this sugar may occur in normal urine, but the amount is ordinarily too small to be demonstrable by the common qualitative tests (see also Chapter 31). The presence of readily detectable amounts of glucose in urine is known as *glucosuria*; the term *glycosuria* is frequently used, but this expression more correctly refers to the presence of any sugar, not necessarily glucose, in the urine. Glucosuria may be either benign or pathological, and it is important to distinguish between these two types. Renal diabetes, in which the kidney threshold for glucose is below normal but the blood sugar level is normal, is an example of a benign glucosuria, as are the glucosurias associated with alimentary and emotional hyperglycemias. Pathological glucosurias include chiefly those of diabetes mellitus and other endocrine disorders, in which there is a marked elevation of the blood sugar and usually an increased volume of urine (polyuria). The glucose content of the urine in diabetes mellitus may be as high as 10 per cent or more, but is usually around 3 to 5 per cent. The urine may be light in color and have a high specific gravity.

### TESTS FOR GLUCOSE

The various tests for glucose in the urine which are embraced in the experiments given herewith are based upon one of the following properties

of this sugar, as discussed in Chapter 2: (1) Its power to *reduce the ions of certain metals in alkaline solution*; (2) its power to *rotate the plane of polarized light*; (3) its power to *form a crystalline osazone with phenylhydrazine*; and (4) its ability to *ferment with ordinary yeast*.

*None of these tests by itself is specific for glucose.* Positive evidence that the sugar is glucose may be obtained by demonstrating that the reducing power disappears after yeast fermentation and that a typical glucosazone is obtained in the absence of a positive test for fructose or mannose (see below). Quantitative measurement of optical rotation in relation to total reducing power is also of value.

The official test for glucose adopted by the Association of Life Insurance Medical Directors of America may be found in Chapter 31.

**1. Phenylhydrazine Reaction.** Yellow crystalline compounds called *osazones* are formed from certain sugars by reaction with phenylhydrazine, in general each individual sugar giving rise to an osazone of a definite crystalline form which is typical for that sugar.

As applied to urine, however, it is frequently difficult to obtain characteristic crystals, even for glucose, since crystal form and growth may be influenced by other substances present. Better results are usually obtained if the urine is clarified first, as described below. Results are more significant if they are positive (i.e., if characteristic crystals are obtained) than if they are negative, but in any event the test should be regarded as a guide or confirmation, to be accompanied by more specific tests. Identification of the individual sugar osazones by their melting points is of little value.

In this connection it is important to remember that of the simple sugars of interest in physiological chemistry, glucose, fructose, and mannose give the same osazone. Fructose may be ruled out by the absence of a positive Selivanoff test (see p. 848); the presence of mannose will be indicated by the formation of a colorless crystalline *hydrazone* on treatment with phenylhydrazine in the cold, prior to the heating which produces the osazone.

**Procedure.** To a small amount of phenylhydrazine mixture<sup>1</sup> (about one-half inch in a small test tube), add 5 ml. of the urine, shake well, and heat on a boiling water bath for one-half to three-quarters of an hour. Allow the tube to cool slowly (not under the tap) and examine the crystals microscopically (see Plate II, opposite p. 63). If the solution has become too concentrated in the boiling process it will be light red in color and no crystals will separate until it is diluted with water.

In case doubtful results are obtained by this test owing to the presence of interfering substances, the urine should be clarified and the test repeated. To clarify the urine introduce 10 ml. into a test tube, add 1 g. of pure blood charcoal, heat to boiling and allow to stand with occasional shaking for five minutes, then filter. Use the filtrate in the test.

**2. Reduction Tests.** It is to their potential aldehyde or ketone structure that many sugars owe the property of readily reducing alkaline solutions of metals like copper, bismuth, mercury, and iron; they also

<sup>1</sup> See Appendix.

possess the property of reducing ammoniacal silver solutions with the separation of metallic silver. Upon this property of reduction the most widely used tests for sugars are based. A positive reduction test is not specific for glucose, or even for reducing sugars in general; non-sugar-reducing material is present in traces in normal urine and may be sufficiently augmented in amount, particularly in concentrated urines, to give a positive test. Other factors which may influence interpretation of results are discussed below. The chemistry of the various reduction tests and reagents is discussed in Chapter 2.

*a. Fehling's Test.* To about 1 ml. of Fehling's solution<sup>2</sup> in a test tube add about 4 ml. of water, and boil.<sup>3</sup> This is done to determine whether the solution will of itself cause the formation of a precipitate of brownish-red cuprous oxide. If such a precipitate forms, the Fehling's solution must not be used. Add urine<sup>4</sup> to the hot Fehling's solution, a few drops at a time, and heat the mixture to boiling after each addition (never add more urine than the original volume of Fehling's solution). The production of yellow or brownish-red cuprous oxide indicates that reduction has taken place. The yellow precipitate is more likely to occur if the urine is added rapidly and in large amount, whereas with a less rapid addition of smaller amounts of urine the brownish-red precipitate is generally formed. The differences in color of the cuprous oxide precipitates under different conditions are apparently due to differences in the size of the particles, the more finely divided precipitates having a yellow color, while the coarser ones are red. In the presence of protective colloidal substances the yellow precipitate is usually formed.

This classical test is not entirely reliable when used to detect sugar in the urine, and has been largely replaced by Benedict's test (see below). Such compounds as conjugate glucuronates, uric acid, nucleoprotein, and homogentisic acid, when present in sufficient amount, may produce a result similar to that produced by sugar. Phosphates of the alkaline earths may be precipitated by the alkali of the Fehling's solution as a grayish-white precipitate which should not be mistaken for the cuprous oxide. Cupric hydroxide may also be reduced to cuprous oxide and this in turn may form a soluble complex with creatinine, a normal urinary constituent. This will give the urine under examination a greenish tinge and may obscure the sugar reaction even when a considerable amount of sugar is present.

Conjugate glucuronates are present in normal urine in small amount (see p. 842) and are increased in amount after the ingestion of such substances as chloral hydrate, camphor, menthol, thymol, antipyrine, phenol, etc. The chloral hydrate is excreted in the urine as trichloroethylglucuronate. This compound reduces Fehling's solution and is levorotatory, whereas glucose also reduces but is dextrorotatory. Therefore by means

---

<sup>2</sup> See Appendix.

<sup>3</sup> More dilute Fehling's solution should be used in testing urines containing small amounts of sugar. In case of urines containing a high concentration of sugar it may sometimes be desirable to use a larger volume of Fehling's solution.

<sup>4</sup> In case doubtful results are obtained by this test owing to the presence of interfering substances the urine should be clarified with charcoal as described above, and the test repeated.

of a polariscopic test a "chloral urine" may be differentiated from a "sugar urine."

In testing urine preserved by chloroform a positive test may be obtained in the absence of sugar. This is due to the fact that the hot alkali produces a reducing substance from the chloroform.

Ammonium salts also interfere with Fehling's test preventing the precipitation of cuprous oxide. If they are present in excess, the urine should be made alkaline with strong sodium carbonate, and boiled (or, better, aerated with a vigorous stream of air) to decompose and liberate the ammonia.

**b. Benedict's Test.** This is the most satisfactory of the copper reduction tests, and in laboratory practice has largely replaced Fehling's. The following is the procedure for the detection of glucose in urine: To 5 ml. of the reagent<sup>5</sup> in a test tube add exactly 8 drops of the urine to be examined. The fluid is then boiled vigorously for from one to two minutes and then allowed to cool spontaneously. (Do not hasten cooling by immersion in cold water.) The test may also be carried out by heating for five minutes in a boiling water bath, removing, and allowing to cool in the air. This procedure is recommended for serial tests. If a water bath is used, it is important that the urine and reagent be thoroughly mixed before placing in the water bath. In the presence of glucose the entire body of the solution will be filled with a colloidal precipitate, which may be green, yellow, or red in color, depending upon the amount of sugar present. In the presence of over 0.2 to 0.3 per cent of glucose, the precipitate will form quickly. If no glucose is present, the solution will either remain perfectly clear, or will show a very faint turbidity, due to precipitated urates.

Even very small quantities of glucose in urine (0.1 per cent) yield precipitates of surprising bulk with this reagent, and the positive reaction for glucose is the filling of the entire body of the solution with a precipitate, so that the solution becomes opaque. Since amount rather than color of the precipitate is made the basis of this test, it may be applied, even for the detection of small quantities of glucose, as readily in artificial light as in daylight. Chloroform does not interfere with this test nor does uric acid or creatinine interfere to such an extent as in the case of Fehling's test. It is common clinical practice to run this test under consistently uniform conditions (same amount of urine, heating time, etc.) and to indicate the intensity of the reaction by arbitrary signs (+, ++, +++, etc.) as an index not only of the presence of sugar but also of its approximate relative concentration.<sup>6</sup>

**c. Bismuth Reduction Test (Nylander).** To 5 ml. of urine in a test tube add one-tenth its volume of Nylander's reagent<sup>5</sup> and heat for 5 minutes in a

---

<sup>5</sup> See Appendix.

<sup>6</sup> A simple modification of the copper reduction test for urine sugar is available commercially in the form of tablets containing copper sulfate, sodium hydroxide, and citric acid ("Clinitest" tablets, obtainable from the Ames Co., Inc., Elkhart, Indiana). In use, a little urine is diluted with 2 volumes of water and a tablet added to the mixture. Application of external heat is unnecessary. After the mixture has stood for a few moments, the typical appearance of a positive copper reduction test is obtained if the urine contains reducing sugar.

boiling water bath.<sup>7</sup> The mixture will darken if reducing sugar is present, and upon standing for a few moments a black color will appear.

This color is due to the precipitation of bismuth.<sup>8</sup> If the test is made on urine containing albumin this must be removed, by boiling and filtering, before applying the test, since with albumin a similar change of color is produced. Glucose when present to the extent of 0.08 per cent or even less may be easily detected by this reaction. Uric acid, creatinine, and homogentisic acid which interfere with the Fehling test, do not interfere with the Nylander reaction.

Urine rich in indican, uroerythrin, urochrome, or porphyrins, as well as urine excreted after the ingestion of large amounts of certain drugs, may give a darkening of the Nylander's reagent similar to that of a true sugar reaction. It has been claimed that the urine after the administration of urotropin will reduce the Nylander reagent.

A positive bismuth reduction test is probably due to the following reactions:

Before testing the urine, Bohmansson treats 10 ml. with 2 ml. of 25 per cent hydrochloric acid and 4 to 5 g. of boneblack. This mixture is shaken one minute, then filtered, and the neutralized filtrate tested by Nylander's reaction. He claims that this procedure removes certain interfering substances, notably urochrome.

### 3. Fermentation Tests.

**a. Saccharometer Method.** Rub up in a mortar about 15 ml. of urine with a small piece of compressed yeast or with about 0.5 g. active dry yeast. Treat in the same way 15 ml. of urine known not to contain glucose and 15 ml. of urine to which glucose has been added. These are necessary controls. Transfer each mixture to a saccharometer (Fig. 15, p. 69) and stand it aside in a warm place for about 12 hours. If glucose is present, alcoholic fermentation will occur and carbon dioxide will collect as a gas in the upper portion of the tube. On the completion of fermentation, fill the bulb portion of the saccharometer with 10 per cent sodium hydroxide solution, close the opening of the apparatus tightly with the thumb, mix the contents thoroughly, and restore the gas space to the limb of the saccharometer. Holding the apparatus at arm's length and with face averted (to avoid accidents) remove the thumb from the opening. Remembering that sodium hydroxide has the power to absorb carbon dioxide, how do you explain the result?

Ordinary bakers' yeast (*Saccharomyces cerevisiae*) will readily ferment glucose, fructose, mannose, maltose, and sucrose. Galactose, lactose, and the various pentoses are not fermentable, or, if so, at such a slow

---

<sup>7</sup> Hammarsten suggests that the solution be boiled for two to five minutes (according to the sugar content) over a free flame and the tube then permitted to stand five minutes before drawing conclusions.

<sup>8</sup> A dry powder containing the ingredients for a Nylander test is available commercially under the name of "Galatest" powder (obtainable from the Denver Chemical Mfg. Co., Inc., New York City). In use, a drop of urine is placed on a small amount of the powder. If reducing sugar is present, the powder turns gray or black.

rate as to be of no practical significance in connection with the above test; yeast which readily ferments galactose may be obtained, however, by incubation and growth of ordinary baker's yeast on a medium rich in galactose. Thus the yeast fermentation test is of considerable practical value in distinguishing between glucosuria, lactosuria, and pentosuria, either simple or mixed, particularly when exhaustive yeast fermentation is used in connection with reduction tests before and after treatment with yeast, as in Mathews' procedure which follows.

**b. Mathews' Modification for Distinguishing Fermentable Sugar (Glucose) from Nonfermentable Reducing Substances (Lactose, etc.).** Mix 20 ml. of urine in a test tube with 2–3 g. of active dry yeast, stirring vigorously. Place at an angle of about 45° in a beaker of water and keep at 42° C. for 50 minutes, mixing occasionally. If 1 per cent or more of glucose is present, an evolution of gas bubbles will be observed after a few minutes and all glucose will be decomposed (up to 6 per cent) in 50 minutes. Filter and apply Benedict's test. A positive test indicates the possibility of lactose, but only if a control test using the same amount of yeast with urine containing added glucose demonstrates that the yeast is capable of removing all glucose under the experimental conditions. Reducing sugar may also be determined quantitatively before and after the fermentation.

**4. Polariscopic Examination.** For directions as to the use of the polariscope, see p. 69, and for application to the quantitative analysis of urine, Chapter 31.

## PROTEINS

Normal urine contains a trace of protein material, but the amount present is so slight as to escape detection by any of the simple tests in general use for the detection of protein urinary constituents. The following are the more important forms of protein material which have been detected in the urine under pathological conditions:

1. Serum albumin
2. Serum globulin
3. Non-blood proteins { Proteoses and peptones  
Proteins of Bence-Jones and of Hektoen,  
Kretschmer, and Welker
4. Nucleoprotein
5. Fibrin
6. Oxyhemoglobin and related compounds
7. Myoglobin

## ALBUMIN

Normal urine contains a trace of albumin which is too slight to be detected by the usual procedures. *Albuminuria* is the condition in which readily detectable amounts of the serum proteins are found in the urine. The proteinuria is most commonly due to the presence of serum albumin, since albumin is the most abundant of these serum proteins, and has the smallest molecular size, thus permitting the greatest diffusion through damaged membranes. It is not uncommon, however, to find significant amounts of globulin material in so-called albuminuria if the proper tests

are applied. There is some uncertainty as to whether or not the serum proteins are altered from their normal state when found in the urine.

There are two distinct forms of albuminuria, viz., renal albuminuria and accidental albuminuria. Sometimes the terms *true albuminuria* and *false albuminuria* are substituted for those just given. In the renal type the albumin is excreted by the kidneys. This indicates a more serious condition and at the same time is more frequently encountered than the accidental type. Associated with renal albuminuria are usually altered blood pressure or kidney structure. In the accidental form of albuminuria the albumin is *not* excreted by the kidneys (as is the case in the renal form of the disorder) but arises from the blood, lymph, or some albumin-containing exudate coming into contact with the urine at some point below the kidneys.

The determination of albumin may be of assistance in following the course of kidney disturbances, but the results can only be interpreted in the light of other clinical findings. Even in nephritis not every sample of urine will be abnormal if the specimens are obtained under ordinary conditions. It is nevertheless rare in this condition to fail to find albumin, casts, or excessive red cells and white cells in a concentrated urine. No diagnosis of the presence or absence of nephritis should be made until such findings are observed.

Benign proteinuria, which is usually transitory and in which there is no evidence of permanent kidney damage, may be due to such causes as severe exercise or cold baths. It is particularly common in young people. In the unusual condition known as *orthostatic albuminuria*, the proteinuria is apparently due to posture; urine formed while the patient is lying down is free from protein, while that formed when the upright position is assumed, particularly the position of military attention, contains protein. This condition is apparently harmless, although it has been used as a deterrent to military service, and may be due, in some instances at least, to mechanical pressure on the renal blood vessels due to a lumbar lordosis.

Foreign proteins injected into the blood stream are excreted by way of the urine, and lead to some excretion of blood proteins also. Pathological albuminuria may in some cases be due to the passage of an abnormal protein from the tissues into the blood.

## TESTS FOR ALBUMIN

The urine should be filtered or centrifuged before these tests are performed, and care should be taken against misinterpretation of the presence of pus or bacteria. None of the tests described here is specific for albumin, since practically all of the proteins which have been found in urine at one time or another will respond to most of these tests. It is common clinical practice, however, to refer to a positive reaction as signifying the presence of albumin in the absence of specific information that some other protein (globulin, hemoglobin, Bence-Jones protein, etc.) is present, since in the vast majority of cases it appears to be really albumin which is concerned. A positive test for albumin would entail its characterization as a heat-coagulable protein, soluble in salt-free water (i.e., after dialysis), and re-

quiring more than half-saturated ammonium sulfate for precipitation (see Chapter 6 for further discussion).

The official test for albumin adopted by the Association of Life Insurance Medical Directors of America may be found in Chapter 31.

**1. Nitric Acid Ring Test (Heller).** Place 5 ml. of concentrated  $\text{HNO}_3$  in a test tube, incline the tube, and by means of a pipet allow the urine to flow slowly down the side. The liquids should stratify with the formation of a white zone of precipitated protein at the zone of contact.

If the albumin is present in very small amount the white zone may not form until the tube has been allowed to stand for several minutes. If the urine is quite concentrated, a white zone, due to uric acid or urates, will form upon treatment with nitric acid as indicated. This ring may be easily differentiated from the albumin ring by repeating the test after diluting the urine with 3 or 4 volumes of water, whereupon the ring, if due to uric acid or urates, will not appear. It is ordinarily possible to differentiate between the albumin ring and the uric acid ring without diluting the urine, since the ring, when due to uric acid, has ordinarily a less sharply defined upper border, is generally broader than the albumin ring, and frequently is situated in the urine above the point of contact with the nitric acid. Concentrated urines also occasionally exhibit the formation, at the point of contact, of a crystalline ring with very sharply defined borders. This is urea nitrate and is easily distinguished from the fluffy ring of albumin. If there is any difficulty in differentiation, a simple dilution of the urine with water, as above described, will remove the difficulty. Various colored zones, due either to the presence of indican, bile pigments, or to the oxidation of other organic urinary constituents, may form in this test under certain conditions. These colored rings should never be confounded with the *white* ring which alone denotes the presence of albumin.

After the administration of certain drugs, a white precipitate of resin acids may form at the point of contact of the two fluids and may cause the observer to draw wrong conclusions. This ring, if composed of resin acids, will dissolve in alcohol, whereas the albumin ring will not dissolve in this solvent.

A ring closely resembling the albumin ring is often obtained in urines preserved for a considerable time by thymol when subjected to the nitric acid test. The ring is due to the formation of nitrosothymol and possibly nitrothymol. If the thymol is removed from the urine by extraction with petroleum ether<sup>9</sup> previous to adding nitric acid, the ring does not form.

**2. Nitric Acid and Magnesium Sulfate Ring Test (Roberts).** Place 5 ml. of Roberts' reagent<sup>10</sup> in a test tube, incline the tube, and by means of a pipet allow the urine to flow slowly down the side. The liquids should stratify with the formation of a white zone of precipitated protein between the layers.

---

<sup>9</sup> Accomplished readily by gently agitating equal volumes of petroleum ether and the urine under examination for *two minutes* in a test tube before applying the test.

<sup>10</sup> See Appendix.

This test is a modification of Heller's ring test and is rather more satisfactory than that test, since the colored rings never form and consequent confusion is avoided.

**3. Sulfosalicylic Acid Test.** To 1 volume of urine add 2 to 3 volumes of 3 per cent sulfosalicylic acid solution. A turbidity (compare against a control diluted with water) or precipitate denotes the presence of albumin or globulin (but not proteose). The precipitate may be intensified by warming.

**4. Coagulation or Boiling Test.** *a.* Heat 5 ml. of urine to boiling in a test tube. (If the urine is not clear it should be filtered.) A precipitate forming at this point is due either to albumin (or globulin) or to phosphates. Acidify the urine slightly by the addition of 3 to 5 drops of very dilute acetic acid, adding the acid drop by drop to the hot solution. If the precipitate is due to phosphates it will disappear under these conditions, whereas if it is due to protein it will not only fail to disappear but will become more flocculent in character, since the reaction of a fluid must be acid to secure the complete precipitation of the protein by this coagulation process.

Too much acid should be avoided since it will cause the protein to go into solution. Certain *resin acids* may be precipitated by the acid, but the precipitate due to this cause may be easily differentiated from the protein precipitate by reason of its solubility in alcohol.

*b.* A modification of this test in quite general use is as follows: Fill a test tube two-thirds full of urine and gently heat the upper half of the fluid to boiling, being careful that this fluid does not mix with the lower half, which serves as a control. A turbidity indicates protein or phosphates. Acidify the urine slightly by the addition of 3 to 5 drops of dilute acetic acid, whereupon the turbidity, if due to phosphates, will disappear.

**5. Osgood-Haskins Test for Urinary Protein.** To 5 volumes of urine add 1 volume of 50 per cent acetic acid, followed by 3 volumes of saturated (30 per cent) sodium chloride. (The appearance of a precipitate after the addition of acetic acid, at room temperature, indicates the presence of bile salts, urates, resin acids, etc., whereas a precipitate after the addition of the salt solution suggests Bence-Jones protein (see p. 832), or globulin in excess of 0.38 g. per liter.) Heat the mixture gradually to boiling. As the temperature is raised the precipitate of Bence-Jones protein, if present, will go into solution; if albumin or globulin are present a precipitate will form. This test has the advantage of indicating the presence of Bence-Jones protein as well as albumin and globulin.

## Globulin

Serum globulin is not a constituent of normal urine but frequently occurs in the urine under pathological conditions and is ordinarily associated with serum albumin. In albuminuria globulin in varying amounts often accompanies the albumin, and the clinical significance of the two is very similar. Under certain conditions globulin may occur in the urine unaccompanied by albumin.

## Tests for Globulin

Globulin will respond to all the tests outlined above under "Albumin." If it is desirable to differentiate between albumin and globulin in any urine, the following procedure may be employed:

Place 25 ml. of neutral urine in a small beaker and add an equal volume of a saturated solution of ammonium sulfate. Globulin, if present, will be precipitated. If no precipitate forms, add ammonium sulfate *in substance* to the point of saturation. If albumin is present it will be precipitated upon saturation of the solution as just indicated. This method may also be used to separate globulin and albumin when they occur in the same urine.

Frequently in urine which contains a large amount of urates a precipitate of ammonium urate may occur when the ammonium sulfate solution is added to the urine. This urate precipitate should not be confounded with the precipitate due to globulin. The two precipitates may be differentiated by means of the fact that the urate precipitate ordinarily appears only after the lapse of several minutes whereas the globulin generally precipitates at once.

### NONBLOOD PROTEINS

Certain proteins are occasionally excreted by the kidneys which do not give the precipitin reactions for any of the normal blood proteins. These

FIG. 227. CRYSTALLINE BENCE-JONES PROTEIN.

Isolated by Summerson from the urine of a case of multiple myeloma.

include proteoses, Bence-Jones protein, and the protein of Hektoen, Kretschmer, and Welker.

Proteoses or substances giving similar precipitation reactions have frequently been found in the urine in cases of pneumonia, diphtheria, intestinal ulcer, carcinoma, dermatitis, osteomalacia, atrophy of the kidneys, and in conditions in which there is absorption of partially digested pus.

Bence-Jones protein is believed to be of diagnostic importance in cases of multiple myeloma and myelogenic osteosarcoma. It has been shown to be chemically and immunologically distinct from any of the blood proteins and has been obtained in crystalline form (see Fig. 227). It appears

to be present normally in small amount in the bone marrow and in certain white blood cells. Its excretion in relatively large amount (30 to 50 g. per day in some instances) under pathological conditions is apparently due either to overproduction or decreased utilization; it is not known which is the true explanation. The presence of Bence-Jones protein in the blood plasma of patients with multiple myeloma has been shown by electrophoretic methods.

The protein of Hektoen, Kretschmer, and Welker resembles the Bence-Jones protein and certain proteoses in solubility and precipitation limits with ammonium sulfate (40 to 60 per cent). It is distinct from these, and from blood proteins in its precipitin reactions, its behavior with heat, and in crystalline form.

## TEST FOR NONBLOOD PROTEINS

**1. Schulte's Method.** Acidify 50 ml. of urine with dilute acetic acid and filter off any precipitate of nucleoprotein which may form. Now test a few ml. of the urine for coagulable protein, by test 4 under "Albumin," p. 831. If coagulable protein is present, remove it by coagulation and filtration before proceeding. Introduce 25 ml. of the urine, freed from coagulable protein, into 150 ml. of absolute alcohol and allow it to stand for 12 to 24 hours. Decant the supernatant fluid and dissolve the precipitate in a small amount of hot water. Now filter this solution, and after testing again for nucleoprotein with *very dilute* acetic acid, try the biuret test. If this test is positive the presence of proteose is indicated.<sup>11</sup>

Urobilin does not ordinarily interfere with this test since it is almost entirely dissolved by the absolute alcohol when the proteose is precipitated.

**2. Boiling Test.** Make the ordinary coagulation test according to the directions given under "Albumin," p. 831. If no coagulable protein is found, allow the boiled urine to stand and note the gradual appearance, in the cooled fluid, of a flaky precipitate of proteose.

**3. Detection of Bence-Jones Protein.** Heat the suspected urine very gently, carefully noting the temperature. At as low a temperature as 40° C. a turbidity may be observed, and as the temperature is raised to about 60° C. a flocculent precipitate forms and clings to the sides of the test tube. If the urine is now acidified *very slightly* with acetic acid and the temperature further raised to 100° C., the precipitate at least partly disappears. Filter while boiling hot. The precipitate returns on cooling the tube. The addition of a few drops of dilute (1 per cent) calcium chloride solution to the urine before testing frequently improves the response to this test.

This property of precipitating at so low a temperature and of dissolving at a higher temperature is typical of Bence-Jones protein and may be used to differentiate it from all other forms of protein material occurring in the urine.

**4. Osgood-Haskins Test for Bence-Jones Protein.** See Exp. 5, p. 831.

---

<sup>11</sup> If it is considered desirable to test for peptone the proteose may be removed by saturation with  $(\text{NH}_4)_2\text{SO}_4$  according to the directions given on p. 197 and the filtrate tested for peptone by the biuret test.

## NUCLEOPROTEIN

There has been considerable controversy as to the proper classification for the protein material which forms the nubecula of normal urine. By different investigators it has been called mucin, mucoid, phosphoprotein, nuclealbumin, and nucleoprotein. Of course, these terms are not synonymous. Mucin and mucoid are glycoproteins and hence contain no phosphorus (see p. 185), whereas phosphoproteins and nucleoproteins are phosphorized compounds. It may possibly be that both these forms of protein, i.e., the glycoprotein and the phosphorized type, occur in the urine under certain conditions (see p. 810). In this connection we will use the term *nucleoprotein*. The pathological conditions under which the content of nucleoprotein is increased include all affections of the urinary passages and in particular pyelitis, nephritis, and inflammation of the urinary bladder.

### TESTS FOR NUCLEOPROTEIN

**1. Detection of Nucleoprotein.** Place 10 ml. of urine in a small beaker, dilute it with three volumes of water to prevent precipitation of urates, and make the reaction very strongly acid with acetic acid. If the urine becomes turbid it is an indication that nucleoprotein is present.

If the urine under examination contains albumin the greater portion of this substance should be removed by boiling the urine before testing it for the presence of nucleoprotein.

**2. Tannic Acid Precipitation Test (Ott).** Mix 25 ml. of the urine with an equal volume of a saturated solution of sodium chloride and slowly add Almén's reagent.<sup>12</sup> In the presence of nucleoprotein a voluminous precipitate forms.

## BLOOD

The pathological conditions in which blood occurs in the urine may be classified under the two divisions *hematuria* and *hemoglobinuria*. In hematuria we are able to detect not only the hemoglobin but the unruptured corpuscles as well, whereas in hemoglobinuria the pigment alone is present. Hematuria is brought about through blood passing into the urine because of some lesion of the kidney or of the urinary tract below the kidney. Hemoglobinuria is brought about through hemolysis, i.e., the rupturing of the stroma of the erythrocyte and the liberation of the hemoglobin. This may occur in malaria, typhoid, yellow fever, hemolytic jaundice, and other diseases. It may also occur as the result of a burn covering a considerable area of the body, through the action of certain hemolytic poisons, or as a result of transfusion with incompatible blood.

### DETECTION OF BLOOD

**1. Benzidine Reaction.** This is one of the most delicate of the reactions for the detection of blood. Different benzidine preparations vary greatly in their sensitiveness, however. Inasmuch as benzidine solutions change readily upon contact with light, it is essential that they be kept in a dark place.

<sup>12</sup> See Appendix.

The test is performed as follows: To 3 ml. of a saturated solution of benzi-dine in glacial acetic acid<sup>13</sup> add 2 ml. of urine and 1 ml. of 3 per cent hydrogen peroxide. A blue or green color indicates a positive test. The following test is more delicate and specific.

**Confirmatory Test.** To 10 ml. of urine add 1 to 2 drops of glacial acetic acid and extract by shaking with 5 ml. of ether. Pour the ether extract into a small evaporating dish. Put on a hot water bath (with flame turned out) and evaporate to dryness. To the residue add a few drops of water, a drop of benzidine solution, and a drop of hydrogen peroxide. A blue or green color indicates blood.

Often when urines containing a small amount of blood are tested by the direct procedure, the mixture is rendered so turbid as to make it difficult to decide as to the presence of a faint green color. The sensitiveness of the benzidine reaction is greater when applied to aqueous solutions than when applied to the urine.

For modifications of this test and further discussion see page 484.

**2. Guaiac Test.** Place 5 ml. of urine<sup>14</sup> in a test tube and by means of a pipet introduce a freshly prepared alcoholic solution of guaiac (strength about 1:60) into the fluid until a turbidity results, then add old turpentine or hydrogen peroxide, drop by drop, until a blue color is obtained.

This test is also much more delicate when applied to the acid-ether extract. The test is positive both before and after boiling the urine for 15 to 20 seconds. Pus does not respond after boiling. Old, partly putrefied pus gives the test even without the addition of hydrogen peroxide or old turpentine, whereas fresh pus responds upon the addition of hydrogen peroxide. See the discussion on p. 480 and the test on p. 484.

**3. Spectroscopic Examination.** Submit the urine to a spectroscopic examination according to the directions given on p. 494, looking especially for the absorption bands of oxyhemoglobin and methemoglobin (see Fig. 110, p. 473).

## MYOGLOBIN

This heme pigment, derived from muscular tissue, is found in the urine after extensive destruction of muscular tissue, as from crushing injuries. Urine containing myoglobin resembles that containing blood; it may be smoky dark brown or red, and will give a positive benzidine test. Red cells, however, are notably absent, and the sediment may contain brown pigmented casts. Myoglobin has a molecular weight only about one-fourth that of hemoglobin (see Chapter 22 for further discussion) which probably explains its ready diffusibility through the kidney membranes. The appearance of myoglobin in the urine is usually associated with concomitant kidney damage, both clinically and experimentally, but whether this has any direct connection with the presence of myoglobin is not known.

---

<sup>13</sup> Glacial acetic acid is preferable, but, if it is not available, alcohol acidified with acetic acid may be used.

<sup>14</sup> Alkaline urine should be made slightly acid with acetic acid as the blue end-reaction is very sensitive to alkali.

## PUS

Pus may be present in the urine in inflammatory affections of various types. Such a condition is termed *pyuria*. Albumin always accompanies the pus. In catarrh of the urinary bladder and in inflammation of the urethra or of the pelvis of the kidney, pus is particularly apt to be present in the urine. If a urine of high pus concentration is voided it may indicate the rupturing of an abscess in some part of the genitourinary tract. Pus may be detected by one of the procedures given below.

### TESTS FOR PUS

**1. Microscopical Detection of Pus.** The characteristic form elements of pus are leukocytes. They may occur in very small number in normal urine. Examine the urine (centrifuged if necessary) under the microscope. Any considerable number of pus corpuscles indicates a pathological urine. In *acid urine* the pus corpuscles appear as round, colorless cells, composed of refractive, granular protoplasm. Sometimes they may exhibit ameboid movements, particularly if the slide containing them be warmed slightly. They are nucleated (one or more nuclei), the nuclei being clearly visible only upon treating the cells with water, acetic acid, or some other suitable reagent. In *alkaline urine* the pus corpuscles are often degenerated. They may occur as swollen, transparent cells, which exhibit no granular structure. If the degeneration has proceeded far enough the nuclei fade and the cell disintegrates and only debris remains.

Sometimes it is almost impossible to differentiate between pus corpuscles and certain types of epithelial cells. In such a case apply the following chemical test.

**2. Guaiac Test.** This test is not specific for pus, but is given by certain other substances and particularly by blood (see p. 835). Perform the test as follows: Acidify the urine (if alkaline) with acetic acid, filter and add tincture of guaiac to the sediment on the paper. If the pus is old and partly putrefied, it will give a blue color. If no blue color is secured, add old turpentine, or hydrogen peroxide, drop by drop. A blue color formed only under these conditions indicates fresh pus.

As a control test boil some of the urine (or sediment) for 15 to 20 seconds and repeat the test. Pus does not respond after boiling. In the case of blood the test is positive both before and after boiling.

## BILE

Both the pigments and the acids of the bile may be detected in the urine under certain pathological conditions. A urine containing bile may be yellowish green to brown in color and when shaken foams readily. The staining of the various tissues of the body through the absorption of bile due to occlusion of the bile duct is a prominent symptom of the condition known as icterus or jaundice. Bile is always present in the urine under such conditions unless the amount of bile reaching the tissues is extremely small.

### TESTS FOR BILE PIGMENTS

Practically all of the tests for bile pigments are based on the oxidation of the pigment by a variety of reagents with the formation of a series of colored derivatives. For detailed chemistry of these tests see the chapter on bile. A simple though satisfactory test for bile consists in shaking the urine in a test tube and observing the yellow foam.

1. *Gmelin's Test.* To about 5 ml. of concentrated nitric acid in a test tube add an equal volume of urine carefully so that the two fluids do not mix. At the point of contact note the various colored rings; green, blue, violet, red, and reddish yellow. (Fuming yellow nitric acid gives the best results.)

2. *Rosenbach's Modification of Gmelin's Test.* Filter 5 ml. of urine through a small filter paper. Introduce a drop of concentrated nitric acid into the cone of the paper and observe the succession of colors as given in Gmelin's test.

3. *Harrison Spot Test.*<sup>15</sup> S & S filter paper No. 470 is impregnated with a 10 per cent barium chloride solution and dried. Dip the dry paper into the urine for 10 seconds and add a drop of Fouchet's reagent<sup>16</sup> at the surface line. A green color indicates bilirubin. This test has been modified by Hawkinson, Watson and Turner.<sup>17</sup>

## TESTS FOR BILE ACIDS

1. *Furfural- $H_2SO_4$  Test (Mylius).* To 5 ml. of urine in a test tube add 3 drops of a very dilute (1:1000) aqueous solution of furfural. Now incline the tube, run about 2 to 3 ml. of concentrated sulfuric acid carefully down the side, and note the red ring at the point of contact. Upon slightly agitating the contents of the tube the whole solution gradually assumes a reddish color. As the tube becomes warm, it should be cooled in running water in order that the temperature may not rise above 70° C.

It is claimed that this test is not satisfactory in the presence of protein and chromogenic substances which yield interfering colors with sulfuric acid.

2. *Surface Tension Test (Hay).* This test is based upon the principle that bile acids have the property of reducing the surface tension of fluids in which they are contained. The test is performed as follows: Cool about 10 ml. of fresh urine in a test tube to 17° C. or lower, and sprinkle a little finely pulverized sulfur upon the surface of the fluid. The presence of bile acids is indicated if the sulfur sinks to the bottom of the liquid, through the surface film. Compare with a control tube of normal urine known to be free from bile. Urines preserved with thymol may respond positively to this test.

## THE ACETONE BODIES

The *acetone* (or *ketone*) *bodies* include the compounds acetoacetic (or diacetic) acid,  $\beta$ -hydroxybutyric acid, and acetone. The chemical relationship between these various acetone bodies is as indicated below; acetoacetic acid and  $\beta$ -hydroxybutyric acid are primary products, the latter probably being formed by reduction of the former. Acetone, however, is a decomposition product of acetoacetic acid and is probably not produced as such within the body, although it is invariably found there when the other two acetone bodies are present.

---

<sup>15</sup> Harrison: *Chemical Methods in Clinical Medicine*, London, J. & A. Churchill, Ltd., 1937.

<sup>16</sup> Fouchet's reagent is 25 per cent trichloroacetic acid containing 0.9 per cent ferric chloride.

<sup>17</sup> *J. Am. Med. Assoc.*, 129, 514 (1945).

Acetoacetic acid and  $\beta$ -hydroxybutyric acid appear to be either intermediate products in the breakdown of fatty acid chains or secondary combinations of 2-carbon fragments formed in this breakdown or closely related to it. Under normal conditions the fatty acids in the animal body are oxidized completely to carbon dioxide and water and intermediate products do not appear to any great extent in the blood or urine. In certain abnormal conditions, however, the ketone bodies accumulate in the blood (*ketonemia*) and are excreted in the urine (*ketonuria*); this general condition is known as a *ketosis*. Ketosis is apparently always associated with some abnormality of carbohydrate metabolism. It is still a disputed question whether ketosis results from the failure on the part of the animal body to oxidize completely the ketone bodies produced normally, or from an overproduction of ketone bodies by the organism in an attempt to meet fuel requirements not supplied by carbohydrates. Ketosis occurs in fasting or during carbohydrate deprivation and in such conditions disappears when carbohydrate is fed. Pathologically it is most severe in diabetes mellitus, in which disease the accumulation of the ketone body acids is largely responsible for the development of diabetic acidosis. Diabetic urine during ketonuria is often high in ammonia which is formed by the body to combat acidosis. Diabetic ketosis is alleviated by insulin treatment. Ketosis also occurs in the acetonemic vomiting of childhood, and frequently in pregnancy, fevers, ether and chloroform anesthesia, malnutrition, prolonged feeding of a carbohydrate-poor diet high in meat and fat, and many other conditions. (See also Chapters 31 and 33.)

**Acetone,  $\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_3$ .** Acetone when pure is a liquid which possesses a characteristic aromatic fruitlike odor, boils at  $56^\circ$  to  $57^\circ$  C., and is miscible with water, alcohol, or ether in all proportions. It reacts with alkali and iodine to yield iodoform. With sodium nitroprusside in alkaline solution it gives a red compound. With salicylic aldehyde, in strongly alkaline solution, it forms a red to orange condensation compound. It forms a nonvolatile compound with bisulfites.

**Acetoacetic Acid,  $\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{COOH}$ .** In the pure state acetoacetic acid is a colorless liquid, miscible with water, alcohol, and ether, in all proportions. Its solution gives a Bordeaux-red color with ferric chloride (not given by acetone). With nitroprusside in alkaline solution it gives a permanganate color, similar to that given by acetone but many times more intense on an equivalent basis. In aqueous solution acetoacetic acid decomposes (most readily on warming in acid solution) to yield acetone. Hence after heating or long standing it gives the tests for acetone, and is probably never found in urine without the concomitant presence of acetone. It is always determined quantitatively as acetone. Acetone and acetoacetic acid may be separated by blowing off the acetone with a current of air under the proper conditions.

**$\beta$ -Hydroxybutyric Acid,  $\text{CH}_3\cdot\text{CHOH}\cdot\text{CH}_2\cdot\text{COOH}$ .** Ordinary  $\beta$ -hydroxybutyric acid is an odorless, transparent, levorotatory syrup easily soluble in water, alcohol, and ether; it may be obtained in crystalline form. It does not respond to the tests for acetone or acetoacetic acid unless it is first oxidized, when it yields acetoacetic acid and, on decomposition, acetone.  $\beta$ -Hydroxybutyric acid in acid urines acts as a urinary antiseptic. Hence ketogenic diets may be useful in cases of infection of the urinary tract.

**Occurrence of Acetone Bodies in Urine.** Total ketone bodies are found in normal urine to the extent of about 20 mg. (expressed as acetone) in 24 hours, but this amount is variable. Of the total, one-half or more is usually in the form of  $\beta$ -hydroxybutyric acid, but this ratio is also variable. Pathologically, values of from 0.02 to 6 g. or more per day of combined acetone and acetoacetic acid have been observed.  $\beta$ -Hydroxybutyric acid has been found in the urine in severe diabetes in amounts of 50 to 100 g. or over. In such conditions the  $\beta$ -hydroxybutyric acid may constitute 60 to 80 per cent of the total acetone bodies. In rare cases excretion of large amounts of  $\beta$ -hydroxybutyric acid may occur with low acetone output.

### TESTS FOR ACETONE BODIES

The three acetone bodies practically always occur together in the urine and have essentially the same significance. The usual tests for ketonuria are tests for acetone or acetoacetic acid or both, since a distillate obtained by heating urine will contain acetone derived by decomposition of acetoacetic acid as well as preformed acetone, and the nitroprusside reaction applied to urine will detect either compound, although with quite different relative sensitivity. There is no satisfactory simple direct test for  $\beta$ -hydroxybutyric acid in urine. The ferric chloride test for acetoacetic acid is not given by acetone, but the test is neither sensitive nor specific and cannot be recommended for clinical work, except perhaps as a confirmatory test. It must be made on the urine directly, and not on a distillate.

The nitroprusside test (particularly the Rothera version) is much more sensitive (at least five or more times) to acetoacetic acid than to acetone; hence when applied to urine directly the result will depend largely on the relative amounts of these two substances present. Fresh urine may give a positive test; the same urine on standing and after decomposition of the acetoacetic acid to acetone may give a negative test. In a distillate, where both compounds are present as acetone, the reaction is sometimes fainter than in the original urine. The test is not entirely specific for the acetone bodies, but when positive it is strongly indicative of their presence. It is probably the most widely used test for ketonuria in clinical work, and many variations in technique have been proposed; nevertheless it cannot be regarded as entirely satisfactory.

The iodoform and salicylic aldehyde tests react with acetone but not directly with acetoacetic acid, and because of interfering substances in urine must be carried out on acetone separated from the urine by distillation or otherwise. The iodoform test on a distillate is quite sensitive and may be of value in suggesting the presence of very small amounts

of acetone bodies, but it is not entirely specific for acetone (alcohol for example also gives a positive test) and it is less satisfactory for clinical work than the other tests described here. The salicylic aldehyde test, carried out as described here on acetone separated from the urine, is probably the most generally satisfactory test for ketonuria.

## TESTS FOR ACETONE AND ACETOACETIC ACID

**1. Isolation from the Urine.** The tests for acetone are more satisfactory if the acetone is separated from the urine by distillation and the tests applied to the distillate. Introduce into a small distilling bulb 10 ml. (or more) of the urine to be tested, and acidify. Distil off about 2 ml. of liquid (containing most of the acetone) into a test tube. A condenser is not necessary but the tube should be kept cool. In the distillation any acetoacetic acid present is decomposed and the acetone from this source also passes into the distillate. Try either of the two following tests on the distillate.

**2. Iodoform Test (Lieben).** To 2 ml. of distillate add 3 to 5 drops of 10 per cent NaOH and then Lugol's iodine solution drop by drop to a faint yellow. Let stand at room temperature if necessary. A definite turbidity changing to a yellow precipitate of iodoform should be noted. The odor is characteristic as is also the crystalline form viewed under the microscope (see p. 68).

This test is given by alcohol which may be formed by fermentation in diabetic urines. Alcohol, however, reacts much more slowly. If ammonia is used, usually 5 to 10 drops, instead of NaOH (Gunning's test) the reaction is more specific for acetone but is less delicate.

**3. Nitroprusside Test (Legal).** Try this test on both the original urine and the distillate. To 2 ml. of liquid add a few drops of a freshly prepared 5 per cent aqueous solution of sodium nitroprusside. Make alkaline with NaOH. A red color indicates acetone. If the test is made directly on urine a red color is given by creatinine which, however, disappears on the addition of acetic acid. A modification of this test in quite general use is as follows: to a few ml. of urine add a few drops of the nitroprusside solution and mix. Add concentrated ammonium hydroxide carefully down the side of the tube so as to form a layer over the sample. A purple (not brown) ring at the zone of contact indicates the presence of acetone bodies.

**4. Nitroprusside Test (Rothera).<sup>18</sup>** Saturate 20 ml. of urine with ammonium sulfate by shaking with the crystals in a test tube. Add 2 to 3 drops of concentrated  $\text{NH}_4\text{OH}$  and a few drops of a freshly prepared 5 per cent solution of sodium nitroprusside and shake. A positive test is indicated by the development of a permanganate tinge which gradually deepens. A brown color is not a positive test. A quick strong reaction indicates about 0.25 per cent acetoacetic acid while a slow weak reaction is given by 0.0005 per cent acetoacetic acid. A faint test has less significance than the ferric chloride test<sup>19</sup> because of the delicacy of the reaction. The test is given by acetone also but is much less delicate for this substance.

**5. Salicylic Aldehyde Test (Behre).<sup>20</sup>** In this test a previous distillation is unnecessary since the acetone, preformed and from acetoacetic acid, is dis-

<sup>18</sup> The dry ingredients of the Rothera test for acetone are available commercially as a powder ("Acetone Test," obtainable from the Denver Chemical Mfg. Co., Inc., New York City). In use, a few drops of urine are placed on a small amount of the powder. A purple color indicates acetone.

<sup>19</sup> See Exp. 6.

<sup>20</sup> Behre: *J. Lab. Clin. Med.*, 13, 770 (1928). Also personal communication.

tilled in the test tube onto the reagents. Place 3 ml. of urine in a clean test tube and 3 ml. of distilled water as a control in another tube, and add 1 drop of 1:1 sulfuric acid to each. Prepare two small thin squares of cotton and in the center of each place a drop of salicylic aldehyde (or of an alcoholic solution of salicylic aldehyde<sup>21</sup>) and two drops of a saturated solution of potassium hydroxide. These reagents solidify to form a yellow disk. When they have solidified, invert a cotton square over each test tube and push in slightly so that the spot of reagents faces down toward the fluid in the tube but does not touch the sides of the tube. Place both tubes upright in boiling water for eight minutes. Remove the cotton and examine the spots. The presence of acetone or acetoacetic acid in the urine is indicated by a pink to deep rose coloration of the spot, as compared with the yellow color of the blank test. The color from acetone bodies deepens on standing and in doubtful cases should be examined after a few minutes. Familiarity with the test makes it possible to estimate roughly the amount of total acetone present.

**6. Ferric Chloride Test for Acetoacetic Acid<sup>22</sup> (Gerhardt).** To 5 ml. of urine in a test tube add ferric chloride solution, drop by drop, until no more precipitate forms. In the presence of acetoacetic acid, a Bordeaux-red color is produced; this color may be somewhat masked by the precipitate of ferric phosphate, in which case the fluid should be filtered.

A positive result from the above manipulation simply indicates the possible presence of acetoacetic acid. Before making a final decision regarding the presence of this substance make the two following control experiments:

**a.** Place 5 ml. of urine in a test tube, small beaker, or Erlenmeyer flask and boil it vigorously for three to five minutes. Cool the vessel and, with the boiled urine, make the test as given above. Compare with the test on the unboiled sample. As has been already stated, acetoacetic acid yields acetone upon decomposition and acetone does not give a Bordeaux-red color with ferric chloride. By boiling as indicated above, therefore, any acetoacetic acid present would be decomposed into acetone and carbon dioxide and the test upon the resulting fluid would be negative. If positive, the color is due to the presence of substances other than acetoacetic acid.

**b.** Place 5 ml. of urine in a test tube, acidify with  $\text{H}_2\text{SO}_4$ , to free acetoacetic acid from its salts, and carefully extract the mixture with ether by shaking. If acetoacetic acid is present, it will be extracted by the ether. Now remove the ethereal solution, evaporate it to dryness, dissolve the residue in 1 to 2 ml. of water, and add 3 to 5 drops of 3 per cent ferric chloride. Acetoacetic acid is indicated by the production of the characteristic Bordeaux-red color.

This color disappears spontaneously in 24 to 48 hours. Such substances as antipyrine, acetophenetidine, salicylic acid, salicylates, sodium acetate, thiocyanates, and thallin yield a similar red color under these conditions; when due to the presence of any of these substances, however, the color does not disappear spontaneously but may remain for days. Many of these disturbing substances are soluble in benzene or chloroform and may

---

<sup>21</sup> Eastman's technical grade or Eimer and Amend's Acid Salicylous, Synthetic, are usually satisfactory for use without dilution. If blackening appears on the cotton during the heating a solution of 1 part salicylic aldehyde in 1 part methyl or ethyl alcohol should be used.

<sup>22</sup> To prepare a solution which may be added to urine, if urines containing this acid are not available for student work, proceed as follows: Treat 13 g. of ethyl acetoacetate with 500 ml. of 0.2 N sodium hydroxide. Allow to stand for 48 hours to hydrolyze the ester. In preparing urine for tests add 1 part of this solution to 10 parts of urine.

be removed from the urine by this means before extracting with ether as above. Acetoacetic acid is insoluble in benzene or chloroform.

## TESTS FOR $\beta$ -HYDROXYBUTYRIC ACID

**1. Black's Reaction.** Inasmuch as the urinary pigments as well as any contained sugar or acetoacetic acid will interfere with the delicacy of this test when applied to the urine directly, the following preliminary procedure is necessary: Concentrate 10 ml. of the urine under examination to one-third or one-fourth of its original volume in an evaporating dish at a gentle heat. Acidify the residue with a few drops of concentrated hydrochloric acid, add sufficient plaster of Paris to make a thick paste, and allow the mixture to stand until it begins to set. It should now be stirred and broken up in the dish by means of a stirring rod with a blunt end. Extract the porous meal thus produced twice with ether by stirring and decantation. Any  $\beta$ -hydroxybutyric acid present will be extracted by the ether. Evaporate the ether extract spontaneously or on a water bath, dissolve the residue in water, and neutralize it with barium carbonate. To 5 to 10 ml. of this neutral fluid in a test tube add 2 to 3 drops of ordinary commercial acid hydrogen peroxide. Mix by shaking and add a few drops of Black's reagent.<sup>23</sup> Permit the tube to stand and note the gradual development of a rose color which increases to its maximum intensity and then gradually fades.<sup>24</sup>

In carrying out the test care should be taken to see that the solution is cold and approximately neutral and that a large excess of hydrogen peroxide and Black's reagent are not added. In case but little  $\beta$ -hydroxybutyric acid is present the color will fail to appear or will be but transitory if the oxidizing agents are added in too great excess. It is preferable to add a few drops of the reagent and at intervals of a few minutes repeat the process until the color undergoes no further increase in intensity. One part of  $\beta$ -hydroxybutyric acid in 10,000 parts of the solution may be detected by this test.

**2. Polariscopic Examination.** Subject some of the urine (free from protein) to the ordinary fermentation test (see p. 827). This will remove glucose and fructose, which would interfere with the polariscopic test. Now examine the fermented fluid in the polariscope and if it is levorotatory the presence of  $\beta$ -hydroxybutyric acid is indicated. This test is not absolutely reliable, however, since conjugate glucuronates are also levorotatory and withstand fermentation.

### GLUCURONIC ACID

Glucuronic acid does not occur free in urine, but is found in combinations known as *conjugate glucuronates* or *glucuronides* with a wide variety of compounds under both normal and pathological conditions or after administration of such compounds for medicinal or experimental purposes. There are two general types of conjugate glucuronates, the *glycoside*

<sup>23</sup> Made by dissolving 5 g. of ferric chloride and 0.4 g. of ferrous chloride in 100 ml. of water.

<sup>24</sup> This disappearance of color is due to the further oxidation of the acetoacetic acid.

type and the *ester* type, both of which involve linkage with glucuronic acid through the OH group on carbon atom number 1 of the cyclic structure. The glycoside type involves the OH group of aliphatic or aromatic alcohols, e.g., phenol, naphthol, borneol, etc., while the ester type involves reaction with the COOH group of such compounds as benzoic acid, phenylacetic acid, etc. Free glucuronic acid is as powerful a reducing substance as glucose, and its quantitative determination may be based upon this fact; ester-type glucuronides likewise show direct reducing properties, probably due to concomitant hydrolysis, while the glycoside type is non-reducing until hydrolyzed. Conjugate glucuronates may therefore interfere with the reducing tests for sugar in urine under certain conditions, but they may be readily distinguished from glucose because of their non-fermentability with yeast. While glucuronic acid is dextrorotatory, the glucuronides as a class are levorotatory; this also serves for distinction from glucose in urine.

The total glucuronic acid content of normal urine appears to approximate 0.5 to 1.0 g. per day; earlier estimates were considerably lower than this, probably because the methods were based on the mistaken assumption that all conjugate glucuronates are soluble in ether. The glucuronides of normal urine include combinations with phenol, indoxyl, skatoxyl, and the estrogenic hormones. Urine glucuronide content may be greatly increased by the administration of a variety of compounds, such as antipyrine, acetylsalicylic acid (aspirin), borneol, camphor, chloral hydrate, menthol, morphine, phenolphthalein, turpentine, and practically all of the sulfonamides (except possibly sulfanilamide). Experimentally, certain carcinogenic substances or derivatives are ultimately excreted in part as glucuronides. Glucuronic acid formation and conjugation appear to take place in the liver. The origin of glucuronic acid is obscure, although it is known to be an end product of the polysaccharide-splitting action of the enzyme hyaluronidase.

## TESTS FOR GLUCURONATES

**1. Naphthoresorcinol Reaction (Tollens).** Introduce 5 ml. of urine in a test tube and add 0.5 to 1 ml. of a 1 per cent solution of naphthoresorcinol in 95 per cent alcohol, and 5 ml. of concentrated hydrochloric acid. Raise the temperature gradually to the boiling point and boil for one minute, shaking the tube continuously. Stand the tube aside four minutes, then cool under the tap. Extract with an equal volume of ether (preferably peroxide-free). Glucuronates are indicated by the ether extract assuming a violet-red color. The spectroscope shows this extract to possess an absorption band in the green to yellow region of the spectrum. The peak absorption is at approximately 570  $m\mu$ .

**2. Preparation of Glucuronic Acid (Method of Quick).<sup>25</sup>** Give 5 g. of pulverized borneol daily to each of several dogs. Collect the urine, acidify with acetic acid, and add lead acetate. Most of the coloring matter is carried down. Filter, heat the filtrate to boiling, and add an excess of zinc acetate. Filter off the precipitate and wash with hot water until no more coloring matter is extracted. This is practically pure zinc borneol glucuronic acid. About 1 g. is obtained for each g. of borneol given.

<sup>25</sup> Quick: *J. Biol. Chem.*, 74, 331 (1927).

Dissolve the finely powdered zinc salt in hot 3.5 N sulfuric acid, using about 140 ml. for each 100 g. of the salt. When completely dissolved, cool rapidly and put in an icebox for several hours. Filter off the crystals of borneol glucuronic acid, wash with a little cold water, and dry in the air.

Dissolve 100 g. of borneol glucuronic acid in 1,500 ml. of 0.2 N sulfuric acid and boil for three hours beneath a reflux condenser. Filter and treat the hot filtrate with sufficient barium hydroxide to precipitate the last traces of sulfuric acid. Allow the mixture to settle. Siphon off the supernatant fluid, and complete the separation by centrifuging. Concentrate the solution under diminished pressure to a syrupy consistency, and let it stand to crystallize. Filter off the crystals and wash them with a small amount of alcohol to remove the pigment. This is a mixture of glucuronic acid and its lactone. Treat 4 g. of the product with 200 ml. of 95 per cent alcohol and set aside for 12 hours. Repeat twice, using 100-ml. portions of alcohol. The residue should be glucuronic acid of 99 per cent purity. To obtain the pure lactone, dissolve some of the mixture of acid and lactone in hot glacial acetic acid, allow the solution to cool, and recrystallize from hot water.

Glucuronic acid is a syrupy liquid, readily soluble in water and slightly soluble in alcohol. When the aqueous solution is boiled, evaporated, or even allowed to stand at the ordinary temperature, the acid loses the elements of water and yields the anhydride or lactone. It is a strong organic acid ( $K > 1 \times 10^{-3}$ ).

Glucuronic anhydride,  $C_6H_8O_6$ , forms monoclinic tables or needles, having a sweet taste, and m.p.  $160^\circ$  when heat is gradually applied, or at  $170^\circ$  to  $180^\circ$  when heated rapidly. The anhydride is insoluble in alcohol, but dissolves readily in water to form a dextrorotatory solution,  $[\alpha]_D = +19.25^\circ$ . The solution prevents the precipitation of cupric ion by alkalies, and powerfully reduces Fehling's solution, the copper-reducing power being 98.8, compared with glucose as 100.

Glucuronic acid itself is dextrorotatory ( $[\alpha]_D = +36^\circ$ ), but many of its compounds are levorotatory. It shows mutarotation with an initial value of  $[\alpha]_D^{20} = +16^\circ$ . It reduces Fehling's solution on heating, and precipitates the metals from hot alkaline solutions of silver, mercury, and bismuth.

FIG. 228. PENTOSAZONE CRYSTALS.

Isolated and purified in the senior author's laboratory by Dr. B. L. Fleming. For color of crystals see Plate II, opposite p. 63.

pentose-rich fruits such as prunes, cherries, grapes, or plums, and fruit juices, in which condition the pentoses appear only temporarily in the urine; and (2) the chronic form of pentosuria, in which the output of

## PENTOSE

There are two distinct types of pentosuria, viz., (1) alimentary pentosuria, resulting from the ingestion of large quantities of

pentoses bears no relation whatever to the quantity and nature of the pentose content of the food eaten. Pentosuria is apparently a harmless abnormality; it is definitely known that pentosuria bears no relation to diabetes mellitus and there is no generally accepted theory to account for the occurrence of the chronic form of pentosuria. The pentose detected most frequently in the urine in chronic pentosuria is L-xyloketose. L-Arabinose has been found in cases of alimentary pentosuria. For pentosazone crystals, see Fig. 228.

## TESTS FOR PENTOSE

**1. Benzidine Reaction (Tauber).<sup>26</sup>** To 0.1 ml. of the urine in a test tube, add 0.5 ml. of a 4 per cent solution of benzidine in glacial acetic acid. Heat to vigorous boiling, cool under the cold-water tap, and add 1 ml. of water. The presence of pentose is indicated by the immediate appearance of a pink to red color. If pentoses are absent, the mixture has a yellowish-brown color.

This test is highly specific for pentoses in the free form but is not given by gum arabic, nucleic acids, or riboflavin in which the pentose is combined. Normal and abnormal constituents of urine do not interfere. Too large amounts of protein may be removed from pathological urine by mixing with an equal volume of 10 per cent trichoroacetic acid solution, warming to 95°, and filtering. The test is applied to the filtrate. This test is said to detect the presence of aldopentoses but not ketopentoses. The 4 per cent benzidine solution is stable for four days.

**2. Orcinol-Hydrochloric Acid Reaction (Bial).** To 5 ml. of Bial's reagent<sup>27</sup> in a test tube, add 2 to 3 ml. of urine and heat the mixture gently until the first bubbles rise to the surface.<sup>28</sup> Immediately or upon cooling the solution becomes green and a flocculent precipitate of the same color may form.

This test is believed to be more accurate than the original orcinol test. It is claimed that urines containing menthol, kreosotal, etc., respond to the old orcinol reaction, but not to Bial's. If so desired the osazone of the pentose (see Fig. 228) may be formed, then distilled with hydrochloric acid and the distillate tested by Bial's test (Jolles).

**3. Phloroglucinol-Hydrochloric Acid Reaction (Tollens).** To equal volumes of urine and hydrochloric acid (sp. gr. 1.09) add a little phloroglucinol and heat the mixture on a boiling water bath. Pentose, galactose, or glucuronic acid will be indicated by the appearance of a red color. To differentiate between these compounds examine by the spectroscope and look for the absorption band in the yellow region of the spectrum given by pentoses and glucuronic acid, and then differentiate between the two latter compounds by the melting points of their osazones.

**4. White-Green Reaction.<sup>29</sup>** To the urine in a test tube add two drops of acetic acid and boil. Add Norit, shake two minutes and filter. To 2 ml. of filtrate add 2 ml. of acetic acid and 5 drops of redistilled aniline. Heat to boiling, allow to stand 2 minutes then cool and extract with 2 ml. of chloro-

<sup>26</sup> Tauber: *Proc. Soc. Exptl. Biol. Med.*, **37**, 600 (1937).

<sup>27</sup> See Appendix.

<sup>28</sup> The test may also be performed by adding the urine to the *hot* reagent. No further heating should be necessary if pentose is present.

<sup>29</sup> White and Green: *Trans. Roy. Soc. Section V, Biological Sciences, Third Series*, **26**, 145 (1932).

form. In the presence of pentose the chloroform extract becomes bright red. Glucose and galactose give a green color, fructose a pale yellow, and glucuronate a very pale yellow.

## LACTOSE

Lactose is rarely found in the urine except when excreted by women during pregnancy, during the nursing period, or soon after weaning, i.e., when the mammary glands are actively functioning. Lactosuria has no pathological significance, representing as it does simply the excretion of a sugar which has found its way into the blood stream by some means and which is not utilizable as such by the organism.<sup>30</sup> It is nevertheless important to be able to identify the condition of lactosuria and to distinguish it from glucosuria, otherwise serious misinterpretation of laboratory data may result. Lactose in urine is readily distinguished from glucose by its lack of fermentability with ordinary yeast; qualitative or better quantitative determination of reducing power before and after exhaustive treatment with yeast is of value in this connection, particularly for the detection of a concomitant glucosuria. The characterization of lactose as its typical osazone is not ordinarily attended with much success in urine; better results may be obtained by adsorption of the lactose on charcoal prior to testing, as described below. The mucic acid test, which is specific for lactose and galactose, may be used to identify lactose in urine, but interpretation of results may be obscured by the presence of other insoluble crystalline substances.

## TESTS FOR LACTOSE

**1. Fermentation Test.** Ferment the urine as in Exp. 3(a) or 3(b), p. 827. If nonfermentable reducing sugar is found it is very probably lactose, especially if the patient be pregnant or lactating. In rare cases it may be pentose. Lactose may be distinguished from pentose by proper application of Tauber's test (p. 845), the mucic acid test, or the osazone test.

**2. Osazone Test (According to Cole).** Shake 25 ml. of urine with 1 g. of Merck's medicinal charcoal, boil a few seconds, cool thoroughly, and shake at intervals for 10 minutes. Filter through a small paper or use a filter pump. Let drain completely. Transfer the charcoal to a dish containing 10 ml. of water and 1 ml. of glacial acetic acid. Boil for about 10 seconds and filter hot into a tube containing as much phenylhydrazine hydrochloride as will lie on a quarter and twice as much sodium acetate. Mix and heat on a boiling water bath for 45 minutes. Remove and let stand for at least an hour. Look for "hedgehog crystals" of lactosazone. Glucose, if present in significant amount, will be adsorbed by the charcoal to some extent and come through along with the lactose to give glucosazone crystals. The value of the charcoal separation is chiefly to increase the concentration of lactose relative to glucose and to facilitate the obtaining of characteristic lactosazone crystals.

**3. Mucic Acid Test.** Transfer 50 ml. of urine to a 150-ml. beaker and add 12 ml. of concentrated  $\text{HNO}_3$ . Heat on a boiling water bath until the volume is reduced to about 10 ml. Cool. Add 10 ml. of water and let stand overnight. A fine white precipitate of mucic acid will form if lactose or galactose is

---

<sup>30</sup> If any lactose is excreted into the intestinal tract and there hydrolyzed into glucose and galactose, these products are capable of absorption and utilization by the body.

present. Examine the crystals under the microscope (see Fig. 19). Other reducing sugars do not give this test. Lactose and galactose may be differentiated by Tollens' test (see tests for pentose).

## GALACTOSE

Galactose has occasionally been detected in the urine, and in particular in that of nursing infants afflicted with a deranged digestive function. It may be present in significant amount in liver disease after the administration of large doses of galactose, as in the galactose tolerance test (analogous to the glucose tolerance test) for liver function. Lactose and galactose may be differentiated from other reducing sugars which may be present in the urine by means of the mucic acid test. For a description of the mucic acid test, see the experiments on lactose above. To differentiate galactose, use Tollens' reaction (see the section on pentose above). The red solution given by galactose shows no absorption bands. Galactose is fermentable very slowly or not at all by ordinary bakers' yeast.

## FRUCTOSE

The occurrence of fructose in the urine is relatively rare. In essential fructosuria small amounts of fructose are constantly excreted regardless of the fructose content of the diet, although it is curious that, if the diet is carbohydrate-free, the excretion of fructose ceases. No satisfactory explanation has as yet been offered for the condition of essential fructosuria, which is apparently a harmless metabolic abnormality. In diabetes mellitus, fructose may at times be excreted along with glucose (never by itself); the significance of this is not known, although it may be recalled that fructose diphosphate is an intermediate in carbohydrate metabolism (see Chapter 33).

## TESTS FOR FRUCTOSE

**1. Borchardt's Reaction.** To about 5 ml. of urine in a test tube add an equal volume of 25 per cent hydrochloric acid and a few crystals of resorcinol. Heat to boiling and after the production of a red color, cool the tube under running water and transfer to an evaporating dish or beaker. Make the mixture slightly alkaline with solid potassium hydroxide, return it to a test tube, add 2 to 3 ml. of ethyl acetate, and shake the tube vigorously. In the presence of fructose the ethyl acetate is colored yellow.

The only urinary constituents which interfere with the test are nitrites and indican, and these interfere only when they are simultaneously present. Under these conditions, the urine should be acidified with acetic acid and heated to boiling for one minute to remove the nitrites. In case the indican content is very large, it will impart a blue color to the ethyl acetate, thus masking the yellow color due to fructose. When such urines are to be examined, the indican should first be removed by Obermayer's test (see p. 804). The chloroform should then be discarded, the acid-urine mixture diluted with one-third its volume of water, and the test applied as described above. The urine of patients who have ingested santonin or rhubarb responds to the test. The test will serve to detect fructose when present in a dilution of 1:2000—i.e., 0.05 per cent.

**2. Resorcinol-Hydrochloric Acid Reaction (Selivanoff).** To 5 ml. of Selivanoff's reagent<sup>31</sup> in a test tube add a few drops of the urine under examination and heat the mixture to boiling, or place in a boiling water bath. The presence of fructose is indicated by the production of a red color which may or may not lead ultimately to the separation of a red precipitate. The latter if formed may be filtered off and dissolved in alcohol to which it will impart a striking red color.

If the boiling be prolonged, a similar reaction may be obtained with urine containing glucose. The precautions necessary for a positive test for fructose are as follows: The concentration of the hydrochloric acid must not be more than 12 per cent; the reaction (red color) and the precipitate must be observed after not more than 20–30 seconds of boiling; glucose must not be present in amounts exceeding 2 per cent; the precipitate must be soluble in alcohol with a bright red color.

**3. Aminoguanidine Test (Tauber).** See p. 73.

**4. Phenylhydrazine Test.** Make the test according to directions under "Glucose," Exp. 1, p. 824. With methylphenylhydrazine fructose gives crystals differing from those given by glucose in their rate of formation (p. 73).

**5. Polariscopic Examination.** A simple polariscopic examination, when taken in connection with other ordinary tests, will furnish the requisite data regarding the presence of fructose, provided fructose is not accompanied by other levorotatory substances, such as conjugate glucuronates and  $\beta$ -hydroxybutyric acid.

## ARSENIC

When any soluble form of arsenic is introduced into the body in any way, it is quickly absorbed and distributed by the blood and lymph. The absorption is influenced by the quantity and character of food in the stomach, and the activity of the circulation of the part in contact with the poison. Some of the absorbed arsenic may be returned to the alimentary canal by way of the bile and gastrointestinal mucous membrane. After absorption it may be deposited in the liver, kidneys, brain, bone, muscles, and walls of the stomach and intestines. It is eliminated in all of the excretions, but chiefly by the kidneys and through the feces. It does not appear very promptly in the urine but continues to be excreted in the urine over a long period of time, in some cases for several months. Testing for arsenic has become of increasing importance because of the widespread use of arsenicals in chemotherapy. Many instances of clinical manifestations of arsenical poisoning have been reported.

## DETECTION AND ESTIMATION OF ARSENIC

**1. Gutzeit Method:<sup>32</sup> Principle.** The presence of arsenic is revealed by the brown stain produced on mercuric bromide paper when arsine is liberated from a test solution by the action of nascent hydrogen.

<sup>31</sup> See Appendix.

<sup>32</sup> Throughout this determination care must be taken to use clean arsenic-free reagents

**Procedure.** Prepare a generator as shown in Fig. 229 using a 50-ml. wide-mouth bottle fitted with a perforated rubber (As-free) stopper. In the central chamber (about 1 cm. wide and 7 cm. long) place loosely packed glass wool or cotton moistened with 10 per cent lead acetate solution. The exit tube should have an internal diameter of about 3 mm. Into this tube insert a strip of mercuric bromide test paper.<sup>33</sup>

To prepare the arsine stain place 5 ml. of 15 per cent potassium iodide, 5 ml. of acid stannous chloride solution (1.6 g.  $\text{SnCl}_2$  dissolved in 100 ml. 10 per cent  $\text{HCl}$ ), 2 ml. of the test solution, and 30 ml. of water in a flask. Add 1.5 g. granulated As-free zinc and stopper immediately with the exit tube arrangement. Immerse the generator bottle in water at 25° C. for 1 hour. Remove the test strip and compare the color and length of stain with strips similarly prepared from standard arsenic solutions.

Depending upon the nature of the material under examination the test solutions may be prepared by direct solution or by digestion (tissues, foods, urine) with As-free concentrated sulfuric acid as in the Kjeldahl nitrogen determination (see p. 874). To prepare the standard arsenic solutions dissolve 100 mg. arsenic trioxide powder in 5 ml. of 20 per cent  $\text{NaOH}$ , neutralize with dilute  $\text{H}_2\text{SO}_4$ , add 10 ml. excess acid and make up to 1000 ml. Prepare dilutions of this stock solution with dilute  $\text{H}_2\text{SO}_4$  so that 2 ml. contain 1, 2, 3, 4 etc.  $\mu\text{g}$ .  $\text{As}_2\text{O}_3$ . These amounts will yield a series of stains of graduated length and intensity.

FIG. 229. GUTZEIT ARSENIC APPARATUS.

**2. Reinsch's Test.** This test is very much simpler, but not so delicate. It has the advantage of application in the presence of organic matter. The test is performed as follows: The urine, acidified with one-fifth its volume of pure hydrochloric acid, is placed in a beaker. A piece of bright copper foil free from arsenic is then introduced, and the urine is heated almost to the boiling point. It is then set aside for six to eight hours. The arsenic is deposited on the copper foil, giving it a bluish-gray color. The foil is then removed, washed successively in pure water, alcohol, ether, and dried without heat. The foil is then rolled into a scroll and inserted into a 3-mm.-bore glass tube 4 inches long, about 1 inch from the end. The tube is then held in the Bunsen flame at an angle of 20 to 25 degrees, heat being applied where the copper foil is situated. The arsenic volatilizes and is oxidized, and deposits as octahedral crystals of arsenic trioxide on the cooler part of the tube. The crystals can readily be recognized by the microscope and sometimes with a simple magnifying lens.

and glassware. A blank determination should be run on the reagents in each generator used in a series. For the precise quantitative determination of arsenic by the Gutzeit method consult *Methods of Analysis of the Association of Official Agricultural Chemists*, 7th ed., 1950, p. 369. Osterberg and Green (*J. Biol. Chem.*, 155, 513 (1944)) have suggested a rapid method for the microdetermination of arsenic in which the arsenic is converted into arsine by electrolysis.

<sup>33</sup> Test paper strips are prepared as follows: Saturate filter paper with 5 per cent solution of mercuric bromide in alcohol allowing the paper to dry spontaneously while suspended in air. Cut into strips 2.5 mm.  $\times$  12 cm. and store in a brown glass bottle.

## MERCURY

The rapidity of absorption of mercury depends upon a number of conditions such as mode of administration, the nature of the compound and its physical state, the state and condition of the stomach and intestines, the quantity and quality of the food in the stomach, and the state of the circulation of the portal of entrance. There is no definite knowledge as to the form in which it is absorbed. Elimination depends upon the state of the excretory organs. It is eliminated in all the excretions of the body—urine, feces, saliva, sweat, tears, and milk. Elimination begins about two hours after introduction. Depending upon the amount introduced and absorbed and the extent of renal injury, the time required for its complete elimination varies from 24 hours to many weeks.

### TESTS FOR MERCURY

**1. Reinsch's Test.** The procedure is carried out in the same manner as for arsenic (see above). A piece of arsenic-free copper foil is introduced into the urine acidified with one-fifth its volume of pure hydrochloric acid. The urine is, however, not heated to boiling, but warmed to 50° C. or 60° C. and set aside for 12 or preferably 24 hours. Metallic mercury is deposited on the foil as a bright lustrous mirror. The foil is then washed with pure water, alcohol, ether, and dried without heat, rolled into a scroll, inserted into a glass tube and heated in the same manner as under "Arsenic." The mercury is deposited in the metallic state in the form of globules readily distinguishable with the microscope.

**2. Amalgamation Test.** A more rapid method than the above is by amalgamation with zinc. Add 5 g. of zinc dust to the urine and heat for 15 minutes, stirring continuously. Allow the amalgamated zinc to settle and decant the urine. Then wash by decantation several times with pure water, then with alcohol, and finally with ether and dry in air. Now introduce the dry zinc into a narrow dry glass tube sealed at one end. With the Bunsen burner soften the tube about 2 inches above the zinc and constrict the tube by pulling the ends apart. Introduce a small bit of glass wool or asbestos sufficient to support a small piece of iodine. Introduce the iodine supported by the asbestos at the constriction. Apply heat to the zinc amalgam, and then gently to the region holding the iodine to gently volatilize it, and immediately reapply heat to the zinc. The mercury volatilizes and, meeting the iodine vapor, unites with it and is deposited as the red iodide of mercury.

## LEAD

Lead may be found to the extent of 0.05 mg. or so per liter in the urine of healthy individuals and may be estimated by the method of Fairhall.<sup>34</sup> It is increased in lead poisoning.

## INOSITOL

Inositol,  $C_6H_6(OH)_6$ , occasionally occurs in the urine in albuminuria, diabetes mellitus, and diabetes insipidus. It is claimed also that copious

---

<sup>34</sup> Fairhall: *J. Biol. Chem.*, **60**, 485 (1924); Aub, Fairhall, Minot, and Reznikoff: *Medicine*, **4**, 1 (1925); Millet: *J. Biol. Chem.*, **83**, 265 (1929). See also Chapters 23 and 31.

water drinking causes this substance to appear in the urine. For further discussion, see Chap. 35.

## TEST FOR INOSITOL

**1. Detection of Inositol (Scherer).** Acidify the urine with concentrated nitric acid and evaporate nearly to dryness. Add a few drops of ammonium hydroxide and a little calcium chloride solution to the moist residue and evaporate the mixture to dryness. In the presence of inositol (0.001 g.) a bright red color is obtained.

For a more satisfactory test, which, however, is more time-consuming, see Salkowski's<sup>35</sup> modification of Scherer's test.

## FAT

When fat finds its way into the urine through a lesion which brings some portion of the urinary passages into communication with the lymphatic system, a condition known as *chyluria* is established. The turbid or milky appearance of such urine is due to its content of chyle. This disease is encountered most frequently in tropical countries, but is not entirely unknown in more temperate climates. Albumin is a constant constituent of the urine in chyluria. Upon shaking a chylous urine with ether, the fat is dissolved by the ether and the urine becomes less turbid or entirely clear. Alimentary *lipuria* may occur following the ingestion of a large amount of fat.

## MELANINS

These pigments never occur normally in the urine, but are present under certain pathological conditions, their presence being especially associated with melanotic tumors. Ordinarily the freshly passed urine is clear, but upon exposure to the air the color deepens and may at last be very dark brown or black in color. The pigment is probably present in the form of a chromogen or melanogen, and upon coming into contact with the air oxidation occurs, causing the transformation of the melanogen into melanin and consequently the darkening of the urine.

It is claimed that melanuria is proof of the formation of a visceral melanotic growth. In many instances, without doubt, urines rich in indican have been wrongly taken as diagnostic proof of melanuria. The pigment melanin is sometimes mistaken for indigo and melanogen for indican. It is comparatively easy to differentiate between indigo and melanin through the solubility of the former in chloroform.

In rare cases melanin is found in urinary sediment in the form of fine amorphous granules.

## TESTS FOR MELANIN

**1. Ferric Chloride Reaction (von Jaksch-Pollak).** Add a few drops of ferric chloride solution to 10 ml. of urine in a test tube and note the formation of a gray color. Upon the further addition of the chloride a dark precipitate forms, consisting of phosphates and adhering melanin. An excess of ferric chloride causes the precipitate to dissolve.

This is the most satisfactory test for the identification of melanin in the urine.

---

<sup>35</sup> Salkowski: *Z. physiol. Chem.*, 69, 478 (1910).

**2. Bromine Test (Zeller).** To 50 ml. of urine in a small beaker add an equal volume of bromine water. In the presence of melanin a yellow precipitate will form and will gradually darken in color, ultimately becoming black.

## UROROSEIN

Urorosein is a urinary pigment which does not occur preformed in the urine, but is present in the form of a chromogen, which is transformed into the pigment upon treatment with a mineral acid. Herter showed this chromogen to be indoleacetic acid,

Indoleacetic acid may be found in urine free or as a compound with glycine. Normal urine responds to the urorosein reaction (see below) if nitrites are present. Pathologically, a positive urorosein reaction is obtained in a variety of diseases, such as pulmonary tuberculosis, typhoid fever, nephritis, stomach disorders, and pellagra. The reaction in the urine of pellagra patients has attracted considerable interest because of its possible metabolic and diagnostic significance.<sup>36</sup>

## TEST FOR UROROSEIN

**Nitrite-Hydrochloric Acid Test (Urorosein Reaction).** To 10 ml. of urine in a test tube add 2 ml. of concentrated hydrochloric acid and a few drops of a 1 per cent solution of potassium nitrite. A rose-red color indicates urorosein. The chromogen (indoleacetic acid) has been changed to urorosein by oxidation.

## PORPHYRINS<sup>37</sup>

Coproporphyrin and uroporphyrin are present in small amount in normal urine. Both are reddish pigments which may be increased in amount in pathological urine or after administration of quinine, tetronal, trional, or sulfonal.

## Urine: Sediments and Calculi

The sedimentary constituents of the urine may be divided into two classes, viz., organized and unorganized. The sediment is collected by centrifuging the urine at low speed or by allowing it to stand for some time in a conical vessel.

### I. UNORGANIZED SEDIMENTS

The more common unorganized sediments consist of ammonium magnesium phosphate ("triple phosphate"), calcium oxalate, calcium phosphate, uric acid, and sodium and ammonium urates. Less commonly observed are calcium carbonate, calcium sulfate, magnesium phosphate, cystine, leucine, tyrosine, hippuric acid, bilirubin, indigo, xanthine, and melanin.

The separation as sediments depends upon the degree of saturation of the urine for these substances, which in turn is influenced by the reaction of the urine. Uric acid most commonly separates out from strongly acid urines, sodium urate from less acid urines. Calcium phosphate comes out most commonly in urines more alkaline than pH 6, while calcium oxalate is found in acid, alkaline, and neutral urines. All of these substances are found as sediments in normal urines, and the majority of normal urines show one or more of these separating out on standing. Ammonium magnesium phosphate, ammonium urate, and calcium carbonate precipitate from urines which have undergone ammoniacal fermentation due to an infection in the urinary tract, and which are hence alkaline in reaction. Maslow studied the sediments forming on long standing in carefully preserved specimens of the urines of normal young men. Sediments were found in 93 per cent of the urines. Uric acid was found in 17 per cent of cases at an average pH of 5.5 and sodium urate in a similar number of cases at an average pH of 5.8. Calcium phosphate was found in 46 per cent of cases with an average pH of 6.2 and calcium oxalate was found in 71 per cent of cases and at all reactions.

**Ammonium Magnesium Phosphate ("Triple Phosphate").** Crystals of "triple phosphate" are a characteristic constituent of the sediment when alkaline fermentation of the urine has taken place either before or after being voided. They may even be detected in neutral or slightly acid urine provided the ammonium salts are present in large enough quantity. This substance may occur in the sediment in two forms, viz., prisms and the feathery type. The prismatic form of crystals is the one most commonly observed in the sediment; the feathery form predominates when the urine is made ammoniacal with ammonia (see Fig. 226).

The sediment of the urine in such disorders as are accompanied by a retention of urine in the lower urinary tract contains "triple phosphate" crystals as a characteristic constituent. The crystals are frequently abundant in the sediment during paraplegia, chronic cystitis, enlarged prostate, and chronic pyelitis.

**Calcium Oxalate.** Calcium oxalate is found in the urine in the form of at least two distinct types of crystals, viz., the dumbbell and "octahedral" types<sup>1</sup> (Fig. 230). Either form may occur in the sediment of neutral, alkaline, or acid urine, but both forms are found most frequently in urine having an acid reaction. Occasionally, in alkaline urine, the octahedral form is confounded with "triple phosphate" crystals. They may be differentiated from the phosphate crystals by the fact that they are insoluble in acetic acid.

The presence of calcium oxalate in the urine is not of itself a sign of any abnormality, since it is a constituent of normal urine. However variations from the normal occur in certain pathological conditions, e.g. parathyroid derangement, urinary calculi, etc.

FIG. 230. CALCIUM OXALATE (OGDEN).

**Calcium Carbonate.** Calcium carbonate crystals form a typical constituent of the urine of herbivorous animals. They occur less frequently in human urine. The reaction of urine containing these crystals is nearly always alkaline, although they may occur in neutral or in slightly acid urine. It generally crystallizes in the form of granules, spherules, or dumbbells (Fig. 231). The crystals of calcium carbonate may be differentiated from calcium oxalate by the fact that they dissolve in acetic acid with the evolution of carbon dioxide gas.

**Calcium Phosphate (Stellar Phosphate).** Calcium phosphate may occur in the urine in three forms, viz., amorphous, granular, or crystalline. The crystals of calcium phosphate are ordinarily pointed, wedge-shaped formations which may occur as individual crystals or grouped together in more or less regularly formed rosettes (see Fig. 64). Acid sodium urate crystals (Fig. 233) are often mistaken for crystals of calcium phosphate. We may differentiate between these two crystalline forms by the fact that acetic acid will readily dissolve the phosphate, whereas the urate is much less soluble and when it is finally brought into solution and recrystallized, one is frequently enabled to identify uric acid crystals which have been formed from the

<sup>1</sup> The so-called octahedral type is strictly speaking a flat, tetragonal dipyramid identical with the mineral weddelite, whereas the dumbbell-shaped spherulite aggregates correspond to whewellite (Phillipsborn: *Arztliche Forsch.*, 9, 391 (1953)).

acid urate solution. The clinical significance of the occurrence of calcium phosphate crystals in the urinary sediment is similar to that of "triple phosphate" (see p. 854).

**Calcium Sulfate.** Crystals of calcium sulfate are of quite rare occurrence in the sediment of urine. Their presence seems to be limited in general to urines which are of a decided acid reaction. Ordinarily it crystallizes in the form of long, thin, colorless

FIG. 231. CALCIUM CARBONATE.

FIG. 232. VARIOUS FORMS OF URIC ACID.

1, Rhombic plates; 2, whetstone forms; 3, 3, quadrate forms; 4, 5, prolonged into points; 6, 8, rosettes; 7, pointed bundles; 9, barrel forms precipitated by adding hydrochloric acid to urine.

needles or prisms (Fig. 225) which may be mistaken for calcium phosphate crystals. There need be no confusion in this respect, however, since the sulfate crystals are insoluble in acetic acid, which reagent readily dissolves the phosphate. As far as is known, their occurrence as a constituent of urinary sediment is of very little clinical significance.

**Uric Acid.** Uric acid forms a very common constituent of the sediment of urines which are acid in reaction. It occurs in more varied forms than any of the other crystalline sediments (see Fig. 232), some of the more common varieties of crystals being rhombic prisms, wedges, dumbbells, whetstones, prismatic rosettes, irregular or hexagonal plates, etc. Crystals of pure uric acid are always colorless (see Fig. 220), but the form occurring in urinary sediments is impure and under the microscope appears pigmented, the depth of color varying from yellow to a dark reddish brown according to the size and form of the crystal.

The presence of a considerable uric acid sediment does not, of necessity, indicate a pathological condition or a urine of increased uric acid content, since this substance very often occurs as a sediment in urines whose uric acid content is diminished from the normal merely as a result of changes in reaction, etc. Pathologically, uric acid sediments occur in gout, acute febrile conditions, chronic interstitial nephritis, etc. If the microscopical examination is not conclusive, uric acid may be differentiated

FIG. 233. ACID SODIUM URATE.

from other crystalline urinary sediments from the fact that it is soluble in alkalis, alkali carbonates, boiling glycerol, concentrated sulfuric acid, and in certain organic bases such as ethylamine and piperidine. It also responds to the murexide test, Schiff's reaction, and to Folin's phosphotungstic acid reaction (see p. 797).

**Urates.** The urate sediment may consist of a mixture of the urates of ammonium, calcium, magnesium, potassium, and sodium. The ammonium urate may occur in neutral, alkaline, or acid urine, whereas the other forms of urates are confined to the sediments of acid urines. Sodium urate occurs in sediments more abundantly than the other urates. There are two sodium urates, the mono- and the di-, which may be expressed thus:

The so-called quadriurate or hemiurate have no existence as chemical units. The urates of calcium, magnesium, and potassium are amorphous in character, whereas the urate of ammonium is crystalline. Sodium urate may be either amorphous or crystalline. When crystalline it forms groups of fan-shaped clusters or colorless, prismatic needles (Fig. 233). Ammonium urate is ordinarily present in the sediment

in the burrlike form of the thorn-apple crystal, i.e., yellow or reddish-brown spheres, covered with sharp spicules or prisms (Fig. 234). The urates are all soluble in hydrochloric acid or acetic acid and their acid solutions yield crystals of uric acid upon standing. They also respond to the murexide test. The clinical significance of urate sediments is very similar to that of uric acid. A considerable sediment of amorphous urates does not necessarily indicate a high uric acid content, but ordinarily signifies a concentrated urine having a very strong acidity.

**Cystine.** Cystine is one of the rarer of the crystalline urinary sediments. It has been claimed that it occurs more often in the urine of men than of women. Cystine crystallizes in the form of thin, colorless, hexagonal plates (see Fig. 45), which are insoluble in water, alcohol, and acetic acid, and soluble in mineral acids, alkalies, and especially in ammonia. Cystine may be identified by burning it upon platinum foil,

FIG. 234. AMMONIUM URATES, SHOWING SPHERULES AND THORN-APPLE-SHAPED CRYSTALS. (AFTER PEYER.)

under which condition it does not melt but yields a bluish-green flame. For the preparation of cystine, see p. 140.

**Cholesterol.** Cholesterol crystals have been but rarely detected in urinary sediments. When present they probably arise from a pathological condition of some portion of the urinary tract. Crystals of cholesterol have been found in the sediment in cystitis, pyelitis, chyluria, and nephritis. Ordinarily they occur as large regular and irregular colorless, transparent plates, some of which possess notched corners (see Fig. 101). Frequently, instead of occurring in the sediment, cholesterol is found in a film on the surface of the urine.

**Hippuric Acid.** This is one of the rare sediments of human urine. It deposits under conditions similar to those which govern the formation of uric acid sediments. The crystals, which are colorless needles or prisms (see Fig. 223) when pure, are invariably pigmented in a manner similar to the uric acid crystals when observed in urinary sediment and because of this fact are frequently confounded with the rarer forms of uric acid. Hippuric acid may be differentiated from uric acid from the fact that it does not respond to the murexide test and is much more soluble in water and in ether. The

detection of crystals of hippuric acid in the urine has very little clinical significance, since its presence in the sediment depends in most instances very greatly upon the nature of the diet. It is particularly prone to occur in the sediment after the ingestion of certain fruits as well as after the ingestion of benzoic acid (see p. 804).

**Leucine and Tyrosine.** Leucine and tyrosine have frequently been detected in the urine, either in solution or as a sediment. Neither of them occurs in the urine ordinarily except in association with the others, i.e., whenever leucine is detected it is more than probable that tyrosine accompanies it. They have been found pathologically in the urine in acute yellow atrophy of the liver, in acute phosphorus poisoning, in cirrhosis of the liver, in severe cases of typhoid fever and smallpox, and in leukemia. In urinary sediments leucine ordinarily crystallizes in characteristic spherical masses which show both radial and concentric striations and are highly refractive (Fig. 235). Some investigators claim that these crystals which are ordinarily called leucine are, in reality, generally urates. For the crystalline form of pure leucine obtained as a decomposition product of protein, see Fig. 42. Tyrosine crystallizes in urinary sediments in the well-known sheaf or tuft formation (Fig. 44). For other tests on leucine and tyrosine, see pp. 135 and 138.

FIG. 235. CRYSTALS OF IMPURE LEUCINE (OGDEN).

**Bilirubin.** Bilirubin crystallizes in the form of tufts of small needles or in the form of small plates which are ordinarily yellowish red in color (Fig. 100). Pathologically, typical crystals of bilirubin have been found in the urinary sediment in jaundice, acute yellow atrophy of the liver, carcinoma of the liver, cirrhosis of the liver, and in phosphorus poisoning, typhoid fever, and scarlatina.

**Magnesium Phosphate.** Magnesium phosphate crystals occur rather infrequently in the sediment of urine which is neutral, alkaline, or feebly acid in reaction. It ordinarily crystallizes in elongated, highly refractive, rhombic plates which are soluble in acetic acid.

**Indigo.** Indigo crystals are frequently found in urine which has undergone alkaline fermentation. They result from the breaking down of indoxyl sulfates or indoxylglycuronates. Ordinarily indigo deposits as dark blue stellate needles or occurs as amorphous particles or broken fragments. These crystalline or amorphous forms may occur in the sediment or may form a blue film on the surface of the urine. Indigo crystals generally occur in urine which is alkaline in reaction, but they have been detected in acid urine.

**Xanthine.** Xanthine is a constituent of normal urine but is found in the sediment in crystalline form very infrequently, and then only in pathological urine. When present in the sediment xanthine generally occurs in the form of whetstone-shaped crystals somewhat similar in form to the whetstone variety of uric acid crystal. They may be differentiated from uric acid by the great ease with which they may be brought into solution in dilute ammonia and on applying heat. Xanthine may also form urinary calculi. The significance of xanthine in urinary sediment is not well understood.

**Melanin.** Melanin is an extremely rare constituent of urinary sediments. Ordinarily in melanuria the melanin remains in solution; if it separates it is generally held in suspension as fine amorphous granules.

**Sulfonamides.** After administration of the sulfonamides (see p. 657 for discussion of chemical nature) crystalline deposits of the free drug or of its acetylated derivative may be found in the urine. Sulfonamide crystals may be recognized by their characteristic appearance (Fig. 236). If the crystals form in the renal tubules during the formation of urine, kidney damage accompanied by hematuria may result. Since the

compounds producing the crystals are much more soluble in the form of their alkali salts, the maintenance of an alkaline urine during sulfonamide therapy will prevent the deposition of the crystals.

FIG. 236. TYPES OF URINARY CRYSTALS OF THE SULFONAMIDE COMPOUNDS.

A, Sulfathiazole; B, sulfapyridine; C, sulfanilamide; D, sulfadiazine.

## II. ORGANIZED SEDIMENTS

Among the more important organized sediments are casts of different types, epithelial cells, pus cells, erythrocytes, and microorganisms. Cylindroids, spermatozoa, urethral filaments, tissue debris, animal parasites, fibrin, and foreign substances due to contamination, are also observed. For detailed discussions of these organized sediments see books on clinical diagnosis or clinical pathology.

### CALCULI

Urinary calculi, also called concretions or concrements, are solid masses of urinary sediment formed in some part of the urinary tract. They vary in shape and size according to their location, the smaller calculi, termed

sand or gravel, in general arising from the kidney or the pelvic portion of the kidney, whereas the large calculi are ordinarily formed in the bladder. The condition in which calculi are formed in the human body is termed *lithiasis*. Very large stones may also form in the kidney. One of these, the so-called staghorn stone, may fill the entire central portion of the kidney. There are two general classes of calculi as regards composition, viz., simple and compound. The simple form is made up of but a single constituent, whereas the compound type contains two or more individual constituents. The structural plan of most calculi consists of an arrangement of concentric rings about a central nucleus, the number of rings frequently being dependent upon the number of individual constituents which enter into the structure of the calculus. However, layers quite different in macroscopical appearance may be almost identical in composition.

In India and China urinary calculi are most frequently found in children. Up to the middle of the nineteenth century this was true for Europe and America also. But with improvement in diet of more recent years, vesical calculus in children has become rare in this country and is now primarily a disease of old age, more than half of persons admitted for operation being between the ages of 50 and 70. Calculi have been found in Egyptian tombs dating as far back as 4800 B.C.

The etiology of stone in man is still obscure. In rats urinary lithiasis can be regularly produced by diets low in vitamin A. It may be secondary to the epithelial degeneration in the urinary bladder which occurs in vitamin-A deficiency. The calculi contain ammonium magnesium phosphate, calcium carbonate, and calcium hydroxide. The greater frequency of lithiasis in earlier times and the prevalence of stone in children in the Orient may very probably be related to dietary deficiency. Whether vitamin A or other dietary deficiency bears any important relationship to the etiology of calculus disease in this country at the present time is uncertain.

Urinary calculi have frequently been noted in patients with a variety of bone disorders. In certain of these, associated with hyperparathyroidism, the calculus formation may be related to the markedly increased excretion of calcium in the urine. Immobilization of the patient may also be a factor.

Stone formation appears often to be secondary to infection in the urinary tract. Clumps of bacteria and epithelial and pus cells may act as foreign-body nuclei for stone formation and the alkaline fermentation frequently associated with infection is favorable to the precipitation of calcium and ammonium magnesium phosphates, which are the most common constituents of secondary calculi. The majority of stones appear, however, to arise in aseptic urines. That stone formation is not commonly due to any metabolic defect is indicated by the fact that most stones are not composed of any one substance but are of a mixed type.

Attempts have been made to account for the greater solubility of uric acid and other substances in the urine than in pure water, on the basis of the presence, in the urine, of protective colloids which hinder precipitation. According to this view stone formation may occur when this colloid is altered or diminished in quantity. In support of this view it is stated that the crystal form of calcium oxalate in calculi is not that noted to

form in pure solutions, but is similar to that produced when precipitation occurs in colloidal solutions. It is possible that precipitation of colloidal material with the crystalloids does conduce to the formation of a concrement rather than a mere precipitate of the latter.

According to the investigation of Meyer, however, the growth of a concrement depends solely on the degree of saturation of the urine for the crystalline constituents and such precipitation of the crystalline constituents occurs in just the same way in urine as in pure aqueous salt solutions. In determining the nature of the sediment or calculus formed the pH is a controlling factor. Uric acid tends to precipitate out of normal urines of average composition when the acidity becomes high (in the neighborhood of pH 5). At pH 6 mixed calculi of uric acid, sodium urate, and calcium oxalate and phosphate will tend to form. At pH 7 calcium phosphate calculi would tend to form and between pH 7 and 8 with the urine ammoniacal mixed calculi of calcium phosphate, magnesium ammonium phosphate, and ammonium urate may form which may be firm if precipitation occurs slowly. At pH values above 8 the rapid precipitation would tend to produce soft stones containing calcium carbonate, ammonium magnesium phosphate, and ammonium urate.

Aside from the question of protective colloids, certain of the stone-forming constituents may, under certain conditions, themselves exist in part in colloidal solution. Thus Hammarsten found that lithium and potassium urates gave true solutions at 37°. Sodium and ammonium urates in saturated solution are present partly in colloidal form. At the average chloride concentration of the urine the solubility products of the latter may be increased 300 per cent. Urates and uric acid in the presence of chlorides thus have a strong tendency to form supersaturated solutions.

According to Stillman,<sup>2</sup> out of 510 urinary calculi submitted for routine examination over a period of five to six years at the New York Hospital, about 44 per cent consisted largely of calcium carbonate, calcium phosphate, or "triple phosphate," either alone or in mixture; about 49 per cent were largely calcium oxalate, with some instances of admixture with phosphate and carbonate; and about 6 per cent were largely uric acid. Cystine calculi occurred to the extent of 0.8 per cent. These examinations refer to the principal constituent of the calculus; no attempt was made to isolate a nucleus and analyze it. Ultzmann has reported that in 545 cases of urinary calculus, uric acid and urates formed the nucleus in about 81 per cent of the cases, earthy phosphates in about 9 per cent, calcium oxalate in about 6 per cent, cystine in a little over 1 per cent, and some foreign body in about 3 per cent.

In the chemical examination of urinary calculi the most valuable data are obtained by subjecting each of the concentric layers of the calculus to a separate analysis. Material for examination may be conveniently obtained by sawing the calculus carefully through the nucleus, then separating the various layers, or by scraping off from each layer (without separating the layers) enough powder to conduct the examination as outlined in the scheme (see p. 863).

|                                            |                |                                  |                                     |                                                 | Effervesces.                                                                                                                                                                                                                                                                                | Calcium carbonate.                                                  |
|                                            |                |                                  |                                     |                                                 |                                                                                                                                                                                                                                                                                             | Calcium oxalate.                                                    |
|                                            |                |                                  |                                     |                                                 | <p>No ammonia or, at least, only traces of ammonia. Powder dissolves in acetic acid or HCl. This solution gives an amorphous precipitate with ammonia.</p> <p>Abundant ammonia. The powder dissolves in acetic acid or HCl. This solution gives a crystalline precipitate with ammonia.</p> | Bone-earth (magnesium and calcium phosphate).                       |
|                                            |                |                                  |                                     |                                                 |                                                                                                                                                                                                                                                                                             | “Triple phosphate” (mixed with unknown amount of earthy phosphate). |

Butt, Hauser, and Seifter<sup>3</sup> have proposed a therapy for renal lithiasis which embraces a pronounced increase in the urinary protective colloids through the subcutaneous injection of *hyaluronidase* in isotonic sodium chloride solution (see "Connective Tissue," p. 243).

## VARIETIES OF CALCULI

**Uric Acid and Urate Calculi.** Uric acid and urates constitute the nuclei of a large proportion of urinary concretions, but stones which consist chiefly of uric acid or urates are found in less than 1 out of 10 cases. Such stones are always colored, the tint varying from a pale yellow to a brownish red. The surface of such calculi is generally smooth but it may be rough and uneven.

**Phosphatic Calculi.** Ordinarily these concretions consist principally of "triple phosphate" and other phosphates of the alkaline earths, with very frequent admixtures of urates and oxalates. The surface of such calculi is generally rough but may occasionally be rather smooth. The calculi are somewhat variable in color, exhibiting gray, white, or yellow tints under different conditions. When composed of earthy phosphates the calculi are characterized by their friability.

**Calcium Oxalate Calculi.** These calculi are quite hard and are rather difficult to crush. They ordinarily occur in two general forms, viz., the small, smooth concretion which is characterized as the hemp-seed calculus, and the medium-sized or large stone possessing an extremely uneven surface, which is generally classed as a mulberry calculus. This roughened surface of the latter form of calculus is due, in many instances, to protruding calcium oxalate crystals of the octahedral type.

**Calcium Carbonate Calculi.** Calcium carbonate concretions are quite common in herbivorous animals, but are of exceedingly rare occurrence in man. They are generally small, white, or grayish calculi, spherical in form, and possess a hard, smooth surface. These considerations apply to stones consisting largely if not entirely of calcium carbonate. Mixed calculi which contain smaller but readily demonstrable amounts of calcium carbonate are rather common in man.

**Cystine Calculi.** Cystine calculi are of very rare occurrence, the incidence being usually less than 1 per cent. Ordinarily they occur as small, smooth, oval, or cylindrical concretions which are white or yellow in color and of a rather soft consistency.

**Xanthine Calculi.** This form of calculus is somewhat more rare than the cystine type. The color may vary from white to brownish yellow. Very often uric acid and urates are associated with xanthine in this type of calculus. Upon rubbing a xanthine calculus it has the property of assuming a waxlike appearance.

**Urostealith Calculi.** This form of calculus is extremely rare. Such concretions are composed principally of fat and fatty acid. When moist they are soft and elastic, but when dried they become brittle. Urostealiths are generally light in color.

**Fibrin Calculi.** Fibrin calculi are produced in the process of blood coagulation within the urinary tract. They frequently occur as nuclei of other forms of calculus. They are rarely found.

**Cholesterol Calculi.** This is an extremely rare form of calculus somewhat resembling the cystine type.

**Indigo Calculi.** Indigo calculi are extremely rare.

The scheme proposed by Heller and given on p. 863 will be found of much assistance in the chemical examination of urinary calculi.

## Urine: Quantitative Analysis

In analyzing a normal or pathological urine quantitatively for any of its constituents, it is particularly necessary that the complete and exact 24-hour sample be obtained. For directions with regard to the collection and preservation of urine for analysis, see Chapter 27 "General Characteristics of Normal and Pathological Urine." Methods for the determination of the specific gravity of the urine are also there described. Before any urine is taken for analysis its total volume should be measured, using a large graduated cylinder, and this volume is thereafter taken as a basis for the calculations of the daily output of the individual constituents determined.

### PREPARATION OF STANDARD ACID AND ALKALI SOLUTIONS

**Principle.** Many of the quantitative methods used in physiological chemistry are volumetric or titration procedures. For these methods solutions of accurately known strength called standard solutions are needed. Their strength is usually expressed in terms of normality. A normal solution is one which in 1000 ml. contains 1 g. of replaceable hydrogen or its equivalent. Thus, to make 1000 ml. of a normal solution of hydrochloric acid (HCl), we would need 36.5 g. of this acid containing 1 g. of replaceable hydrogen. This we derive from the fact that the atomic weight of Cl is 35.5 and of H is 1, so that the molecular weight of HCl is 36.5, and each 36.5 g. of this acid contains 1 g. of replaceable hydrogen.<sup>1</sup> Sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) has a molecular weight of 2 + 32 + 64 = 98, but 98 g. of sulfuric acid contains 2 g. of replaceable hydrogen. Therefore, to prepare a normal solution of this acid, we must use one-half of 98 or 49 g. of sulfuric acid (containing 1 g. of hydrogen) for 1000 ml. of normal solution. Oxalic acid (H<sub>2</sub>C<sub>2</sub>O<sub>4</sub> + 2H<sub>2</sub>O) has a molecular weight of 2 + 24 + 64 + 36 = 126. It also is a dibasic acid so we must use only one-half of 126 or 63 g. of oxalic acid in making a liter of normal solution.

A normal alkali solution is exactly equivalent to a normal acid solution, i.e., 1 liter of the alkali will neutralize 1 liter of the acid. According to the reaction of neutralization, therefore, the 36.5 g. of HCl in a liter of this normal acid will require 40.0 g. of sodium hydroxide to neutralize it, and 1 liter of normal sodium hydroxide must contain 40.0 g. of the alkali.

<sup>1</sup> See table of atomic weights, Appendix.

Having prepared solutions of acid and alkali of definitely known strength, it is then possible to determine the strength of any unknown acid or alkali by finding out much much of these standard solutions is required to neutralize a definite volume of the unknown solution.

In order to tell when the unknown solution has been exactly neutralized, we titrate in the presence of a small amount of one of a class of substances called indicators. An indicator is a substance which undergoes a sharp color change at a particular range of hydrogen-ion concentration, and this color change indicates the end-point of the titration.

When strong acids (as HCl) are being titrated with strong alkalies (as NaOH), almost any one of the common indicators is satisfactory. If weak acids (acetic acid) or weak bases (as ammonia) are being titrated, it is necessary to be very careful in the choice of an indicator as all indicators are not equally satisfactory in these instances.<sup>2</sup> (See p. 39.)

**Preparation of 0.1 N Oxalic Acid Solution.** Weigh accurately a watch glass or a piece of glazed paper. Then add to the weights on the balance pan 3.1512 g. With a spatula transfer to the watch glass enough pure oxalic acid in the form of clear crystals to counterbalance exactly the weights in the opposite pan. Transfer completely to a 250-ml. beaker, using a little water for rinsing purposes. Add about 150 ml. of distilled water and stir with a glass rod until dissolved, warming gently if necessary. Transfer every particle of this solution to a clean 500-ml. volumetric flask, rinsing rod and beaker several times with distilled water. Hold under the tap until cooled to room temperature. Then add distilled water until the bottom of the meniscus is level with the mark on the neck of the flask (the lower mark if there are two). Insert a stopper and mix thoroughly by inverting the flask again and again. Transfer to a clean dry bottle. Label. This solution will not keep indefinitely and is to be used only in the standardization of 0.1 N alkali.

**Preparation of 0.1 N Sodium Hydroxide Solution.**

(a) PREPARATION OF CONCENTRATED CARBONATE-FREE SODIUM HYDROXIDE SOLUTION. Shake up about 110 g. of best quality NaOH with 100 ml. of distilled water in a 300-ml. Erlenmeyer flask (pyrex) to make a saturated solution. Stopper and allow to stand for a couple of days or until the sodium carbonate settles to the bottom, leaving a clear solution of NaOH practically free from carbonate.

(b) PREPARATION OF A STANDARD SODIUM HYDROXIDE SOLUTION. Measure out 6.3 ml. of the saturated NaOH solution from a buret into a 1-liter flask. Add 750 ml. of distilled water and mix thoroughly. Clean a buret by allowing it to stand filled with cleaning mixture (sodium dichromate and sulfuric acid) for a few minutes or longer if necessary. Empty, rinse several times with tap water, finally with distilled water, and allow to drain. Introduce a few ml. of the NaOH solution, and invert a couple of times to rinse the buret, discarding this NaOH. Repeat this process at least twice more. Then fill the buret with the alkali solution, making sure that the tip contains no air bubbles, and run out solution until the bottom of the meniscus is exactly at 0.

Into a clean Erlenmeyer flask (150 to 250 ml.) now introduce 25 ml. of 0.1 N oxalic acid solution measured from an accurate, clean pipet, previously rinsed by means of a little of the acid solution drawn up into it. Allow the pipet to drain about 15 seconds against the side of the flask. Add 2 to 3 drops of a 1 per cent alcoholic solution of phenolphthalein.

<sup>2</sup> For further consideration of indicators see pp. 38 and 378.

Now run in NaOH solution from the buret, rotating the flask. Ten ml. can be added quite rapidly, then add more slowly, and finally drop by drop until the last drop changes the color of the solution permanently throughout to a definite pink. Take the buret reading, estimating as closely as possible to the second decimal place. Repeat the titration until two closely agreeing duplicate readings are obtained, then average the two readings for calculation.

Calculate the strength of the NaOH solution. Divide 25 (the number of ml. of 0.1 N oxalic acid used) by the buret reading to obtain the strength of the NaOH in terms of 0.1 N solution. Then multiply by 0.1 to obtain the normality. For example, if 15.67 ml. were required:  $25 \div 15.67 = 1.595$ ;  $1.595 \times 0.1 = 0.1595$  N.

(c) PREPARATION OF THE 0.1 N NaOH SOLUTION. Calculate how much of the standard NaOH solution just prepared will be required to make 1 liter of 0.1 N solution. To do this divide 1000 ml. by the strength of the NaOH in terms of 0.1 N solution. Thus in the example cited above:  $1000 \div 1.595 = 626.9$  ml. required. Measure out the exact amount of alkali required (using the buret, pipet, and volumetric flasks) into a 1000-ml. flask. Dilute with distilled water exactly to the mark. Mix very thoroughly and transfer to a clean, dry bottle with a rubber (not glass) stopper. Check the strength of the solution by again titrating 25-ml. portions of oxalic acid solution.<sup>3</sup>

*Preparation of 0.1 N Hydrochloric Acid.* Concentrated hydrochloric acid is about 12 N or 44 per cent HCl weight in volume. Approximately 0.1 N HCl may, therefore, be prepared by diluting 9 ml. of the concentrated acid to 1 liter in a volumetric flask. This must be standardized by titration with 0.1 N alkali, using alizarin red or methyl red as an indicator.

Or introduce into a 1-liter flask 12 ml. of concentrated HCl and 750 ml. of distilled water. Mix well and titrate 10, 15, or 25 ml. portions of the acid solution with 0.1 N NaOH, using alizarin as an indicator. Dividing the number of ml. of 0.1 N NaOH required by the number of ml. of acid used gives the strength of the HCl in terms of 0.1 N solution. Dividing 1000 by this quotient gives the number of ml. of HCl solution to be measured into a volumetric flask and made up to 1000 ml.

This diluted solution will be 0.1 N HCl. It should be mixed thoroughly and 25-ml. portions of it checked by titration with the 0.1 N NaOH.<sup>4</sup>

Standard acid and alkali solutions are best kept in paraffin-lined bottles. The acid solution is the more permanent of the two; and standard sulfuric acid solutions are more permanent than hydrochloric acid solutions. Alkali solutions must be protected from the carbonic acid of the air, the solution being best drawn over into the buret by means of a siphon tube leading from the top of the buret to the interior of the alkali bottle. The

---

<sup>3</sup> If a very high degree of accuracy is desired, the alkali may be checked against pure acid potassium phthalate (mol. wt. 204.139). Dodge: *J. Ind. Eng. Chem.*, 7, 29 (1915); *J. Am. Chem. Soc.*, 42, 1655 (1920).

<sup>4</sup> The acid solution may be standardized directly in the following manner: Introduce a platinum dish containing very pure sodium bicarbonate or the highest grade anhydrous sodium carbonate into a hot-air oven previously heated to 200° C. Raise the temperature to 270° to 280°, but not above 300° C. Heat for half an hour, allow to cool in a desiccator, but while still a little warm, transfer to a glass-stoppered weighing bottle. Weigh out rapidly 0.1- to 0.2-g. portions of the sodium carbonate, dissolve in about 50 ml. of water in an Erlenmeyer flask, and titrate, using methyl orange as an indicator. One hundred ml. of 0.1 N acid is equivalent to 0.530 g. of dried sodium carbonate.

air inlet through the stopper of the bottle should be guarded by a tube containing soda lime.

**Preparation of Standard Hydrochloric Acid from a Constant Boiling Solution (Method of Hulett and Bonner): Procedure.** Make up by hydrometer about 200 ml. of HCl of specific gravity about 1.10. Distil off about three-fourths of the liquid and discard. Then collect about 25 ml. of the constant-boiling distillate. Weigh 18.017 g. of distillate using a capillary pipet for final adjustment (or measure out 16.442 ml. at 25° C.). Dilute to 1 liter. This is a 0.1 N solution of HCl. The figures given are for a barometric pressure of 760 mm. At 770 mm. use 18.039 g.; at 750 mm. use 17.996 g.; at 740 mm. use 17.975 g. and at 730 mm. use 17.953 g. The composition of the distillate should not vary more than 1 part in 10,000 from the figures given.

## TITRATABLE ACIDITY OF URINE

**Introduction.** The titratable acidity of the urine, as determined by the Folin method described here, is expressed in terms of the amount of standard alkali necessary to bring the urine from its original pH to the phenolphthalein end point, around pH 8.5 or 9. In normal urine, the "acid" titrated consists almost entirely of the acid phosphate ion,  $\text{H}_2\text{PO}_4^-$ , the reaction being as follows:

Small amounts of titratable acidity may be contributed normally by acid organic salts (acid urate, acid oxalate, etc.). In certain conditions, such as severe ketosis, significant amounts of free  $\beta$ -hydroxybutyric acid, for example, may be present in the urine and contribute to the titratable acidity. In general, however, monobasic organic acids are found in the urine largely if not entirely as their salts, and in this form contribute little or nothing to the total titratable acidity. To evaluate the significance of the excretion of organic acids on acid-base balance, they may be determined as such (see "Determination of Organic Acids," p. 871) or the urinary ammonia content determined as an index of base replacement (see p. 888).

The Folin method is theoretically unsound as an exact measure of acid excretion relative to the normal acid-base balance in the body, and cannot be used for such purposes. A more accurate picture is obtained if the urine is titrated back to the pH of the blood (pH 7.4) rather than to pH 9, since it is the difference between the pH of blood and urine which reflects the excretion of acid or base in excess of the amounts normally required for acid-base balance. A method for determining titratable acidity by titrating urine to pH 7.4 against a color standard is described by Henderson and Palmer;<sup>5</sup> a pH meter may also be used. In the Folin method, urines even more alkaline than the blood may show a positive "titratable acidity," the quantitative significance of which is obscure. Despite these limitations, the method is simple and has been widely used, especially for comparative purposes and in conjunction with

<sup>5</sup> Henderson and Palmer: *J. Biol. Chem.*, 17, 305 (1914).

the determination of urinary ammonia as an aid in estimating the severity of acidosis, as described by Fitz and Van Slyke.<sup>5a</sup>

**Folin's Method: Principle.** The urine is titrated with standard sodium hydroxide solution, using phenolphthalein as an indicator. Potassium oxalate is added to precipitate the calcium which would otherwise interfere with the end point due to the precipitation of calcium phosphate on neutralization of the urine.

**Procedure.** Place 25 ml. of urine in a 200-ml. Erlenmeyer flask and add 5 grams of finely pulverized potassium oxalate and 1 to 2 drops of a 1 per cent phenolphthalein solution to the fluid. Shake the mixture vigorously for 1 to 2 minutes and titrate it immediately with 0.1 N sodium hydroxide until a faint but unmistakable pink remains permanent on further shaking. For more accurate results, particularly with deeply colored urine, compare during the titration against a control sample of urine plus oxalate, until there is a distinct difference in color in the titrated sample. The control sample may then be used for a duplicate estimation, titrating it to color match against the first sample. Take the buret reading and calculate the titratable acidity of the urine under examination.

**CALCULATION.** If  $y$  represents the number of milliliters of 0.1 N sodium hydroxide used and  $y'$  represents the volume of urine excreted in 24 hours, the total acidity of the 24-hour urine specimen ( $x$ ) may be calculated by means of the following proportion:

$$25/y = y'/x \text{ (titratable acidity of 24-hour urine expressed in ml. of 0.1 NaOH)}$$

**Interpretation.**<sup>6</sup> The titratable acidity of the urine, expressed in ml. of 0.1 N alkali required to neutralize the 24-hour output by the method described, varies ordinarily from 200 to 500 under normal conditions with an average of perhaps 350. It is dependent almost entirely upon the diet, being low on a vegetable (base-forming) diet and high on a diet containing much meat, milk, cheese, rice, whole wheat products, etc. (acid-forming foods). On the administration of 15 g. of sodium bicarbonate it may go down to 100; the ingestion of much acid-forming food may increase it to 600. In fasting it may rise in a few days to 800. Acidities of less than 250 usually indicate a true alkalinity of the urine inasmuch as phenolphthalein changes at a pH significantly more alkaline than that of the blood, as discussed above. Samples of urine collected shortly after a meal may be alkaline due to the so-called "alkaline tide."

Bacterial decomposition of the urea of the urine occurring in the urinary tract will increase the amount of ammonia and decrease the acidity of the urine. The same change usually occurs in urine left in contact with the air. The acidity of the urine is increased in acidosis and cardiorenal and certain other disorders. The acidity of the urine may be somewhat increased by administration of mineral acids, acid phosphates,

---

<sup>5a</sup> Fitz and Van Slyke: *J. Biol. Chem.*, **30**, 389 (1917); Van Slyke: *J. Biol. Chem.*, **33**, 271 (1918); Barnett: *J. Biol. Chem.*, **33**, 267 (1918).

<sup>6</sup> Under the heading "Interpretation" there will be found, in connection with the various quantitative methods which follow, brief notes as to the possible significance of the results obtained. For further discussion see Chapters 27, 33, and 34. General references will be found listed at the end of the chapter, particularly with reference to clinical aspects.

or ammonium chloride, but it is much more difficult to increase than to decrease this acidity.

**Determination of Organic Acids (Method of Van Slyke and Palmer):<sup>7</sup>**

**Principle.** Carbonates and phosphates are precipitated and the filtrate titrated with acid from pH 8 to pH 2.7. In the procedure described, the indicators phenolphthalein and tropeolin OO are used to define the pH range; a pH meter may also be used. Variations in the technique are required in the albuminous or high-bicarbonate urines.

**Procedure.** Mix 100 ml. of urine with 2 g. of finely powdered calcium hydroxide and stir occasionally for 15 minutes. Filter. Carbonates and phosphates are removed. Transfer 25 ml. of filtrate to a 125- to 150-ml. test tube, add 0.5 ml. of 1 per cent phenolphthalein and 0.2 N HCl from a buret until pink color just disappears. This amount need not be measured. The pH is now about 8. Add 5 ml. of 0.02 per cent tropeolin OO<sup>8</sup> little by little with stirring to prevent precipitation of the dye. Titrate with 0.2 N HCl until the red color matches that of a standard (pH 2.7) made from 0.6 ml. 0.2 N HCl, 5 ml. of tropeolin OO solution and water to make 60 ml. When the end point is nearly reached dilute unknown to 60 ml. before completing the titration.

To avoid the buffering effect of protein in albuminous urine, acidify with a few drops of concentrated HCl, boil, and filter before proceeding with the addition of calcium hydroxide as described above. Similar acidification and aeration by pouring will sufficiently reduce the CO<sub>2</sub> content of high-bicarbonate urines (pH over 7).

**CALCULATION.** Subtract from ml. 0.2 N HCl the amount (usually 0.7 ml.) of the acid required to titrate a control tube of water between the same limits. Multiply the difference by 2 to get results in terms of 0.1 N acid (the usual basis) and by 1000/25 to get the value for 1000 ml. of urine.

**Interpretation.** The titration includes organic acids, creatine, creatinine, and a small amount of amino acids. Normally the excretion for 24 hours corresponds to 400 to 750 ml. of 0.1 N HCl or about 8 ml. per kg. of body weight. In diabetic acidosis values from 20 to 180 ml. per kg. have been observed. In diabetes this titration approximates closely the amount of  $\beta$ -hydroxybutyric and acetoacetic acids in the urine and may be substituted for the determination of these substances for clinical purposes.

## HYDROGEN-ION CONCENTRATION OR TRUE ACIDITY

**Colorimetric Method: Principle.** The reaction of the urine is determined by matching the colors produced when pH indicators are added respectively to the diluted urine and to the standard solutions of known reaction. This method is subject to salt and dilution errors but is sufficiently accurate for most clinical purposes.

**Procedure: Preparation of Standard Buffer Solutions.** The Sørensen phosphate buffer standards, together with the Walpole acetate standards, cover satisfactorily the range of pH of urine. The acetate buffers are prepared by mixing 0.1 N acetic acid and 0.1 N sodium acetate in the following proportions:

<sup>7</sup> Van Slyke and Palmer: *J. Biol. Chem.*, **41**, 567 (1920). Palmer: *J. Biol. Chem.*, **68**, 245 (1926). According to Widmark and Ljungberg (*Biochem. Z.*, **216**, 1 (1929)) the CaO used in this method carries down from 7 to 10 per cent of the ether-soluble acids of urine and thus gives slightly low results.

<sup>8</sup> In certain urines this indicator fades under acid conditions. Bromophenol blue may be substituted or, preferably, a pH meter may be used.

| <i>pH</i> | <i>0.1 N Acetic Acid</i> | <i>0.1 N Sodium Acetate</i> |
|-----------|--------------------------|-----------------------------|
|           | <i>ml.</i>               | <i>ml.</i>                  |
| 3.6       | 185                      | 15                          |
| 3.8       | 176                      | 24                          |
| 4.0       | 164                      | 36                          |
| 4.2       | 147                      | 53                          |
| 4.4       | 126                      | 74                          |
| 4.6       | 102                      | 98                          |
| 4.8       | 80                       | 120                         |
| 5.0       | 59                       | 141                         |
| 5.2       | 42                       | 158                         |
| 5.4       | 29                       | 171                         |
| 5.6       | 19                       | 181                         |

The phosphate buffers are prepared by mixing M/15 disodium phosphate and M/15 potassium acid phosphate in the proportions<sup>9</sup> given in the table below.

| <i>pH</i> | <i>M/15 Na<sub>2</sub>HPO<sub>4</sub></i> | <i>M/15 KH<sub>2</sub>PO<sub>4</sub></i> |
|-----------|-------------------------------------------|------------------------------------------|
|           | <i>ml.</i>                                | <i>ml.</i>                               |
| 5.4       | 3.0                                       | 97.0                                     |
| 5.6       | 5.0                                       | 95.0                                     |
| 5.8       | 7.8                                       | 92.2                                     |

| 7.2       | 71.5                                      | 28.5                                     |
| 7.4       | 80.4                                      | 19.6                                     |
| 7.6       | 86.8                                      | 13.2                                     |
| 7.8       | 91.4                                      | 8.6                                      |
| 8.0       | 94.5                                      | 5.5                                      |

If it is desired to use the Clark and Lubs standard buffer mixtures these may be prepared as described on p. 35, *et seq.*

**Choice of Indicator.** The selection of indicators depends on the pH range. See the table on p. 381. For urine, bromocresol green (pH 4.0 to 5.6), bromocresol purple (pH 5.4 to 7.0) and phenol red (pH 6.6 to 8.2) may be used. Methyl red (pH 4.4 to 6.0) may be substituted for bromocresol green, but is not so stable. Aqueous solutions of 0.04 per cent strength are used. Ten drops (or 0.5 ml.) of these indicators are added to 10-ml. portions of the standard buffer solutions covering the effective pH range of the particular indicator. For preparation of indicator solutions, see p. 39.

**Determination.** The urine is collected and kept under mineral oil. Into a test tube of the same diameter as those used to contain the indicator stand-

<sup>9</sup> Interpolated from the data of Sørensen. For the preparation of the M/15 solutions see p. 35.

ards, introduce 8 ml. of recently boiled distilled water and 10 drops (or 0.5 ml.) of a particular indicator solution, say bromocresol purple. To this diluted indicator solution now add a layer of mineral oil and then introduce, without exposure to air, 2 ml. of urine. Stir gently and match with indicator standards in a comparator block. A control tube containing the urine diluted 1:5 should be used in making the comparison, as described in the hydrogen-ion determination of blood (see p. 699).

If the urine is too acid or alkaline to come within the range of the indicator selected, repeat, using a more suitable indicator, until a satisfactory one is found.

**CALCULATION.** The colorimetric reading made on the diluted urine at room temperature may be approximately corrected to give the actual pH at 38° C., by subtracting 0.2 pH. The latter factor is, however, not constant, Hastings, Sendroy, and Robson warm the diluted urine to 38° C. before reading, and correct only for the dilution by subtracting 0.1 pH. This gives results which are claimed to be within 0.05 pH of the electrometric pH of the undiluted urine at 38° C.

**Interpretation.** The pH of urine may vary over the extreme range of pH 4.8 to 8.0; normal pH values lie between about 5.5 and 8.0, with a mean value of about 6.0. In most pathological conditions the mean pH is lowered (increased acidity). The factors influencing urinary pH are similar to those influencing the titratable acidity of the urine (diets containing acid- and base-forming foods and the administration of acid or alkali); the two are not necessarily related quantitatively, however. Thus a dilute urine and a concentrated urine may have the same pH, but quite different titratable acidities. The pH may be considered as an *intensity* factor, while the titratable acidity is a *capacity* factor. The determination of urinary pH is of importance clinically largely in relation to the precipitation of insoluble material from the urine and the possible formation of urinary calculi. For example, in acid urine, urates and certain sulfonamides may precipitate out; prophylaxis entails the maintenance of an alkaline urine in which these substances are more soluble. The reverse is true for phosphate calculi, which form in alkaline urine but are soluble in acid urine. Urinary pH may be lowered by the administration of ammonium chloride or raised by sodium bicarbonate.

**Electrometric Method.** The colorimetric determination of urinary pH has been largely replaced for research purposes by the use of the glass-electrode pH meter (see p. 48). More accurate results are obtained, and color or turbidity of the urine does not influence results.

## TOTAL SOLIDS

**Drying Method.** Place 5 ml. of urine in a weighed shallow dish, acidify *very slightly* with acetic acid (1 to 3 drops), and dry it *in vacuo* in the presence of sulfuric acid to constant weight. Calculate the percentage of solids in the urine sample and the total solids for the 24-hour period.

**Interpretation.** The average excretion of total solids by a normal adult man is about 70 g. It is largely dependent upon the protein and salts of the diet. It may be decreased in severe nephritis due to impaired excretion, and greatly increased in diabetes with high sugar elimination.

Practically all the methods whose technique includes evaporation at an

increased temperature, either under atmospheric conditions or *in vacuo*, are attended with error.

Shackell's method which entails the vacuum desiccation of the frozen sample is extremely satisfactory and should be used where the greatest accuracy is desired.

Long's coefficient (2.6) was at one time used to compute the solids content of urine. The second and third decimal figures of the specific gravity were multiplied by 2.6 to give the number of grams of solid matter in 1 liter of urine. This procedure is now obsolete.

## TOTAL NITROGEN

**1. Kjeldahl Method:**<sup>10</sup> **Principle.** The principle of this method is the conversion of the various nitrogenous compounds of the urine into ammonium sulfate by boiling with concentrated sulfuric acid, the subsequent decomposition of the ammonium sulfate by means of a fixed alkali (NaOH), and the collection of the liberated ammonia in an acid of known strength. Finally, this partly neutralized acid solution is titrated with an alkali of known strength and the nitrogen content of the urine under examination computed.

FIG. 237. FOLIN FUME ABSORBER.

**Procedure.** Place 5 ml. of urine in a 500-ml. long-necked pyrex-glass Kjeldahl flask, add 20 ml. of concentrated sulfuric acid and about 0.2 g. of copper sulfate and boil the mixture until it becomes light green or almost colorless, and then for about an hour longer. Avoid too strong a flame at this point, to prevent loss of acid. If a suitable hood or fume chamber is not available the sulfuric acid vapors may be carried away by suction. Various devices for this purpose are listed in laboratory supply dealers' catalogues; the Folin fume-absorber (Fig. 237), placed in the mouth of the flask, may also be used.

When oxidation of the sample is complete, allow the flask to cool and dilute the contents with about 200 ml. of ammonia-free water. Add a little more of a concentrated solution of NaOH than is necessary to neutralize the sulfuric acid<sup>11</sup> down the side of the flask in such a way that the alkali does not mix with the solution in the flask but forms a layer beneath it, and introduce into the flask a little coarse pumice stone, a scoop of talcum, or a few pieces of granulated zinc,<sup>12</sup> to prevent bumping. A small piece of paraffin may be added to lessen the tendency to froth. By means of a safety tube connect the flask with a condenser so arranged that the delivery tube passes into a receiving flask containing a few drops of methyl red indicator and a known volume (the volume used depending upon the nitrogen content of the urine) of 0.1 N sulfuric acid. The end of the delivery tube must reach beneath the surface of the fluid.<sup>13</sup> Mix the contents of the distillation flask very thoroughly by

<sup>10</sup> There are numerous modifications of the original Kjeldahl method; the one described here, however, has given excellent satisfaction and is recommended for the determination of the nitrogen content of urine. With more resistant materials the addition of 10 g. of potassium sulfate in the acid digestion helps by raising the boiling point.

<sup>11</sup> This concentrated sodium hydroxide solution should be prepared in quantity and check tests should be made to determine the volume of the solution necessary to neutralize the volume (20 ml.) of concentrated sulfuric acid used. A few drops of phenolphthalein may be added prior to introducing the concentrated alkali to insure the addition of an excess.

<sup>12</sup> Powdered zinc may be substituted.

<sup>13</sup> This delivery tube should be of large caliber in order to avoid the sucking back of the fluid.

rotatory shaking and distil the mixture until its volume has diminished about one-half. Titrate the partly neutralized 0.1 N sulfuric acid solution by means of 0.1 N sodium hydroxide, and calculate the content of nitrogen of the urine examined.

**CALCULATION.** Subtract the number of ml. of 0.1 N sodium hydroxide used in the titration from the number of ml. of 0.1 N sulfuric acid taken. The remainder is equivalent to the number of ml. of 0.1 N sulfuric acid neutralized by the ammonia of the urine. One ml. of 0.1 N sulfuric acid is equivalent to 0.0014 g. of nitrogen. Therefore, if  $y$  represents the volume of urine used in the determination, and  $y'$  the number of ml. of 0.1 N sulfuric acid neutralized by the ammonia of the urine, we have the following proportion:

$$y/100 = (y' \times 0.0014)/x \text{ in which } x \text{ equals g. nitrogen per 100 ml. urine examined}$$

Calculate the quantity of nitrogen in the 24-hour urine specimen.

**Interpretation.** An adult of medium size on a mixed diet will usually excrete 12 to 18 g. of nitrogen per day in the urine. On a low-protein diet the urinary nitrogen may drop to as low as 5 g. or so per day; on a high-protein diet, it may rise to 22 to 25 g. or even more. The total nitrogen determination includes the nitrogen from *all* the nitrogenous constituents of the urine; under ordinary circumstances the compound *urea* contributes about 80 per cent or more of the total nitrogen, the remainder being distributed between the various other nitrogenous constituents present (see below). In a normal adult, the total nitrogen of the urine and of the feces will often be almost exactly equal to the total nitrogen of the diet. Such a condition is called "nitrogen equilibrium." The feces usually contain very little nitrogen; it is a customary approximation in metabolic studies to assume that the fecal nitrogen will be 10 per cent of the urinary nitrogen.

**CALCULATION OF PERCENTAGE NITROGEN DISTRIBUTION.** In modern metabolism studies where the various forms of nitrogen are determined, in addition to the total nitrogen as yielded by the Kjeldahl method, it is customary to indicate what portion of the total nitrogen was present in the form of each of the individual nitrogenous constituents. These percentage values are secured by dividing the weight (grams) of nitrogen excreted for the day in the form of each individual nitrogenous constituent by the weight of the total nitrogen output for the same period. For example, if the total nitrogen excretion is 9.814 g. and the excretion of urea-nitrogen is 8.520 g. and the excretions of nitrogen in the forms of ammonia and creatinine are 0.271 g. and 0.639 g. respectively, the percentage distribution for these forms of nitrogen would be calculated as follows:

$$\begin{array}{lcl} 8.520 \text{ g. urea-nitrogen} & \div & 9.814 \text{ g. total nitrogen} = 84.3 \text{ per cent} \\ 0.271 \text{ g. ammonia-nitrogen} & \div & 9.814 \text{ g. total nitrogen} = 2.7 \text{ per cent} \\ 0.639 \text{ g. creatinine-nitrogen} & \div & 9.814 \text{ g. total nitrogen} = 6.5 \text{ per cent} \end{array}$$

**NITROGEN PARTITION IN URINES CONTAINING ALBUMIN.** If the urine to be tested contains albumin, this must be removed before an attempt at a nitrogen partition is made. This may be done by heating to boiling, acidifying with acetic acid to coagulate the protein, filtering, and making up the filtrate to the original volume of the urine. If very small amounts

of albumin are present, removal is more difficult. In these cases the use of aluminum hydroxide cream is recommended since it removes none of the nitrogenous constituents of normal urine.

**Procedure.** One liter of urine (containing not over 1 per cent of albumin) is mixed with 1 liter of aluminum hydroxide cream<sup>14</sup> and filtered.

**2. Folin-Farmer Micro-Kjeldahl Method:**<sup>15</sup> **Principle.** This method belongs with the so-called microchemical methods inasmuch as it is adapted to the determination of amounts of nitrogen in the neighborhood of 1 mg. while in the ordinary Kjeldahl procedure 30 to 100 mg. of nitrogen is generally manipulated. One ml. of diluted urine is decomposed with sulfuric acid; as in the Kjeldahl method, the ammonia formed is set free by the addition of alkali, and carried over into an acid solution by means of a current of air. The ammonia solution is then treated with Nessler's reagent and the color produced compared with that of a standard solution of an ammonium salt treated in the same way. The reaction is

The solution of dimercuric ammonium iodide is colloidal. The conditions of formation must be carefully controlled to obtain uniformity and prevent precipitation. Chlorides decrease the color formation.

**Procedure.** Introduce 5 ml. of urine into a 50-ml. volumetric flask if the specific gravity of the urine is over 1.018, or into a 25-ml. flask if the specific gravity is less than 1.018.<sup>16</sup> Fill the flask to the mark with distilled water and invert it several times in order to guarantee thorough mixing. Transfer 1 ml. of the diluted urine to a large (20 to 25 mm. by 200 mm.) pyrex-glass test tube. To this add 1 ml. of concentrated sulfuric acid, 1 g. of potassium sulfate, 1 drop of 5 per cent copper sulfate solution, and a small, clean, quartz pebble or glass bead. (The pebble or bead is added to prevent bumping.) Boil the mixture over a microburner for about 6 minutes, i.e., about 2 minutes after the mixture has become clear and light green or almost colorless. Allow to cool until the digestion mixture begins to become viscous. This ordinarily takes about 3 minutes, but in any event the mixture must not be permitted to solidify. Add about 6 ml. of water (a few drops at a time, at first, then more rapidly) to prevent solidification. To this acid solution add an excess of sodium hydroxide solution (3 ml. of a saturated solution are sufficient), adding the alkali down the side of the tube so that it does not mix with the acid solution but forms a layer beneath it. Connect the tube with a suitable receiver in an aeration train (see Figs. 238 and 239) placing in the receiver<sup>17</sup> about 20 ml. of dilute (approximately 0.02 N) sulfuric acid. Start the air current (which mixes the alkali and acid in the digestion tube) and aspirate the

<sup>14</sup> See Appendix.

<sup>15</sup> Folin and Farmer: *J. Biol. Chem.*, 11, 493 (1912).

<sup>16</sup> The purpose is to dilute the urine so that 1 ml. of the diluted fluid shall contain 0.75 to 1.5 mg. of nitrogen.

<sup>17</sup> For a single analysis, a volumetric flask is used as receiver, and compressed air is used for aspiration. For serial analyses, a receiving tube similar to the digestion tube and fitted with a two-hole rubber stopper carrying a long inlet and a short outlet tube is used. Either compressed air, or suction obtained from a water pump and applied at the end of the train, may be used. The entering air must be washed by passage through a wash bottle containing dilute (1:10) sulfuric acid, to remove any ammonia which may be present. As many pairs of tubes as desired may be connected in series. For method of cleaning rubber tubing used for connection, see p. 553. If suction is used, in disconnecting when aeration is complete, decrease the rate of air passage to a slow stream and start at the end farthest from the pump to avoid back pressure.

liberated ammonia into the receiving solution. The air current should be started slowly and should be only moderately rapid for the first 2 minutes, but at the end of this two-minute period the current should be run at its maximum speed for an interval of 8 minutes, or until all the ammonia has been driven over. The time required for complete aspiration of the ammonia will differ under different conditions and should be established by trial.<sup>18</sup>

FIGS. 238 (left) AND 239 (right). FORMS OF AERATION APPARATUS (FOLIN AND FARMER).

When all the ammonia has been aerated over, disconnect the receiver, dilute the contents to about 60 ml. with ammonia-free water in a 100 ml. volumetric flask (if such a flask has not itself been used as receiver), and dilute similarly 1 mg. of nitrogen in the form of ammonium sulfate<sup>19</sup> in a second volumetric flask. Nesslerize both solutions as nearly as possible at the same time with 10 ml. of Nessler solution<sup>20</sup> measured in a graduated cylinder and diluted, immediately before using, with about 20 ml. of ammonia-free water to avoid turbidity. Immediately fill the two flasks to the mark with ammonia-free water, mix well and allow to stand 5 minutes before

<sup>18</sup> Run a trial analysis and have several receivers ready. After 8 minutes' aspiration, remove the first receiver and replace by a fresh one. Repeat at several later time intervals. Treat the contents of each receiver with Nessler solution, as described above for an analysis, and estimate from the color reaction the aeration time which gives complete transference of ammonia.

<sup>19</sup> Care should be taken to secure the pure salt. Ammonium salts may contain pyridine bases which titrate like ammonia but do not react with Nessler's reagent. Pure ammonium sulfate may be prepared by decomposing a high-grade ammonium salt with sodium hydroxide and passing the liberated ammonia into pure sulfuric acid. The salt is then precipitated by means of alcohol, brought into solution in water and then reprecipitated by alcohol. The final product should be dried in a desiccator over sulfuric acid. Pyridine-free ammonium salts are now obtainable on the market. A solution containing 0.4714 g. of ammonium sulfate in 1 liter of water, plus a few drops of concentrated sulfuric acid as preservative, contains 1 mg. of nitrogen in 10 ml. It is stable indefinitely.

<sup>20</sup> See Appendix.

reading in the colorimeter or photometer. For colorimetric comparison, match the standard against itself, and then the unknown against the standard, in the usual way (see p. 510). For photometric measurement, set the photometer to zero density (or 100 per cent transmittance) at 480  $m\mu$  (see below) with a blank prepared by diluting 10 ml. of Nessler reagent to 100 ml. with water. This blank will correct for any ammonia present in the diluting water, but not in the digestion reagents, etc. For more accurate results, run a blank and a standard through the entire analytical procedure (digestion, aeration, nesslerization), set the photometer to zero density with the blank, and obtain results in terms of the density of the analyzed standard. This should correct for ammonia in the reagents as well as systematic errors in the analysis.

*CALCULATION. For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. N in Standard} = \text{mg. N in volume of urine used}$$

At a 1:10 dilution of the urine, 1 ml. represents 0.1 ml. of urine; at a 1:5 dilution, 0.2 ml. of urine. Multiply the result of the above calculation by the dilution (10 or 5) to obtain the nitrogen content of the urine, in mg. per ml. or g. per liter (the two are identical). From this, the total nitrogen content of the 24-hour sample may be calculated.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. N in Standard} = \text{mg. N in volume of urine used}$$

Further calculation is similar to that described for colorimetric measurement.

**Interpretation.** See p. 875.

**Spectrophotometric Characteristics of the Nessler Color with Ammonia.** The color reaction between Nessler's reagent and ammonia is the basis for many other quantitative methods of biochemical importance, in addition to its use as described here for the determination of total nitrogen. The spectrophotometric characteristics of the Nessler color therefore deserve detailed consideration, since they determine the conditions for accurate photometric measurement, such as the choice of wavelength or filter, solution depth, and range of concentration over which Beer's law is applicable. The data presented here are based on nesslerization under the conditions described above, i.e., using 10 ml. of Nessler reagent in a final volume of 100 ml., in the absence of excess strong acid or alkali, or of protective substances such as gum ghatti. The values represent the conditions prevailing in the authors' laboratory at the time the analyses were made, and cannot be used for calibration purposes elsewhere, as discussed in Chapter 23, under "Colorimetry and Photometry," but may be used as a guide for such calibration.

The relation between the wavelength at which measurements are made, and light transmittance (optical density) for various amounts of ammonia nitrogen, measured at 1 cm. solution depth, is shown in Fig. 240A. There is no wavelength of peak or maximum light absorption in the visible portion of the spectrum for the amounts of nitrogen ordinarily encountered and under the prescribed conditions. The choice of wave-

length therefore depends largely upon the sensitivity desired and the range of concentration over which Beer's law is applicable. This information is supplied by Fig. 240B, which represents the data of Fig. 240A, plotted in terms of the relation between transmittance or density and concentration at various wavelengths.

It is shown in Fig. 240B that in a 1-cm. cuvette (or 12.5-mm. test tube, since the two are approximately equivalent) amounts of nitrogen up to 1.5 mg. in 100 ml. of nesslerized solution will read within the accurate portion of the photometer scale (see p. 523) at any wavelength between 480 and 520  $m\mu$ . Such amounts may be determined by calculation based upon the density of a 1 mg. standard in accordance with Beer's law, as

FIG. 240. SPECTROPHOTOMETRIC CHARACTERISTICS OF COLOR OBTAINED IN NESSLER REACTION WITH AMMONIA.

A, Relation between optical density and wave-length for solutions containing 0.5 mg. (a), 1.0 mg. (b), and 1.5 mg. (c), of ammonia nitrogen per 100 ml. final volume, at a solution depth of 1 cm. B, Relation between optical density and concentration at the wavelength indicated for each curve.

evidenced by the linearity of the "calibration curves" over this range. Above 520  $m\mu$  the sensitivity decreases and slight deviation from Beer's law is noted at higher concentrations of nitrogen. Below 480  $m\mu$ , agreement with Beer's law is excellent over the usable portion of the photometer scale, but the sensitivity is so great that only small amounts of nitrogen may be accurately measured. In a 2-cm. cuvette (a 22-mm. test tube is approximately equivalent to this) the same considerations apply, but at only half the concentration range specified for a 1-cm. cuvette. Under these conditions, the standard should contain 0.5 mg. of nitrogen, and the unknown not over 1 mg. of nitrogen per 100 ml. of nesslerized solution.

The proportionality between density and concentration with the wavelength or filter chosen should be tested for a particular photometer over the concentration range expected; significant deviation from Beer's law greater than that expected from the data of Fig. 240 usually indicates

that either the photometer or filter is at fault. In this event, results must be based upon the actual calibration data obtained with the instrument; the use of such a "calibration curve" and the precautions which must be associated with its use, are discussed in Chapter 23.

**Alternate Aeration Procedures with Titrimetric Estimation.** Instead of nesslerizing the aerated ammonia for colorimetric estimation, one may aerate it into acid and make the determination by titration. Two such procedures are described. They have the advantage over the colorimetric method of permitting the accurate determination of larger amounts of nitrogen (up to 3 mg. or so). A disadvantage is that too vigorous aeration may carry over a small amount of the fixed alkali used to liberate the ammonia, and thus lead to titrimetric (but not colorimetric) error. To catch any spray, the bulb portion of the aeration outlet tube may be loosely packed with glass wool; in any event, the apparatus should be tested for this possibility of error by running a blank determination or analyzing a solution containing a known amount of nitrogen.

**Aeration into Boric Acid.** Place 25 ml. of 2 per cent boric acid solution containing bromocresol green indicator, as described on p. 552 in connection with the determination of blood-urea nitrogen, in the receiving flask or test tube. Liberate the ammonia from the digest by alkali as described for the Folin-Farmer method, and aerate the liberated ammonia into the boric acid solution. When aeration is complete, remove the receiver and titrate the contents with 0.0143 N sulfuric acid (see p. 552) until the more or less blue color is exactly restored to its original yellow-green shade, as evidenced by matching against a control 25-ml. portion of boric acid plus indicator which is diluted with water to approximately the same final volume as the titrated sample. The end point should be sensitive to about 0.02 ml. of the standard acid.

**CALCULATION.** Each ml. of 0.0143 N acid is equivalent to 0.2 mg. of nitrogen. Multiply the number of milliliters of 0.0143 N acid used by 0.2 to give milligrams of nitrogen in the volume of urine used.

**Aeration into Standard Acid.** Aerate the liberated ammonia into a receiver containing 25 ml. of 0.01 N sulfuric acid. When aeration is complete, remove the receiver, add a drop of methyl red indicator solution, and titrate with 0.01 N sodium hydroxide to an orange or beginning yellow shade.

**CALCULATION.** Subtract the number of ml. of 0.01 N alkali used from 25.0, to obtain the amount of 0.01 N acid neutralized by the ammonia. Multiply this value by 0.14 to obtain the nitrogen content in mg. of the volume of undiluted urine used in the analysis, since each ml. of 0.01 N acid represents 0.14 mg. of nitrogen.

**3. Determination of Nitrogen by Micro-Kjeldahl and Distillation.** Instead of aerating over the ammonia of a micro-Kjeldahl determination, it may be distilled over and collected in acid for subsequent determination by colorimetric or titrimetric methods. In general, more accurate and consistent results are obtained by distillation than by aeration. Bock and Benedict have described a simple distillation procedure using an ordinary small Liebig condenser.<sup>21</sup> For research work, steam distillation has largely replaced simple distillation, and is the method of choice for all accurate micro-Kjeldahl analyses. Modern steam-distillation apparatus (see Fig. 241) is compact,

---

<sup>21</sup> Bock and Benedict: *J. Biol. Chem.*, 20, 47 (1915).

easy to use, almost automatic in operation, and requires but a few minutes for each sample.

**Procedure.** Digest the sample as described for the Folin-Farmer method, p. 876; or digest it with 1 ml. of concentrated sulfuric acid plus a few small grains of metallic selenium or a "Hengar granule" (a quartz chip coated with selenium).<sup>22</sup> Digestion must be continued until all of the nitrogen has been converted to ammonia; the time required for complete conversion varies with different types of material and should be established by trial.

Transfer the digested sample with rinsings to the chamber of the steam-distillation apparatus, which has previously been cleared of any contaminating ammonia by a blank distillation. Place the receiving fluid (this varies with the procedure, see below) in a small flask arranged so that the tip of the condenser outlet dips below the surface of the receiving fluid. Add sufficient concentrated sodium hydroxide to the digest in the chamber to more than neutralize the amount of acid present (determine by trial). Start the generation of steam in the boiler, and steam-distil the sample until 8 to 10 ml. or more of distillate have been collected in the receiving flask. Remove the receiver, rinsing down the sides of the condenser outlet tube with a little water in the process, and determine the ammonia in the distillate by any of the following procedures.<sup>23</sup>

(a) **COLORIMETRIC OR PHOTOMETRIC ESTIMATION.** Use 1 to 2 ml. of dilute (0.1 N) acid in the receiving flask and collect the distillate as described. Transfer the distillate to a container graduated at 25 ml., with rinsings up to about 20-ml. volume. Add 2.5 ml. of Nessler solution, dilute to 25 ml. with water, and mix.

Compare in a colorimeter or photometer with a standard containing 0.2 mg. of nitrogen, prepared in a second 25-ml. container in the same way as for the distillate. In photometric measurement, if the standard is digested and distilled as for the sample, and the photometer is set to zero density with a digested and distilled blank, correction is automatically obtained for any systematic error or for ammonia in the reagents.

FIG. 241. STEAM DISTILLATION APPARATUS.

<sup>22</sup> Obtainable from the Hengar Co., Philadelphia, or from dealers in laboratory supplies.

<sup>23</sup> On disconnection or diversion of the steam flow from the chamber of the apparatus, the residue of the sample will usually be removed automatically by siphoning in a few moments as the chamber cools down. The apparatus is then ready for the next sample, without further rinsing.

**CALCULATION.** Similar to that given for the Folin-Farmer procedure, p. 876. The result gives the mg. of nitrogen present in the portion of sample analyzed. The conditions for photometric measurement have been presented on p. 878. For accurate measurement, not more than 0.5 mg. of nitrogen may be present if a 1-cm. cuvette is used, or half this amount with a 2-cm. cuvette. Much smaller amounts than this (down to 0.01 mg. or less) may be accurately estimated by using 1 ml. of receiving acid in a test tube graduated at 10 ml., collecting the distillate up to the 10-ml. mark, adding 1 ml. of Nessler solution, and comparing photometrically with a suitable standard.

(b) **TITRIMETRIC ESTIMATION.** Place 10 ml. of 2 per cent boric acid, containing bromocresol green indicator as described on p. 552 for the determination of blood urea nitrogen, in the receiving flask, collect 10 to 15 ml. of distillate as described, and titrate the contents of the receiving flask with 0.0143 N (or 0.02 N) sulfuric acid until the solution has been brought back to its original yellow-green color. Match against a 10-ml. control portion of boric acid-indicator diluted with water to approximately the final volume of the titrated sample.

**CALCULATION.** Multiply the number of ml. of 0.0143 N (or 0.02 N) acid used by 0.2 (or 0.28) to obtain the mg. of nitrogen in the portion of sample used. Titration of a digested and distilled standard and blank will serve as a basis for correction for any ammonia present in the reagents. Amounts of nitrogen from 0.05 to 3 mg. or more may be accurately determined by this procedure. Alternatively, the distillate may be collected in 25 ml. of 0.01 N acid and the excess acid back-titrated with 0.01 N alkali in the presence of methyl red indicator, as described under the Folin-Farmer procedure. The boric acid method is preferred because it is a direct titration and requires only one standard solution, which is quite stable.

**4. Other Methods.** Many other modifications of the macro-Kjeldahl and micro-Kjeldahl determination of total nitrogen have been proposed; those described here are believed to be as satisfactory as any. For micro-Kjeldahl analyses, direct nesslerization of the diluted digest has been proposed by Folin and Denis and by Koch and McMeekin; these procedures are similar in details to the direct nesslerization methods for the determination of blood nonprotein nitrogen, as described in Chapter 23. In general, direct nesslerization is less satisfactory for urinary nitrogen than for blood nonprotein nitrogen, because of the difficulty of avoiding turbidity. Other methods of determining nitrogen include those based upon gasometric estimation; their use with urine is similar to that for blood nonprotein nitrogen, and references may be found in this connection in Chapter 23.

## UREA

### 1. UREASE METHODS

These methods depend upon the principle that the enzyme urease is able, at ordinary temperatures, to transform urea, quickly and completely, into ammonium carbonate. Takeuchi in 1909 discovered the presence of this enzyme in the soja or soy bean. The application of this enzyme to the determination of urea in urine, blood, etc., was first proposed by Marshall, whose methods have been modified by Van Slyke and Cullen. These latter investigators prepared a permanent preparation of the enzyme, in a water-soluble form, the use of which makes more con-

venient the rapid and accurate determination of urea in urine, blood, and other biological fluids.

The urease method is probably the most satisfactory of all methods for the determination of urea. Other nitrogenous constituents such as allantoin are not decomposed by urease. The method involves no carefully regulated heating procedures, and is applicable to diabetic urines. Since, however, the basis for the urea determination is essentially an analysis for the ammonia produced by the action of the enzyme, every analysis will include the preformed ammonia which is also present in the urine, so that uncorrected results represent *urea plus ammonia*. To obtain the urea content, it is necessary to know the amount of preformed ammonia present, as established by separate analysis, and to subtract this from the results of the urea determination. Urea (and ammonia) determinations should be carried out on fresh or recently collected and preserved samples of urine, since on long standing, even in the presence of preservatives, significant amounts of urea may undergo hydrolysis to form ammonia, thus leading to misinterpretation of the significance of both the urea and the ammonia values. Kinetic studies have shown that a high concentration of urea or ammonium ion tends to inhibit the action of urease.<sup>24</sup> The conversion of urea to ammonia may take place quite rapidly in urine contaminated with bacteria.

**a. Method of Van Slyke and Cullen: Principle.** The urine sample is treated with urease, and the ammonia formed is aerated into 0.02 N acid, which is then back-titrated with 0.02 N alkali. A modification based on aeration into boric acid and direct titration with standard acid is also described; this is preferred over the original method because just as accurate results are obtained and only one standard solution is required in a direct titration.

**PREPARATION OF SOLID UREASE.**<sup>25</sup> Digest 1 part of jack-bean meal<sup>26</sup> with 5 parts of water at room temperature, with occasional stirring, for an hour, and clear the solution by filtration through paper pulp or centrifuging. Pour this extract slowly, with stirring, into at least 10 volumes of acetone. The acetone dehydrates the enzyme preparation. Filter, dry in vacuum, and powder. The activity of the preparation is retained indefinitely. Thus prepared it is not perfectly soluble in water, but this fact interferes in no way with its use.

**STANDARDIZATION OF THE ENZYME PREPARATION.** Make up accurately a 3 per cent solution of pure urea. Treat this solution exactly as the urine is treated in the following method, using 0.5 ml. of the solution. The ammonia formed should neutralize 25 ml. of 0.02 N acid, or an equivalent amount of acid of other strength. If it does so the preparation is of sufficient strength to use as indicated. If not, more of the preparation must be used for a determination.

**Procedure.** Dilute 5 ml. of urine to 50 ml. with ammonia-free water. Measure 5 ml. of the diluted urine into a large test tube suitable for aeration (see Fig. 238, p. 877, and also Fig. 147, p. 552), add 1 drop of caprylic alcohol (to

---

<sup>24</sup> Laidler and Hoare: *J. Am. Chem. Soc.*, **71**, 2699 (1949).

<sup>25</sup> Van Slyke and Cullen: *J. Biol. Chem.*, **19**, 211 (1914). Dry urease prepared in this way is available commercially in powder and tablet form.

<sup>26</sup> Watermelon seeds have also been shown to be an excellent source of urease (Damodaran and Sivaramakrishnan: *Biochem. J.*, **31**, 1041 (1937)).

prevent frothing), and 1 ml. of enzyme solution.<sup>27</sup> Close the tube with a two-hole rubber stopper fitted with a long inlet tube and a short outlet tube, as illustrated in the figures cited, and let the tube stand 15 minutes for the enzyme to act. Measure into a second similar tube 25 ml. of 0.02 N HCl or H<sub>2</sub>SO<sub>4</sub>. Add 1 drop of caprylic alcohol and 1 drop of methyl red indicator solution. Connect the two tubes for aeration with washed air by either pressure or suction, as described on p. 876. At the end of 15 minutes aspirate for about one-half minute to transfer any ammonia present in the free condition to the receiving solution. After this aspiration, open the tube containing the sample and introduce 5 ml. of saturated potassium carbonate. Close the tube at once and aspirate until all the ammonia has been carried over into the acid in the receiver. The time needed for the aspiration varies for different pumps from 5 to 30 minutes, and should be determined by trial for the particular apparatus used. At the end of the time needed for the aeration, the pump is disconnected (care being taken to avoid back suction) and the excess acid in the receiver is titrated by means of 0.02 N NaOH.

**CALCULATION.** Subtract the number of ml. of 0.02 N alkali required for the titration from 25.0 to obtain the volume of 0.02 N acid equivalent to the ammonia present. Since 1 ml. of 0.02 N acid is equivalent to 0.28 mg. of nitrogen, and 0.5 ml. of urine is used in an analysis (5 ml. of a 1:10 dilution), multiply the volume of 0.02 N acid found equal to the ammonia by 0.56 ( $= 2 \times 0.28$ ) to obtain the *urea plus ammonia* nitrogen content, in g. per liter (mg. per ml.). Subtract from this value the ammonia-nitrogen content, in g. per liter, as established by a separate analysis (see p. 888), to obtain the urea-nitrogen content of the urine, in g. per liter. From this, and the total volume of the sample, the urea-nitrogen content of the 24-hour sample is readily obtained.

**Aeration into Boric Acid.** Proceed exactly as described above, but aerate the ammonia into 25 ml. of the 2 per cent boric acid-indicator solution described on p. 552 in connection with the determination of blood-urea nitrogen (see also the modified Folin-Farmer method, p. 880). When aeration is complete, titrate the boric acid solution with 0.0143 N (or 0.02 N) sulfuric acid until the more or less blue color has been restored to the original yellow-green color, as established by comparison with a control 25-ml. portion of boric acid-indicator solution which is diluted with water to approximately the same final volume as the titrated sample. The end point should be sharp to about 0.02 ml. of the standard acid.

**CALCULATION.** Each ml. of 0.0143 N acid is equivalent to 0.2 mg. nitrogen; if 0.02 N acid is used, 1 ml. equals 0.28 mg. nitrogen. Multiply the volume in ml. of acid required for the titration by 0.2 (or 0.28), and then further by 2, to obtain the urea plus ammonia nitrogen content of the urine, in g. per liter. Subtract the ammonia-nitrogen content of the urine, determined separately, to obtain the urea-nitrogen content.

**Interpretation.** The mean average daily excretion of urea by normal adults is usually placed at about 25 to 35 g. (10 to 15 g. of urea nitrogen) but is very closely dependent upon the protein ingestion and metabolism and hence may vary widely. In disorders associated with increased tissue catabolism, as in fevers, the excretion of urea is increased. It may be decreased in pronounced kidney and liver disorders due to decreased formation and decreased power of elimination, but these findings are not

<sup>27</sup> The enzyme solution is prepared by dissolving 2 g. of the enzyme preparation, 0.6 g. of dipotassium phosphate, and 0.4 g. of monopotassium phosphate in 10 ml. of water. Solution is aided by stirring with a glass rod. The slightly opalescent solution should be covered with toluene and may be kept for two weeks without losing activity.

constant. The determination of urinary urea, in conjunction with the determination of blood urea, is, however, of major clinical value as an index of kidney function (see urea clearance test, p. 965).

The percentage of the total nitrogen of the urine occurring as urea varies on the average from 80 to 90. On a high-protein diet it is nearer 90 per cent; on a very low-nitrogen but high-calorie diet it may not be over 60 per cent. In marked acidosis it may be considerably decreased relative to the total nitrogen (see "Ammonia," p. 888).

**b. Direct Nesslerization Method (Folin and Youngburg<sup>28</sup> Modified):**

**Principle.** The diluted urine is treated with an alcoholic urease solution to convert urea into ammonia, and the ammonia present is then determined by direct nesslerization. In the original procedure, preformed ammonia is removed by treatment with Permutit (a synthetic "exchange silicate," see p. 890) and the determination carried out on the ammonia-free solution. It has been found, however, that Permutit may at times remove a significant amount of the urea as well, and its use has been dispensed with in the modification described here. The total urea plus ammonia nitrogen is determined by direct nesslerization after urease treatment; the preformed ammonia content of the urine, as determined by a separate analysis (p. 888) is subtracted from the result to give the urea-nitrogen content of the urine.

Direct nesslerization is perhaps not quite so accurate as the aeration procedures because of the possibility of turbidity produced by interfering substances in the color reaction, but the procedure has the advantage of simplicity and the results are quite suitable for most purposes.

**Procedure.** Dilute 5 ml. of urine to 100 ml. in a volumetric flask and mix well. Transfer 1 ml. of the diluted urine to a test tube, add 1 ml. of the alcoholic urease solution,<sup>29</sup> and 1 drop of buffer solution.<sup>30</sup> Digest in a beaker of warm water (40° to 55° C.) for 5 minutes or at room temperature for 15 minutes, at the end of which time transfer the contents of the test tube, with rinsings, to a 100-ml. volumetric flask, diluting to a volume of about 80 ml. Prepare a standard in a second flask by adding sufficient standard nitrogen solution to contain 0.5 mg. of nitrogen,<sup>31</sup> 1 ml. of urease solution, and water to a volume of about 80 ml. To each flask add 1 ml. of gum ghatti solution,<sup>32</sup> set the flask contents to swirling and add from a graduated cylinder 10 ml. of Nessler reagent.<sup>32</sup> Dilute immediately to 100 ml. mix, and allow to stand 5 minutes. Read in a colorimeter or photometer in the usual way. For photometric measurement, set the photometer to zero density with a blank prepared similarly to the standard except that the standard nitrogen solution is omitted.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. N in Standard}}{\text{Dilution}} = \frac{\text{mg. urea- plus ammonia-nitrogen}}{\text{in 1 ml. of undiluted urine}}$$

<sup>28</sup> Folin and Youngburg: *J. Biol. Chem.*, **38**, 111 (1919); and Youngburg: *J. Biol. Chem.*, **45**, 391 (1921).

<sup>29</sup> To prepare the alcoholic urease solution place 3 g. of Permutit in a flask, wash once with 2 per cent acetic acid, then twice with water; add 5 g. of fine jack-bean meal and 100 ml. of 30 per cent alcohol. Shake gently but continuously for 10 to 15 minutes and filter. The filtrate contains practically all of the urease and extremely little of other materials.

<sup>30</sup> Dissolve 14.2 g. of Na<sub>2</sub>HPO<sub>4</sub> and 12.0 g. of NaH<sub>2</sub>PO<sub>4</sub>, or equivalent amounts of the crystalline salts, in water and make up to 100 ml.

<sup>31</sup> See footnote 19, p. 877.

<sup>32</sup> See Appendix.

Subtract from this value the ammonia content of the urine, as determined separately, to obtain the urea-nitrogen content of the urine. Under the conditions described, the dilution is 20, and urines containing 5 to 20 g. of urea nitrogen per liter may be accurately analyzed. For values outside this range, repeat the analysis at a more satisfactory dilution.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \frac{\text{mg. N in Standard}}{\text{mg. urea- plus ammonia-nitrogen in 1 ml. undiluted urine}} \times \text{Dilution} =$$

Correct for the preformed ammonia content as described above. The conditions for photometric measurement of the Nessler color have already been described (p. 878). At 480  $m\mu$ , and in a 1-cm. cuvette, the standard has a density of approximately 0.400, permitting measurement with urines containing up to about 25 g. of urea nitrogen per liter under these conditions. For higher values, or for photometric measurement at greater depth of solution, use a greater dilution of the urine.

**Interpretation.** See p. 884.

**c. Microdiffusion Method of Conway:**<sup>33</sup> **Principle.** The sample of diluted urine is incubated with urease in the outer compartment of a "Conway diffusion cell" (Fig. 242).<sup>34</sup> The ammonia formed is then liberated by addition of saturated potassium carbonate solution, and the cell is covered. The ammonia diffuses over into and is absorbed by acid in the inner compartment of the cell, where it may there be determined by titrimetric or colorimetric means. As with all urease methods for urine, separate determination of the ammonia N present is necessary in order to obtain the urea N content.

FIG. 242. CONWAY CELL.

The same principle may be employed for the determination of urea N in blood, of total N in micro-Kjeldahl digests, and in general wherever a volatile absorbable substance is to be determined (see p. 668).

Because of the simplicity of the procedure and its application to microanalysis, increasing use is being made of this principle in routine and research laboratories.

**Procedure: Determination of Urea N Plus Ammonia N.** Dilute 1 ml. of urine to 10 ml. with water and mix. With an accurate pipet transfer 0.2 ml. of this diluted urine to the outer compartment of a Conway diffusion cell (Fig. 242). Place 1 ml. of 2 per cent boric acid solution containing added bromocresol green indicator<sup>35</sup> in the inner compartment. Smear a glass cover plate with a

<sup>33</sup> Conway and Byrne: *Biochem. J.*, **27**, 419 (1933); Conway: *ibid.*, **27**, 430 (1933). The procedure as described here is a slight modification of the original Conway procedure, and includes some suggestions of Steinitz (*J. Lab. Clin. Med.*, **25**, 288 (1939-1940)). For application of the microdiffusion principle to the determination of small amounts of nitrogen in tissue preparations, see Borsook: *J. Biol. Chem.*, **110**, 481 (1935). For application to the determination of acetone in blood and urine, see Werch: *J. Lab. Clin. Med.*, **25**, 414 (1939-1940); **26**, 878 (1940-1941).

<sup>34</sup> The unit shown here is made of Coors porcelain and may be obtained from the Arthur H. Thomas Co., Philadelphia.

<sup>35</sup> See p. 552 for preparation of this solution.

thin film of fixative<sup>36</sup> and place on the cell, greased side down. Slide the cover aside far enough to permit the introduction of a pipet tip, and add to the outer chamber 0.5 ml. of urease-phosphate solution.<sup>37</sup> Replace the cover, and mix the fluids in the outer chamber by slight tilting and rotation of the cell. Set aside at room temperature for 15 minutes. At the end of this time, tilt the cell slightly to displace the fluid in the outer chamber to one side, slide the cover aside slightly to permit the introduction of a pipet at a point opposite to the displaced fluid, and add 1 ml. of saturated potassium carbonate solution to the outer chamber. At once replace the cover, mix the fluids in the outer chamber by tilting and rotation as above, and set aside for 90 minutes at room temperature (or place in an incubator at 38° C. for 1 hour). Be sure the cover is firmly in place during this period. At the end of the period, remove the cover and titrate the contents of the inner chamber with 0.0143 N sulfuric acid,<sup>38</sup> using a microburet with a fine tip which dips below the surface of the solution being titrated. Titrate until the color of the fluid in the inner chamber exactly matches that in a control cell. The control consists of a second cell treated exactly as described for an analysis except that 0.5 ml. of water replaces the urine sample.

**Ammonia N Determination.** Proceed as above, but use 0.2 ml. of undiluted urine and omit the treatment with urease, adding the 1 ml. of saturated potassium carbonate solution directly to the urine in the outer compartment, allowing to stand covered for diffusion and absorption of ammonia to take place, titrating, etc., as described.

CALCULATION. Since 1 ml. of 0.0143 N sulfuric acid is equivalent to 0.2 mg. of nitrogen, the calculation is as follows:

a. *Urea N + Ammonia N:*

ml. 0.0143 N acid required  $\times 0.2 \times 50 =$  mg. urea N + NH<sub>3</sub> N per ml.  
undiluted urine

b. *Ammonia N:*

ml. 0.0143 N acid required  $\times 0.2 \times 5 =$  mg. NH<sub>3</sub> N per ml. undiluted urine

c. *Urea N:* subtract (b) from (a) to obtain the urea N content of the urine, in mg. per ml. (or g. per liter).

During the titration, the fluid in the inner compartment should be stirred continuously; a convenient arrangement consists of a fine glass tip delivering compressed air in a slow stream of bubbles below the surface of the solution. A magnetic stirrer acting on a "flea" (small piece of iron wire enclosed in a small sealed glass tube) placed in the inner compartment is also an excellent method of stirring during the titration. If desired, the determination may be made colorimetrically or photometrically by placing 1 ml. of 0.1 N sulfuric acid (without indicator) in the inner compartment,

<sup>36</sup> Ordinary petrolatum is satisfactory at room temperatures. If the cells are to be incubated at 38° C., a petrolatum-paraffin wax mixture is recommended. Melt 3 parts petrolatum with 1 part paraffin wax (M.P. 55°) and allow to cool.

<sup>37</sup> Dissolve 400 mg. of urease powder (prepared as described on p. 883; commercial preparations may also be used) in 10 ml. of water and add 0.4 ml. of phosphate buffer (6.9 g. of NaH<sub>2</sub>PO<sub>4</sub>·H<sub>2</sub>O and 17.9 g. of Na<sub>2</sub>HPO<sub>4</sub>·12H<sub>2</sub>O in 100 ml. of water). Prepare the urease solution fresh daily, and discard any unused portion. The activity of the powder may be tested by a control analysis on pure urea solution. Dilute a 2.14 per cent solution of urea 1:10 with water and analyze 0.2 ml. of the diluted solution; 0.2 mg. of nitrogen should be found.

<sup>38</sup> Dilute 14.3 ml. of N sulfuric acid to 1 liter in a volumetric flask and mix. This solution is quite stable.

instead of the boric acid solution. After absorption of ammonia is complete, the contents of the inner chamber are transferred by means of a rubber-bulb pipet, with rinsings, to a test tube graduated at 25 ml. and nesslerized at this volume in the presence of 2.5 ml. of Nessler reagent. Colorimetric or photometric estimation may then be made in terms of a standard containing 0.2 mg. of nitrogen, nesslerized similarly.

**Interpretation.** See previous methods.

## 2. OTHER METHODS

Many other methods for the determination of urinary urea content have been described, some of which combine certain features of the various procedures described here. Rose and Coleman suggested colorimetric determination of the aerated ammonia (as in the Folin-Farmer micro-Kjeldahl method, p. 876), after treatment of the urine with urease. Marshall described a simple clinical method based upon direct titration of the ammonia liberated by urease treatment.<sup>39</sup> Gasometric measurement in the Van Slyke-Neill apparatus (p. 709) of the carbon dioxide liberated by the action of urease on urea<sup>40</sup> is simple, rapid, and accurate; the only disadvantage is when many analyses are to be done, since each analysis must be carried to completion before the next is begun. Gasometric determination based on the liberation of nitrogen by treatment with hypobromite has been described by Stehle.<sup>41</sup> Methods based upon isolation of urea as the insoluble xanthidrol compound have been described by Barrett and Jones<sup>42</sup> and by Allen and Luck.<sup>43</sup> Direct colorimetric methods which do not involve the action of urease have been proposed by Ormsby,<sup>44</sup> Barker,<sup>45</sup> and Archibald.<sup>46</sup>

## AMMONIA

**Introduction.** Many of the methods which have been proposed for the determination of urinary ammonia are based upon principles similar to those already described in connection with the micro-Kjeldahl determination, and the determination of urinary urea, since these consist essentially in the determination of ammonia produced as a result of the analytical treatment. For the accurate determination of urinary ammonia, it is necessary to separate the ammonia from interfering material, and to avoid the use of excessive heat or strong alkali in the treatment of the urine, since these may lead to the production of ammonia from other nitrogenous constituents of the urine. The successful separation of ammonia from urine by aeration was first described by Folin;<sup>47</sup> his method was modified and improved by Van Slyke and Cullen, and their method (with modification) is described here, since it requires less urine than Folin's method, gives just as accurate results, and utilizes the same appa-

<sup>47</sup> Folin's method is described in the Eleventh Edition of this book.

ratus, reagents, and technique as have already been described for the determination of urea in blood (p. 551) and in urine (p. 883).

**1. Aeration Method (Van Slyke and Cullen, Modified): Principle.** The urine is treated with an equal volume of saturated potassium carbonate solution, and the liberated ammonia is transferred by aeration into an acid receiving solution, where it is then determined by titration. In the original procedure, the ammonia is aerated into 0.02 N acid which is then back-titrated with 0.02 N alkali. In the modification described here, boric acid solution is used to receive the ammonia, which is then titrated directly with standard acid. Results are the same by either procedure; the boric acid method has the advantage of being a direct titration and requires only one standard solution which is quite stable.

**Procedure.** Measure 5 ml. of undiluted urine into one of the two large test tubes used in an aeration train (see Fig. 238, p. 877, and Fig. 147, p. 552) and connect this tube for aeration, as shown in the illustrations, with a second tube containing 25 ml. of the 2 per cent boric acid containing added bromocresol green indicator, described on p. 552 in connection with the determination of blood-urea nitrogen. Add a drop of caprylic alcohol to each tube to minimize foaming. When ready, remove the stopper of the tube containing the urine and add 5 ml. of saturated potassium carbonate solution. Replace the stopper tightly and start the air current (pressure or suction; the incoming air must be washed by preliminary passage through a wash-bottle containing dilute (1:10) sulfuric acid, to remove any ammonia present). The air current should be run slowly for the first two minutes, and then increased to a rate as fast as the apparatus will stand. Aeration is continued until all the ammonia has been driven over; this may take from 5 to 30 minutes depending upon the apparatus, and the time required should be established by trial.

When aeration is complete, remove the tube containing the boric acid, rinsing down the inlet tube in the process, and titrate the contents with 0.0143 N (or 0.02 N) sulfuric acid, until the more or less blue color is replaced by the original yellow-green color, as determined by matching against a control 25-ml. portion of the boric acid indicator solution which has been diluted with water to approximately the final volume of the titrated sample. The end point should be sharp to about 0.02 ml. of standard acid.

**CALCULATION.** Each ml. of 0.0143 N acid is equivalent to 0.2 mg. of ammonia nitrogen; if 0.02 N acid is used, 1 ml. equals 0.28 mg. of ammonia nitrogen. Multiply the volume in ml. of acid required for the titration by 0.2 (or 0.28), to obtain the ammonia-nitrogen content of 5 ml. of urine; divide the result by 5 to obtain the ammonia-nitrogen content of the urine in mg. per ml. (or g. per liter). Results on any other basis (e.g., g. per 100 ml. or per 24-hour sample) may then be readily obtained.

If the original Van Slyke-Cullen procedure based on back-titration of 0.02 N acid with 0.02 N alkali is used, the conditions and the calculations are similar to those described on p. 883 in connection with the determination of urinary urea, except that results are divided by 10 because 10 times as much urine is used for the ammonia determination as for the urea determination.

The ammonia aerated into dilute (0.02 N) sulfuric acid may be nesslerized and determined colorimetrically or photometrically as described for the Folin-Farmer micro-Kjeldahl procedure, p. 876; this procedure was suggested by Folin and MacCallum. The amount of urine taken should not contain over 0.5 to 1.0 mg. of ammonia nitrogen, i.e., 1 to 2 ml. of normal urine, or less in acidosis, diluted to about 5 ml. with water. Comparison is made against a suitable standard, nesslerized in the same way, and the calculations are similar to those for the Folin-Farmer procedure.

**Interpretation.** The average daily output of ammonia nitrogen in the urine of an adult on a mixed diet is about 0.7 g., corresponding to about 50 milliequivalents, or 500 ml. of 0.1 N base, per day, and representing about 2.5 to 4.5 per cent of the total nitrogen. The amount excreted may vary widely from this average value, however, since (along with the titratable acidity of the urine, see p. 869) the ammonia content of the urine appears to parallel the state of acid-base balance within the body. It is increased in amount by the ingestion of acids or acid-forming foods and in the acidosis of starvation or diabetes (but not of nephritis), and decreased by the ingestion of alkalis or base-forming foods and in alkalosis. The ammonia of the urine is liberated enzymatically in the kidneys principally from glutamine but also from amino acids and other possible precursors. Urinary ammonia appears to function as a "synthetic" base, capable of replacing "fixed base" (sodium, potassium) in the excretion of acids as their neutralized salts, and thus conserving such fixed base to the organism.

**2. Formol Titration Method (Malfatti): Principle.** This method is based on the reaction that takes place when formalin solution is added to a solution containing ammonium salts (see "Amino Acid Nitrogen" methods). An acid reaction is produced in the mixture, which is then titrated with standard alkali using phenolphthalein as an indicator. Amino acids give the same reaction so that the result of the titration represents ammonia + amino acid nitrogen. This method may be used for the rapid clinical estimation of these forms of nitrogen as a substitute for an ammonia determination, but the results do not represent ammonia as is sometimes stated.

**Procedure.** To 25 ml. of urine in a 200-ml. Erlenmeyer flask add 5 g. of finely pulverized potassium oxalate, a few drops of phenolphthalein, and titrate to a faint but permanent pink color with 0.1 N NaOH. (The urine mixture just after neutralization in the urinary titratable acidity determination may be used.) (See p. 870.) Then add 10 ml. of neutral formalin solution (see "Amino Acid Nitrogen"), mix well, and titrate with 0.1 N sodium hydroxide to a permanent pink color.

**CALCULATION.** One ml. of 0.1 N sodium hydroxide is equivalent to 1.7 mg. of ammonia. Multiply the number of ml. of 0.1 N alkali required after the addition of the formalin by 1.7 and by 4 to get the number of mg. of ammonia + amino acid nitrogen (expressed as ammonia) in 100 ml. of the urine examined.

**3. Permutit Method:<sup>48</sup> Principle.** The urine is shaken with particles of an "exchange silicate," which remove the ammonia from solution. The ammonia is set free from the silicate by treating with alkali solution. This is then nesslerized and compared with a standard ammonia solution nesslerized in the same way.

**Procedure.** Introduce about 2 g. of Permutit powder into a 100-ml. volumetric flask. Add about 5 ml. of water (no more), followed by 2 ml. of urine,<sup>49</sup>

<sup>48</sup> Folin and Bell: *J. Biol. Chem.*, **29**, 329 (1917). Permutit is a synthetic aluminum silicate which has the property of taking up ammonia quantitatively in neutral or weakly acid solution and of releasing it in strongly alkaline solution. The 60–80 mesh powder should be used. A suspension in water should settle quickly leaving the supernatant fluid clear. After use, it may be regenerated for further use if it is washed with water, 2 per cent acetic acid, and finally with water again.

<sup>49</sup> With urines very low in ammonia it may be necessary to use more urine (5 ml.) but so far as it is practicable it is better not to use more than 2 ml. and to employ a weaker

accurately measured. Rinse down the added urine by means of a little water (1 to 5 ml.), and shake gently but continuously for 5 minutes. Rinse the powder to the bottom of the flask by the addition of water (25 to 40 ml.) and decant. Add water once more and decant. (In the case of urines rich in bile it is advisable to wash once or twice more.) Add a little water to the powder, introduce 2 ml. of 10 per cent sodium hydroxide, shake for a few moments and set aside, while preparing the standard ammonium sulfate solution as follows:

Transfer 10 ml. of the standard ammonium sulfate solution (see p. 877) containing 1 mg. of nitrogen (or 5 ml. containing 0.5 mg. of nitrogen if a half-strength standard is desired) to another 100-ml. volumetric flask and add 2 ml. of 10 per cent sodium hydroxide (to balance the alkali added to the Permutit mixture in the other flask). Dilute to about 75 ml. and mix. Transfer 10 ml. of Nessler's solution (see p. 877) to a measuring cylinder. Now give the volumetric flask a vigorous whirl so as to set the solution spinning within the flask and add at once the whole of the Nessler solution in the cylinder. With another whirling movement complete the mixing of the contents of the flask. If the process of nesslerization has been successful a deep-red but crystal-clear solution is obtained. If it is not perfectly clear discard it and prepare a fresh standard. Then dilute the contents of the flask containing the Permutit and the urinary ammonia to about 75 ml., whirl the mixture, and add the Nessler reagent (10 ml.) exactly as in the case of the standard solution. Dilute the contents of both flasks to volume (100 ml.) and compare in a colorimeter with the standard set at 20 mm., or determine the densities of unknown and standard in a photometer at 480  $m\mu$ . For photometric measurement, set the photometer to zero density with a blank prepared by treating about 75 ml. of water plus 2 ml. of 10 per cent sodium hydroxide in a 100-ml. volumetric flask with 10 ml. of Nessler solution as described, diluting to 100 ml., and mixing.

*CALCULATION. For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \text{mg. N in Standard} = \text{mg. NH}_3 \text{ N in volume of urine used}$$

Divide the result of the above calculation by the volume of urine used to obtain the ammonia-nitrogen content of the urine, in mg. per ml. (or g. per liter). From this, and the volume of the 24-hour specimen, the daily output of urinary ammonia is readily obtained.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times \text{mg. N in Standard} = \text{mg. NH}_3 \text{ N in volume of urine used}$$

Further calculation is the same as for colorimetric measurement. The spectrophotometric characteristics of the Nessler color, and the conditions for accurate photometric measurement, are similar to those given on p. 878 in connection with the Folin-Farmer micro-Kjeldahl method, since similar amounts of nitrogen are dealt with here, under equivalent conditions.

**Interpretation.** See p. 890.

---

standard (0.5 mg. instead of 1 mg. of nitrogen) for colorimetric comparison. If there is doubt about which standard to use, it is sound analytical practice to prepare both and to match the unknown against the most suitable standard as determined by inspection.

## AMINO ACID NITROGEN

**1. Ninhydrin Method of Van Slyke, MacFadyen, and Hamilton:<sup>50</sup> Principle.**

The urine sample, previously freed from urea by treatment with urease, is heated at 100° C. in a closed reaction vessel with ninhydrin (see p. 129). Amino acids present yield carbon dioxide quantitatively under these conditions. The carbon dioxide produced is transferred to the chamber of the Van Slyke-Neill manometric apparatus and there determined. From the amount of carbon dioxide found, the  $\alpha$ -amino nitrogen content of the sample is readily obtained, since all of the common amino acids yield 1 mole of carbon dioxide (except aspartic acid, which yields 2 moles) per mole of  $\alpha$ -amino nitrogen present. Proteins, peptones, peptides (other than glutathione, which has a free  $\alpha$ -amino group), and substances other than amino acids do not react significantly. This procedure is considered to be the most specific yet devised for free amino acids.

**Procedure: Removal of Urea and Preformed CO<sub>2</sub>.** Place 2 ml. of fresh urine (or urine preserved by saturation with thymol and storage in the cold) in the all-glass reaction vessel<sup>51</sup> (Fig. 243) and add 1 drop of 0.04 per cent bromothymol blue.<sup>52</sup> If a blue color is obtained, add 1 N sulfuric acid drop by drop until color turns yellow, and then 1 N sodium hydroxide until just blue. If a yellow color is obtained initially, add 1 N sodium hydroxide until just blue. Then add 175 mg. of dry phosphate buffer mixture,<sup>53</sup> 0.2 ml. of a 1 per cent solution of urease,<sup>54</sup> and a crystal of thymol. Stopper loosely to prevent loss of water but not of carbon dioxide and incubate overnight at 37° to 40° C.

After incubation add 1 drop of 0.04 per cent bromocresol green and a drop of caprylic alcohol. Cautiously add 5 N sulfuric acid drop by drop, with gentle whirling to minimize foaming, until the solution is just yellow (pH about 3), then add 100 mg. of dry citrate buffer mixture.<sup>55</sup> Add several pieces of alundum to prevent bumping and heat to boiling over a microburner.

<sup>50</sup> Van Slyke, MacFadyen, and Hamilton: *J. Biol. Chem.*, **150**, 251 (1943). See also Hamilton and Van Slyke: *J. Biol. Chem.*, **150**, 231 (1943); Van Slyke, Dillon, MacFadyen, and Hamilton: *ibid.*, **141**, 627 (1941); Van Slyke and Folch: *ibid.*, **136**, 509 (1940).

<sup>51</sup> Obtainable from E. Machlett and Son, New York, N.Y.

<sup>52</sup> See Chapter 1 for the preparation of indicator solutions.

<sup>53</sup> *Dry Phosphate Buffer Mixture.* Grind separately in a mortar 3 parts by weight of anhydrous monopotassium phosphate and 1 part of anhydrous disodium phosphate (or 2.5 parts of disodium phosphate containing 12 molecules of water). Mix the two ground solids and grind intimately together. Dispense with a glass spoon calibrated to deliver  $175 \pm 15$  mg. of the powder. This mixture produces a pH of 6.2 when in solution.

<sup>54</sup> *Urease Solution.* This is made from urease powder, prepared as described on p. 883. Dissolve the powder in water in the proportion of 1 g. to 10 ml. of water. Dilute this 10 per cent solution 1:10 with water before use to make the 1 per cent solution required. This solution contains sufficient amino acid to produce a correction (as established by the blank analysis described in the procedure) equal to several per cent of the usual amino acid content of the urine. To decrease this correction to about one-third of its initial value, wash the dry urease powder with alcohol as follows: Grind 5 g. of the urease powder in a mortar with 10 successive portions of 50 ml. each of 80 per cent ethyl alcohol. Dry the solid residue (about 2.5 g.) at room temperature *in vacuo*, and use this purified material for the preparation of the 10 per cent solution. To free the urease completely from amino acids, the dialysis purification procedure of Archibald and Hamilton (*J. Biol. Chem.*, **150**, 155 (1943)) may be used. The activity of the urease powder should be established as described by Van Slyke: *J. Biol. Chem.*, **73**, 695 (1927). (See also Van Slyke, MacFadyen, and Hamilton: *loc. cit.*) If the urease splits less than 0.1 its weight of urea per minute, a proportionately stronger solution than 1 per cent should be used.

<sup>55</sup> *Dry Citrate Buffer Mixture.* Grind separately in a mortar 2.06 g. of sodium citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$ ) and 19.15 g. of citric acid ( $\text{C}_6\text{H}_8\text{O}_7 \cdot \text{H}_2\text{O}$ ). Mix the two ground solids and grind intimately together. Dispense with a glass spoon calibrated to deliver  $100 \pm 10$  mg. of the powder. This mixture produces a pH of 2.5 in solution.

Boil exactly 1 minute (no longer). Cool to below 25° C. (placing in ice water for three minutes is satisfactory). Attach the short rubber connector<sup>56</sup> to the side arm (Fig. 243), and wipe off any water from the inside ground-glass surface of the vessel top.

**Treatment with Ninhydrin.** Add 100 mg. of ninhydrin<sup>57</sup> to the cooled reaction mixture with the aid of a small funnel having a short stem. Have the glass stopper ready with a thin film of special lubricant<sup>58</sup> spread over the ground-glass surface, and as soon as the ninhydrin has been added, remove the funnel and set the stopper in place, with the hole in line with the side arm, as shown in Fig. 243. Immediately attach the side arm to a good source of vacuum (preferably with attached manometer) and evacuate quickly to 30 mm. or less pressure, shaking gently if necessary to minimize effervescence. When the vessel is evacuated (10 seconds may be sufficient time), turn the stopper through 180° to close off the vessel. Press the rubber connector flat with the fingers, detach vessel and connector from the vacuum line, and insert a glass plug moistened with water or glycerol into the connector, trapping as little air as possible in the process. Tighten the stopper in place—it may be held more securely by a heavy rubber band linking stopper and side arm. Place the closed vessel upright in a wire rack and immerse completely in vigorously boiling water for 8 minutes. Remove, tighten the stopper again by a slight twist if necessary, and allow to cool to room temperature. The closed vessel may be kept for several days at this point if necessary, and if many analyses are to be done they may all be brought to this stage before proceeding.

FIG. 243. REACTION VESSEL FOR NINHYDRIN AMINO ACID METHOD.

Courtesy, Hamilton and Van Slyke: *J. Biol. Chem.*, 150, 231 (1943).

**Absorption and Measurement of CO<sub>2</sub>.** Warm the contents of the reaction vessel to 38° to 40° C. by immersion in a beaker of water at this temperature for 10 minutes. While waiting, deliver 2 ml. of the carbonate-free 0.5 N sodium hydroxide in sodium chloride solution<sup>59</sup> from the storage container

<sup>56</sup> A 5-cm. length of stethoscope tubing is used (3 mm. bore, 12 mm. outside diameter). Before using for the first time, clean the tubes inside with a test-tube brush, immerse in acidified water in a round bottomed flask, and boil for 30 minutes. Remove the flame, stopper the flask, and cool under the tap. The vacuum caused by cooling draws excess gases from the rubber. When bubbles no longer appear, open the flask and wash the tubes with water. One treatment suffices.

<sup>57</sup> Dispense with a glass spoon calibrated to deliver approximately the required amount (within 10 per cent).

<sup>58</sup> A lubricant which does not leak at high temperatures must be used. "Nevastane XX heavy lubricating grease," obtainable from E. Machlett and Son, New York, is satisfactory. A suitable lubricant may be prepared in the laboratory as follows: Mix 35 g. of aluminum distearate to a paste in 100 ml. of heavy paraffin mineral oil. Heat with continuous stirring in a beaker over a low flame to effect solution of the soap. Allow to cool, then work up the friable gel to a smooth translucent paste on a glass plate with a steel spatula, preferably with warming to 45° to 50° C.

<sup>59</sup> Dissolve solid sodium hydroxide in an equal weight of water and allow to stand until

FIG. 244. STORAGE CONTAINER FOR ALKALINE SOLUTIONS, HUNG WITH TIP PROTECTED FROM ATMOSPHERIC CARBON DIOXIDE.

the carbonate settles. Standardize the supernatant solution by pipeting 7 ml. into water and titrating with standard (2 N or stronger) acid. From the result, determine how much of the 1:1 NaOH is required to make 250 ml. of 0.5 N solution. Fill a 250-ml. volumetric flask to within about 10 ml. of the mark with concentrated CO<sub>2</sub>-free NaCl solution (dissolve 250 g. of NaCl in 750 ml. of water, deaerate and store as described on p. 715). Pipet the correct amount of 1:1 NaOH solution into the flask, delivering it below the surface of the salt solution. Add a few drops of 1 per cent alizarin solution as indicator, fill to the mark with salt solution, and mix. Transfer to a storage container (Fig. 244 in text) to protect from atmospheric carbon dioxide.

equipped with a rubber tip (Fig. 244), into the chamber of the Van Slyke-Neill apparatus (Fig. 188), through a mercury seal in the cup (see Fig. 190 and p. 711 for method of delivery). Seal the cup capillary with a little mercury, lower the mercury in the chamber to about the middle of the chamber, and close the cock leading to the leveling bulb (cock *a* in Fig. 245). By this time the reaction-vessel contents should be sufficiently warm. Remove the vessel from the water bath, remove the glass plug from the side arm, attach the rubber connector to a source of vacuum, and reevacuate the side arm for

FIG. 246. SMALL BOTTLE OF MERCURY ARRANGED FOR SEALING CAPILLARY OF MANOMETER STOPCOCK.

Courtesy, Van Slyke and Folch: *J. Biol. Chem.*, 136, 509 (1940).

a few seconds. Pinch the rubber connector flat with the fingers, detach from the vacuum line, and at once attach to the side arm of the Van Slyke-Neill apparatus. Fig. 245 shows the conditions prevailing at this point. Turn the stopcock of the reaction vessel and cock *b* of the chamber so as to connect vessel and chamber and permit gas to pass from one to the other. Transfer the  $\text{CO}_2$  in the reaction vessel to the chamber (where it is absorbed by the alkali present) by repeatedly raising and lowering the mercury in the chamber by manipulation of the leveling bulb and cock *a*. The first lowering of the mercury must be done carefully to prevent bumping in the reaction vessel, and at each lowering the reaction vessel is shaken by hand to distribute the fluid along the walls. Five excursions of the mercury suffice to transfer all the  $\text{CO}_2$ , each excursion taking about 10 seconds. After the last upward excursion, lower the mercury in the chamber to about the middle point, and close cocks *a* and *b*.

Remove the reaction vessel and fill the side arm of the cock capillary of the manometric apparatus with mercury by suction from a small bottle containing mercury (see Fig. 246).

Open cock *a*, raise the leveling bulb to about even with cock *b*, then close *a*. Open *b* carefully to the right-hand cup at the top, allow the gases present to escape through the cup, then admit mercury to the chamber through cock *a* until the fluid in the chamber just reaches the top of the chamber, at cock *b*. Close *a* and then *b*. Place the leveling bulb at its normal position (approximately even with the 50-ml. mark at the bottom of the chamber), place a little mercury in the cup, and seal the cock capillary with mercury in the usual way.

Through the mercury seal, add exactly 1 ml. of 2 N lactic acid in sodium chloride solution<sup>60</sup> from a stopcock pipet provided with a rubber ring on the tip, as illustrated in Fig. 190, p. 711, then seal the cock with a little mercury. By manipulation of the leveling bulb and cock *a*, lower the mercury in the chamber to the 50-ml. mark, close *a*, and shake the chamber for 20 to 30 seconds. The liberated  $\text{CO}_2$  drives the mercury below the 50-ml. mark. Raise the leveling bulb, open *a* carefully, and adjust the mercury level to the 50-ml. mark. Close *a* and shake the chamber for 3 minutes. Place the leveling bulb high, open *a*, and admit mercury into the chamber until the level of the fluid (not mercury) meniscus is exactly at the 2-ml. mark on the chamber. This adjustment must be done in a consistent manner. Allow the mercury to enter through *a* steadily, without jerky oscillation of the chamber contents,

<sup>60</sup> Dilute 1 volume of concentrated lactic acid (sp. gr. 1.20) with 4 volumes of the concentrated NaCl solution described in the previous footnote.

and complete the adjustment in 30 to 40 seconds. If the adjustment is missed the first time (or for a duplicate reading) lower the mercury to the 50-ml. mark, shake for one minute, and repeat. With the fluid meniscus at the 2-ml. mark, read the manometer. This reading is  $p_1$ .

Replace the leveling bulb to the normal position, open cock *a*, and place 0.5 ml. of 5 N sodium hydroxide solution<sup>61</sup> in the cup above cock *b*. Admit the alkali to the chamber slowly, over a period of about half a minute, until only enough is left to fill the capillary beneath the cup. Add a little water and mercury to the cup, and seal the cock with mercury. If the viscous alkali forms a solid column in the top of the chamber, it may be broken up by admitting a little mercury in short bursts. Mix the alkali and ensure complete absorption of CO<sub>2</sub> by raising and lowering the mercury in the chamber 3 times in short excursions, then bring the fluid meniscus to just below the 2-ml. mark on the chamber. Allow 1 minute for drainage, then adjust exactly to the 2-ml. mark. Read the manometer; this reading is  $p_2$ .

CALCULATION. The pressure  $P_{CO_2}$  due to the carboxyl carbon dioxide of the amino acids present is found as follows:

$$P_{CO_2} = p_1 - p_2 - c$$

where *c* is the correction due to the blank. To establish *c*, run through an entire analysis as described above (including incubation with urease, etc.) on 2 ml. of water instead of urine. The difference between the  $p_1$  and  $p_2$  readings for the water blank analysis equals *c*. This blank will serve to correct for small amounts of amino acids which may be present in the urease preparation, as well as for certain possible variables in the manometric measurement itself.

To obtain the amino acid nitrogen content of the sample, multiply  $P_{CO_2}$  by the proper factor, obtained from the accompanying table.

$$P_{CO_2} \times \text{factor} = \text{mg. } \alpha\text{-amino nitrogen per liter of urine}$$

The temperature column in the table refers to the temperature of the water in the jacket surrounding the chamber at the time the  $p_1$  and  $p_2$  readings are made, and *a* is the volume of the gas phase when the manometer is read; *a* is ordinarily 2 ml., but may be reduced to 0.5 ml. if only small amounts of amino acids are present.

<sup>61</sup> Mix 1 volume of 1:1 NaOH solution with 3 volumes of water.

**Interpretation.** The  $\alpha$ -amino acid nitrogen content of normal urine appears to make up about 1 per cent (or possibly even less) of the total urinary nitrogen, corresponding to a daily excretion of 100 to 150 mg. of  $\alpha$ -amino nitrogen. Results by other methods, e.g., the nitrous acid method of Van Slyke and Kirk,<sup>62</sup> the formol titration procedure (see following method), and the copper titration procedure of Albanese and Irby,<sup>63</sup> tend to be either slightly or significantly higher than results by the ninhydrin procedure described here, presumably because of differences in specificity for  $\alpha$ -amino nitrogen. Little is known concerning the significance of normal or pathological variation in amount of urinary  $\alpha$ -amino nitrogen. Excretion may be largely increased in disorders associated with tissue waste as typhoid, in pronounced atrophy of the liver, acidosis, etc.

Microbiological assays for individual free amino acids in human urine show a preponderance of histidine, cystine, and glycine, average daily excretions being 150 to 250, 60 to 110, and 120 mg., respectively. Threonine, 50 to 60 mg., and lesser amounts of other amino acids are also found.<sup>64</sup> Glycine, glutamic and aspartic acids, and lysine are also found in conjugated form.

**2. Henriques-Sørensen Formol Titration Method:<sup>65</sup> Principle.** A solution containing amino acids is nearly neutral in reaction. If formaldehyde be added, however, a reaction takes place with the formation of derivatives which are more strongly acid in reaction due to the destruction of the basic properties of the amino groups (see p. 130 for discussion and equations). The carboxyl groups may then be titrated using phenolphthalein as an indicator. The acidity as shown by the titration is a measure of the amount of amino acid nitrogen present. Ammonia likewise reacts with formaldehyde in a similar manner as is shown in the following equation:

Hence the formol titration in the presence of ammonia gives results which include both amino acid and ammonia nitrogen. Ammonia may be determined and a correction applied, or the ammonia may be removed by means of phosphotungstic acid. Phosphates also interfere by obscuring the end point and are removed by the addition of barium salts. Polypeptides and still more complex protein derivatives likewise react with formol to a certain degree so that the results do not strictly represent "amino acid nitrogen."

The method is, with some modifications involving the preparation of the solution to be titrated, applicable in the determination of amino acids in any medium, e.g., urine, protein digests,<sup>66</sup> etc. The presence of buffers or poorly dissociated acids, e.g., some fatty acids, will tend to give values which are too high. Certain of the amino acids when present in large amounts will give erroneous results, but in the ordinary urine or digest these errors are either negligible or compensate each other. In the titration of colored solutions the control solution which is necessary in this method must be

<sup>62</sup> Van Slyke and Kirk: *J. Biol. Chem.*, **102**, 651 (1933).

<sup>63</sup> Albanese and Irby: *J. Biol. Chem.*, **153**, 583 (1944).

<sup>64</sup> Dunn, Camien, Shankman, and Block: *Arch. Biochem.*, **13**, 207 (1947); Gutman and Alexander: *J. Biol. Chem.*, **168**, 527 (1947); Christensen, Cooper, Johnson, and Lynch: *ibid.*, **168**, 191 (1947); Sheffner, Kirsner, and Palmer: *ibid.*, **175**, 107 (1948).

<sup>65</sup> Henriques and Sørensen: *Z. physiol. Chem.*, **64**, 120 (1909). See also Northrop: *J. Gen. Physiol.*, **9**, 767 (1926).

<sup>66</sup> Northrop (*J. Gen. Physiol.*, **9**, 767 (1926)) has improved the formol titration by titrating first to pH 7 with neutral red as the indicator, then adding formaldehyde and titrating to pH 9 with phenolphthalein.

colored to correspond with the color of the unknown solution. The accuracy of the formol titration is considerably improved by controlling the final pH adjustment and titration potentiometrically.

**Procedure.** The solution to be analyzed, if carbonates, phosphates, and ammonia are absent, is made neutral to litmus (paper) and the solution titrated with formaldehyde as below.<sup>67</sup> In case carbonates, phosphates, or ammonia are present a preliminary treatment is necessary which will vary according to the quantity of ammonia present.

(a) FOR SMALL AMOUNTS OF AMMONIA. Applicable to most urines. Fifty ml. of the material under examination are pipeted into a 100-ml. measuring flask and 1 ml. of phenolphthalein solution<sup>68</sup> and 2 g. of solid barium chloride are added; the whole is shaken, to saturate the solution with barium chloride; saturated barium hydroxide solution is added until the red color of the phenolphthalein develops and then an excess of 5 ml. is added. The flask is filled to the graduation mark with water, shaken and permitted to stand for 15 minutes, after which it is filtered through a dry filter. Place 80 ml. of the clear red filtrate (which corresponds to 40 ml. of the liquid under examination) in a 100-ml. measuring flask, neutralize to litmus and dilute to 100 ml. with freshly boiled water. Equal portions of this solution, 40 ml. (equivalent to 16 ml. of the original solution), may be taken for analysis, one for the formol titration and the other for the determination of ammonia nitrogen.<sup>69</sup>

(b) FOR LARGE AMOUNTS OF AMMONIA. After the treatment with phenolphthalein, barium chloride, and barium hydroxide, and after the solution has been diluted to 100 ml. as in (a) above, the ammonia is distilled off, *in vacuo*.<sup>70</sup>

In case the solution is deeply colored, as in protein digests, it may be necessary to decolorize<sup>71</sup> before the titration is attempted.

**Final Titration.** For the final titration a volume of from 20 to 40 ml. which contains approximately 25 mg. of nitrogen is the most desirable. A control solution is run composed of an equal volume of boiled distilled water and 20 ml. of the formaldehyde mixture.<sup>72</sup> This control solution is colored<sup>73</sup> so that its tint matches that of the solution to be titrated.

To this control is added about half the volume of 0.2 N alkali which will be used in the titration of the solution under investigation and it is then titrated with 0.2 N acid to a faint red (first stage).<sup>74</sup>

An additional drop of 0.2 N alkali is added, which imparts a distinct red to the solution (second stage).

<sup>67</sup> As a standard of comparison the litmus paper used for neutralization is contrasted with a similar piece dipped in a phosphate solution having a neutral reaction (M/15  $\text{KH}_2\text{PO}_4$  and M/15  $\text{Na}_2\text{HPO}_4$  in the proportion 40:60).

<sup>68</sup> A solution of 0.5 g. of phenolphthalein in 50 ml. of alcohol and 50 ml. of water.

<sup>69</sup> The determination of ammonia may be dispensed with in case a separate determination is made.

<sup>70</sup> For particulars with regard to the distillation, etc., see Henriques and Sørensen: *Z. physiol. Chem.*, **64**, 137 (1909).

<sup>71</sup> For methods see Jessen-Hansen: *Abderhalden's Arbeitsmethoden*, Vol. 6, p. 262, 1912.

<sup>72</sup> The formaldehyde solution is freshly prepared for each set of determinations as follows: to 50 ml. of commercial formaldehyde (formol) (30 to 40 per cent) add 1 ml. of the phenolphthalein solution. 0.2 N alkali is then added until the mixture acquires a faint red color. The volume of the formaldehyde used will vary with the volume of the solution to be analyzed; approximately 10 ml. of the formalin solution are added for each 20 ml. of the unknown solution.

<sup>73</sup> Solution of Bismarck brown is very satisfactory for urines. Tropeolin O, tropeolin OO, *p*-nitrophenol, methyl orange, or alizarin sulfonate may be used.

<sup>74</sup> This procedure is recommended in order that the final volume of the control and the unknown solutions shall be approximately the same when the process is complete.

The solution to be analyzed is now titrated to the color produced in the second stage of the control. The formaldehyde mixture is now added; 10 ml. for each 20 ml. of the solution, and the mixture again titrated to the second stage with 0.2 N alkali.<sup>75</sup>

Two drops of the 0.2 N alkali are now added to the control solution which assumes a deep red color (third stage). 0.2 N alkali is now added to the solution under examination until it assumes a color corresponding to the third stage of the control. This completes the titration.

**CALCULATION.** The calculations are similar to those which pertain to any acidimetry procedure. Each ml. of an 0.2 N alkali or acid solution is equivalent to 0.0028 g. of nitrogen. An example will illustrate the procedure: 40 ml. of solution (16 ml. of urine) required 5.10 ml. of 0.2 N NaOH; control, 0.10 ml. of 0.2 N NaOH; total required for amino acids 5.00 ml. equivalent to 0.014 g. of nitrogen. Ammonia nitrogen in 16 ml. of urine, 0.007 g. of N. Then  $0.014 - 0.007 = 0.007$  g. amino acid nitrogen in 16 ml. of urine.

**Interpretation.** The excretion of total amino acid nitrogen by a normal adult, as determined by this procedure, averages between 0.4 to 1.0 g. per day or from 2 to 6 per cent of the total nitrogen. Free amino acid nitrogen (see previous procedure) is considerably less than this, ordinarily 0.5 to 1.0 per cent of the total nitrogen. This discrepancy is due to the relative nonspecificity of the formol titration. For further aspects of interpretation, see preliminary discussion, and also previous procedure.

**3. Other Methods.** Folin proposed the colorimetric determination of amino acids in urine by reaction with naphthoquinone sulfonic acid,<sup>76</sup> after preliminary treatment of the urine with Permutit to remove ammonia, which interferes. Although this color reaction is sufficiently reliable for its use in the determination of blood amino acids where interference by ammonia does not arise, the procedure is not recommended for urine analysis since the Permutit treatment removes some of the amino acids as well as ammonia. A more satisfactory procedure for removal of ammonia might render the method applicable to urine. Albanese and Irby<sup>77</sup> have proposed a simple titrimetric method for the determination of urinary amino acid nitrogen; their procedure appears to have approximately the specificity of the formol titration. For details of the nitrous acid reaction for urinary amino acids, see Van Slyke and Kirk.<sup>78</sup>

## CREATININE

**Folin's Method: Principle.** This method is based upon the characteristic property possessed by creatinine, of yielding a certain definite color reaction in the presence of picric acid in alkaline solution. This reaction (Jaffé reaction) is due to the formation of a red tautomer of creatinine picrate.<sup>79</sup> The production of this tautomer is "dependent upon the formation of a salt, a keto-enol change within the creatinine molecule, and a change in the picric acid molecule involving the hydrogens in the *meta* positions and, probably all three nitro groups."<sup>80</sup>

<sup>75</sup> This is best accomplished by adding alkali until the color is deeper than that of the control, then acid again until lighter, and finally alkali to the desired color.

<sup>76</sup> This procedure is described for amino acids in blood. See p. 565.

<sup>77</sup> Albanese and Irby: *J. Biol. Chem.*, **153**, 583 (1944).

<sup>78</sup> Van Slyke and Kirk: *J. Biol. Chem.*, **102**, 651 (1933).

<sup>79</sup> Greenwald and Gross: *J. Biol. Chem.*, **59**, 601 (1924).

<sup>80</sup> Greenwald: *J. Am. Chem. Soc.*, **47**, 1443 (1925); *J. Biol. Chem.*, **80**, 103 (1928).

In the original Folin macromethod,<sup>81</sup> 10 ml. of urine are used for a determination, the color is developed at a final volume of 500 ml., and comparison is made visually against an artificial standard (0.5 N potassium bichromate solution) under rigorously defined conditions. The Folin micro modification described here is preferred because it requires less urine, is based upon comparison against standard creatinine solutions, and is therefore more flexible and accurate, and is adaptable to either colorimetric or photometric measurement.<sup>82</sup>

### Procedure.

(a) FOR COLORIMETRIC COMPARISON. Measure 1 ml. of urine into a 100-ml. volumetric flask, and in a second similar flask place 1 ml. of the standard creatinine solution,<sup>83</sup> containing 1 mg. of creatinine per ml. To each flask add 20 ml. of 1 per cent picric acid solution<sup>84</sup> (measured with sufficient accuracy from a graduated cylinder), followed by 1.5 ml. of 10 per cent sodium hydroxide solution. Mix gently and allow to stand 15 minutes. Dilute to the mark with water and mix by inversion. Compare standard against unknown in the usual way, setting the standard at 20 mm.

(b) FOR PHOTOMETRIC MEASUREMENT. Measure 0.5 ml. of urine into a 100-ml. volumetric flask and add 0.5 ml. of water. In a second flask, which serves as a blank, place 1 ml. of water. To each flask add 20 ml. of 1 per cent picric acid solution, followed by 1.5 ml. of 10 per cent sodium hydroxide solution. Mix gently and allow to stand 15 minutes. Dilute to the mark with water and mix by inversion. Transfer portions of blank and unknown to photometer cuvettes. Set the photometer to zero density with the blank, at 520 m $\mu$ , and determine the density of the unknown. Alternately, the photometer may be set to zero density with water, and the densities of both blank and unknown determined. The density of the blank is then subtracted from the measured density of the unknown, to obtain the true density of the unknown.

CALCULATION. For colorimetric measurement:

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. creatinine}}{\text{in Standard}} = \frac{\text{mg. creatinine in volume}}{\text{of urine analyzed}}$$

With a urine volume of 1 ml., and a 1-mg. standard, the result of the calculation gives the creatinine content of the urine directly, in mg. per ml., or g. per liter. Urines containing 0.75 to 1.25 g. of creatinine per liter (i.e., the standard and unknown read within a few mm. of each other) may be accurately determined with the 1-mg. standard described. For values outside this range, the calculation is not accurate because of the deviation from Beer's law shown by the Jaffé reaction for creatinine. In such cases the determination must be repeated using less or more urine as the case may be, to provide a portion of sample containing approximately 1 mg. of creatinine. When this is done, differences in volume between standard and unknown *before adding the*

<sup>81</sup> Folin: *J. Biol. Chem.*, **17**, 469 (1914).

<sup>82</sup> For studies on the photometric determination of creatinine by the Jaffé reaction, see Bonsnes and Taussky: *J. Biol. Chem.*, **158**, 581 (1945); Peters: *J. Biol. Chem.*, **146**, 179 (1942). The use of 3,5-dinitrobenzoic acid for the colorimetric determination of creatinine has been proposed by Benedict and Behre: *J. Biol. Chem.*, **114**, 515 (1936), and Langley and Evans: *ibid.*, **115**, 333 (1936).

<sup>83</sup> *Standard Creatinine Solution*: Dissolve 1 g. of pure dry creatinine in sufficient 0.1 N hydrochloric acid to make 1 liter, and mix well. This solution contains 1 mg. of creatinine per ml., and is stable indefinitely. Pure creatinine may be purchased from laboratory supply houses, or may be made from urine by Benedict's method (see p. 800). Creatinine-zinc chloride may be used in place of creatinine, in which case 1.61 g. of the creatinine-zinc chloride salt is used per liter of 0.1 N acid to give the standard solution containing 1 mg. of creatinine per ml.

<sup>84</sup> Prepared from purified picric acid (see Appendix). Keep in a dark bottle.

*picric acid* must be equalized by the proper addition of water to one or the other as required. The further procedure and the calculations are as described. For very dilute urines (creatinine content less than 0.2 g. per liter), the Shaffer modification of the Folin procedure may be used.<sup>85</sup>

*For photometric measurement:* the creatinine content of the unknown is established from its photometric density by reference to a calibration curve showing the densities for known amounts of creatinine determined by the procedure described. Direct calculation of results in terms of Beer's law is not valid in this procedure because of the lack of adherence to Beer's law over the concentration range in question.

To prepare a calibration curve, measure 0.0, 0.25, 0.50, 0.75, and 1.00 ml. portions of standard creatinine solution, containing 1 mg. per ml., into separate 100-ml. volumetric flasks (preferably in duplicate). Add water, where necessary, to bring each to 1 ml. volume, and treat with picric acid and alkali exactly as described under "Procedure for Photometric Measurement," above. Determine the densities for each of the standards, using the first or blank solution to set the photometer to zero density, or set the photometer to zero density with water and subtract the determined density of the blank from that for each standard to obtain the true densities of the standards. On a sheet of ordinary cross-section paper, plot the density of each standard on the *y*-axis against the amount of creatinine present, in mg., on the *x*-axis. Draw a smooth curve to include all the points. A curve similar to that shown in Fig. 247 will be obtained.

The amount of creatinine present in an unknown is obtained by reference to the curve. If 0.5 ml. of urine is used in an analysis, the result from the curve gives the creatinine content in this volume of sample. Multiply by 2 to obtain the creatinine content in mg. per ml. or grams per liter.

The spectrophotometric characteristics of the creatinine color are shown in Fig. 248. At 520  $m\mu$ , and in a 1-cm. cuvette, the densities for various amounts of creatinine have approximately the values indicated in Fig. 247. Any creatinine content up to about 2 g. per liter may be accurately determined under these conditions. For higher values, or for photometric measurement at greater depth of solution, the urine should be diluted, a portion of the diluted sample used for analysis, and the creatinine content as read from the curve multiplied by the dilution to obtain the true creatinine content of the original undiluted urine.

The sources of error in the use of a previously prepared calibration curve have been discussed in Chapter 23. For accurate results the curve should be checked at intervals and reconstructed if necessary. In an analysis, every effort should be made to have the conditions as nearly identical as possible with those prevailing at the time the curve was established; the time of standing (after adding the alkali and after

FIG. 247. TYPICAL CALIBRATION CURVE FOR PHOTOMETRIC DETERMINATION OF CREATININE IN URINE.

<sup>85</sup> Shaffer: *J. Biol. Chem.*, 18, 525 (1914).

diluting) and the room temperature are particularly important in this connection. The curve should be checked or reestablished with each new lot of picric acid.

**Interpretation.** The daily excretion of creatinine by normal adults ranges from about 1.0 to 1.8 g.; under certain conditions it may be considerably higher.<sup>86</sup> The value is nearly constant from day to day for a given normal individual, being influenced by the diet only to the extent that the diet itself contains significant amounts of creatinine, as in the case of a heavy meat diet. Creatinine excretion is not influenced by exercise or by the level of nitrogen metabolism in the body. Creatinine appears to be entirely a waste product, unutilizable by the body, and is excreted almost if not entirely quantitatively when ingested or injected. The relative constancy of creatinine excretion on a creatinine-free diet

FIG. 248. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN URINARY CREATININE METHOD.

For the alkaline picrate blank (*bl*), blank plus 0.25 mg. (*a*), and 0.50 mg. (*b*) of creatinine. Solution depth, 1 cm.

appears to reflect some constant metabolic process involving the body creatine (from which creatinine is almost certainly derived), but the nature of this process is still obscure (see p. 797 for further discussion) and therefore the significance of a constant creatinine excretion cannot be too precisely evaluated. Since the bulk of the creatine of the body is in the muscles, there is a rough correlation between the creatinine excretion and the amount of muscular tissue in the body; for example, obese individuals excrete less creatinine relative to their body weight than do thin persons. The number of mg. of creatinine excreted daily per kg. of body weight is known as the *creatinine coefficient*. It has a normal range of 19 to 30. Some investigators designate the creatinine coefficient in terms of the number of mg. of creatinine-nitrogen excreted daily per kg. of body weight; the normal range in this case is 7 to 11.

Creatinine excretion is decreased in disorders associated with muscular atrophy and muscular weakness. It increases with increased tissue catabolism as in fever.

<sup>86</sup> See Hobson: *Biochem. J.*, **33**, 1425 (1939).

## CREATINE

**1. Folin Method:**<sup>87</sup> *Principle.* Creatine on boiling with acid is transformed into creatinine. By determining the creatinine content before and after treatment with acid (picric acid is used here), the amount of creatine present may be obtained by difference. The method is not applicable to diabetic urines, since acetone and glucose interfere.

*Procedure.*<sup>88</sup> Measure the urine (1 ml. for colorimetric measurement, 0.5 ml. for photometric measurement) into a 300-ml. flask. Add 20 ml. of 1 per cent picric acid solution and a few small pebbles or pieces of alundum. Weigh the flask and contents on a rough balance to the nearest gram. Add about 150 ml. of water and heat to boiling. Boil gently for 45 minutes, then more rapidly until the volume has been reduced to somewhat under the original volume of urine plus picric acid solution, as established by weighing. Add sufficient water to the flask to restore the original weight, within about a gram. Cool to room temperature (this is important). Add 1.5 ml. of 10 per cent sodium hydroxide solution, and mix. Let stand 15 minutes. Rinse into a 100-ml. volumetric flask, dilute with water to the mark, and mix. For colorimetric measurement, compare against a standard creatinine solution, containing 1 mg. of creatinine, prepared in a second 100-ml. volumetric flask as described on p. 900 for the determination of urinary creatinine. For photometric measurement, determine the density (corrected for the picrate blank) as described on p. 900, and obtain results from a calibration curve, as described below.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. creatinine in Standard}}{\text{mg. "total" creatinine in vol. of urine used}} =$$

From this, the "total" creatinine content per liter or in the 24-hour sample may be obtained. Subtract from the "total" creatinine value the preformed creatinine content, determined separately as described on p. 900, to obtain the creatine content (expressed as creatinine).

$$(\text{Total creatinine} - \text{Preformed creatinine}) = \text{Creatine (as creatinine)}$$

To convert creatine expressed as creatinine into the amount of creatine itself, multiply by 1.16:

$$(\text{Total creatinine} - \text{Preformed creatinine}) \times 1.16 = \text{Creatine}$$

The same precautions concerning close agreement between standard and unknown that are emphasized in the determination of urinary creatinine are applicable here. The total creatinine content of the sample should not be greater than about 1.25 g. per liter, when a 1-mg. standard is used. If it is higher than this, repeat the analysis using less urine, or an aliquot of diluted urine.

*For photometric measurement:* from the determined density of the unknown (corrected for the picrate blank), obtain the "total" creatinine content of the volume of urine used by reference to a calibration curve, as described on p. 901 for the photometric determination of urinary creatinine (the same curve may be used). Determine the creatine content as described above, by subtracting from the "total" creatinine

<sup>87</sup> Folin: *J. Biol. Chem.*, 17, 469 (1914).

<sup>88</sup> The reagents required are those used for the determination of urinary creatinine (p. 900).

content the amount of preformed creatinine present, determined separately. If the photometric density of the unknown is beyond the limits of the calibration curve, repeat the analysis using less urine.

**Interpretation.** Creatine occurs only in small amount (approximate range 0 to 200 mg. per day) in the urine of normal adults, but is found in larger amounts in the urine of children. More creatine is found in the urine during activity than when at rest. Hobson<sup>89</sup> found significant creatinuria (in one instance 1.4 g. per day) in the case of adult male athletes in training, on a high carbohydrate diet; decrease in carbohydrate intake resulted in a markedly decreased excretion of creatine. Albanese and Wangerin<sup>90</sup> found significant amounts of creatine in the urine of 30 normal adults, with no differences between sexes. According to these investigators, earlier views that creatinuria is not found in normal adults are possibly due to technical difficulties in the analysis.

Increased creatine excretion is noted in pregnancy, in fasting, and after high water ingestion. A significant creatinuria is noted in many pathological conditions associated with malnutrition and disintegration of muscular tissue, etc. Ingestion of creatine by normal adults does not increase the creatine content of the urine, i.e., the ingested creatine is completely retained. In certain pathological conditions, however, notably progressive muscular dystrophy, this ability to retain ingested creatine is impaired and extra creatine appears in the urine after a test dose. This is the basis for the *creatinine tolerance test*,<sup>91</sup> which is sometimes used clinically for diagnostic purposes.

**2. Other Methods.** Various modifications of the acid treatment for the conversion of creatine to creatinine have been described. In the original Folin method, the urine is heated with an equal volume of 1 N hydrochloric acid for three hours on a boiling water bath; Folin felt that the picric acid method described here is superior to this first procedure. Autoclaving with picric acid solution at 115° to 120° C. for 20 minutes has also been proposed; according to Albanese and Wangerin,<sup>90</sup> this does not give complete conversion, and Bonsnes and Taussky<sup>92</sup> have confirmed this. In the Benedict<sup>93</sup> procedure, the urine is taken to dryness in the presence of 1 to 2 volumes of normal hydrochloric acid, with a few granules of lead to minimize pigment formation. This procedure appears to give complete conversion, but it has not as yet been shown to be applicable to the small amounts of creatine concerned in modern micro-methods. Bonsnes and Taussky<sup>92</sup> and Peters<sup>94</sup> have described procedures for the determination of urinary creatine under conditions whereby the diluted sample is treated by procedures similar to those used for blood filtrates,<sup>95</sup> thus permitting the determination of both blood and urine creatine and creatinine in essentially the same manner.

## URIC ACID

**1. Direct Colorimetric Method of Benedict and Franke:<sup>96</sup> Principle.** The diluted urine is treated directly with arsenophosphotungstic acid reagent and sodium cyanide. The blue color obtained is compared with that of a standard uric acid solution treated in the same way. This method is known to be somewhat nonspecific for uric acid, as are all "direct" methods (see discussion under the other methods described in this section) but is believed to be quite satisfactory for many purposes.

**Procedure.<sup>97</sup>** The urine<sup>98</sup> is so diluted that 10 ml. will contain between 0.15 and 0.30 mg. of uric acid. (Usually a dilution of 1 to 20 is satisfactory.) Ten ml. of the diluted urine are measured into a 50 ml. volumetric flask, 5 ml. of the 5 per cent sodium cyanide solution (*poisonous!*) are added from a buret, followed by 1 ml. of the arsenophosphotungstic acid reagent. The contents of the flask are mixed by gentle shaking, and at the end of 5 minutes diluted to the 50-ml. mark with distilled water and mixed. For colorimetric measurement, this blue solution is then compared with a simultaneously prepared solution obtained by treating 10 ml. of the standard uric acid solution (0.2 mg. of uric acid) in a 50-ml. flask with 5 ml. of the sodium cyanide solution, 1 ml. of the reagent, and diluting to the mark at the end of five minutes. For photometric measurement, determine the densities of unknown and standard at 520 m $\mu$ , setting the photometer to zero density with a blank solution obtained by treating 10 ml. of water in a 50-ml. flask with cyanide and reagent exactly as described for unknown and standard.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.2 \times \frac{D}{10} = \text{uric acid content of the urine, in g. per liter}$$

*D* is the dilution (usually 20) of the urine. For most accurate results, the standard and unknown should read within a few mm. of each other. If they differ significantly, repeat the analysis using a greater or lesser dilution of the urine as required.

<sup>96</sup> Benedict and Franke: *J. Biol. Chem.*, **52**, 387 (1922). For a modification of this method, claimed to be superior, see Christman and Ravwitch: *J. Biol. Chem.*, **95**, 115 (1932). A photometric version of the Christman-Ravwitch procedure is used in the uricase procedure of Buchanan, Block, and Christman described in the text (p. 907).

<sup>97</sup> Solutions Required for Uric Acid Determination: 1. *Reagent.* The reagent employed is the one used in the Benedict procedure for the direct determination of uric acid in blood (Benedict: *J. Biol. Chem.*, **51**, 187 (1922)) and is prepared as follows: 100 g. of pure sodium tungstate (preferably Merck's or J. T. Baker's C. P. product) are placed in a liter pyrex flask and dissolved in about 600 ml. of water. Now add 50 g. of pure arsenic acid (As<sub>2</sub>O<sub>5</sub>) followed by 25 ml. of 85 per cent phosphoric acid and 20 ml. of concentrated hydrochloric acid. The mixture is boiled for about 20 minutes, cooled, and diluted to 1 liter. The reagent appears to keep indefinitely.

2. *Sodium Cyanide.* A 5 per cent solution of sodium cyanide, containing 2 ml. of concentrated NH<sub>4</sub>OH per liter, which should be prepared fresh once in about 6 to 7 weeks.

3. *Uric Acid.* A standard solution of uric acid, acidified with hydrochloric acid, containing 0.2 mg. of uric acid in 10 ml. is employed. This solution may be readily prepared by dilution of Benedict's phosphate standard uric acid solution described in connection with the Newton uric acid method for blood (see p. 563). Measure 50 ml. of the phosphate standard solution (containing 10 mg. of uric acid) into a 500-ml. volumetric flask and dilute to about 400 ml. with distilled water. Add 25 ml. of dilute hydrochloric acid (made by diluting 1 volume of the concentrated acid with 9 volumes of water), and dilute the solution to 500 ml. and mix. This dilute standard solution should be prepared fresh from the phosphate standard every 10 days to 2 weeks.

<sup>98</sup> Uric acid tends to precipitate out of urine on short standing, particularly if the urine is concentrated or acid. Analyses should therefore be carried out as soon as possible after obtaining the urine, and on the well-mixed sample, otherwise results will be misleading.

For photometric measurement:

$$\frac{\text{Density of Standard}}{\text{Density of Unknown}} \times 0.2 \times \frac{D}{10} = \text{uric acid content of the urine, in g. per liter}$$

As above  $D$ , is the dilution of the urine. The spectrophotometric characteristics of the uric acid color are shown in Fig. 249. At 520  $m\mu$ , and in a 1-cm. cuvette, the standard has a density of approximately 0.300. Agreement with Beer's law is satisfactory only at a uric acid content about equal to that of the standard. For higher values, or for photometric measurement at greater depths of solution, carry out the analysis on a greater dilution of the urine. For more accurate results, prepare a calibration curve as described for the following method (p. 908).

FIG. 249. ABSORPTION SPECTRA OF COLORED SOLUTIONS OBTAINED IN BENEDICT-FRANKE METHOD FOR URIC ACID IN URINE.

For standards containing 0.2 mg. (a) and 0.4 mg. (b) of uric acid. Solution depth, 1 cm.

**Interpretation.** For adults on a mixed diet the average excretion of uric acid is about 0.7 g. It arises from the purines of ingested food (exogenous uric acid) and from purines derived from the body tissues by disintegration of nuclear material (endogenous uric acid). This distinction between two metabolic sources of urinary uric acid, first postulated by Folin many years ago, appears to be confirmed by more recent work based on the use of isotopes.<sup>99</sup> Exogenous uric acid depending entirely upon the diet is greatly increased by the ingestion of purine-rich foods (meat, liver, sweetbreads, etc.) and reduced to a very low level on purine-free foods, e.g., milk, eggs, etc. (see table, Chapter 33). Endogenous uric acid is influenced by exercise and by the diet (protein foods particularly giving rise to increases). It appears to be partly the result of gastrointestinal secretory activity. On a purine-free diet the average excretion is 0.1 to 0.5 g. On a high-purine diet the uric acid output may be 2 g. per day.

In gout the uric acid content of the urine is low preceding an attack and increases during the attack, this fall and rise being more or less characteristic. The excretion rises after cincophen administration, apparently because of increased kidney activity, and after the administration of

<sup>99</sup> Plentl and Schoenheimer: *J. Biol. Chem.*, **153**, 203 (1944).

ACTH. In leukemia the excretion is extremely high due to nuclear destruction. The uric acid content of the urine is of importance in relation to the formation of uric acid calculi. The administration of alkali carbonates and citrates by decreasing the acidity of the urine increases its solvent power for uric acid, and decreases the possibility of the formation of this type of calculus.

**2. Uricase Method of Buchanan, Block, and Christman:**<sup>100</sup> **Principle.** The color intensity resulting from the application of a uric acid color reaction directly to a portion of the diluted urine is determined photometrically. A second portion of urine is incubated with a preparation of the enzyme uricase, which specifically destroys uric acid, and the uric acid color reaction applied to this incubated sample. The difference in color value before and after treatment with uricase is considered to be a measure of the true uric acid content of the urine.

**Procedure.**<sup>101</sup>

(a) **TOTAL COLOR.** Transfer 5 ml. of urine to a 250-ml. volumetric flask, dilute with water to the mark, and mix. Transfer 10 ml. of this diluted urine to a 50-ml. volumetric flask and add 15 ml. of water. In a second similar flask place 25 ml. of water; this serves as a photometric blank. To each flask add 2.5 ml. of urea-cyanide solution, followed by 1 ml. of arsenophosphotungstic

---

<sup>100</sup> Buchanan, Block, and Christman: *J. Biol. Chem.*, **157**, 181 (1945). For a similar procedure see Schaffer: *J. Biol. Chem.*, **153**, 163 (1944).

<sup>101</sup> Reagents Required: *Urea-Cyanide Solution.* Dissolve 25 g. of pure sodium cyanide and 50 g. of anhydrous sodium carbonate in 400 ml. of water. Cool, add 75 g. of pure urea and dilute with water to 500 ml. This solution is usable for several months, even though a slight precipitate will settle out on standing. *It is extremely poisonous and must be handled carefully.*

*Arsenophosphotungstic Acid.* This is the same reagent that is used in the Benedict-Franke method (see p. 905).

*Uricase Powder.* Remove the superficial fat from 5 pounds of fresh beef kidneys and grind in a meat-chopper. Transfer to a large wide-mouthed bottle and wash by running in cold tap water slowly through a tube reaching to the bottom of the bottle until the supernatant fluid is quite clear and colorless. Homogenize small portions of the resulting material in a Waring blender with an approximately equal weight of benzene. To the combined total homogenate add 2 volumes of cold acetone. Allow the precipitate to settle, filter through cheesecloth or a towel, and squeeze dry. Suspend the solid material in about three times its weight of acetone, allow it to settle, and again filter off. Repeat until the resulting powder is thoroughly dehydrated and defatted. Spread the material on towels and allow to dry in air overnight. Screen the powder through a 40-mesh sieve and store in a vacuum desiccator.

This powder should give no blank color when carried through the incubation procedure and subsequent color reaction described in the text. To test for *activity*, prepare a special lithium carbonate solution of uric acid containing 1 g. of uric acid and 0.6 g. of lithium carbonate per liter by following the procedure described on p. 560 for the preparation of the Folin stock uric acid solution *up to* but *not including* the addition of formaldehyde and sulfuric acid, which if present will interfere with uricase activity. Each ml. of this solution contains 1 mg. of uric acid. Incubate 3 to 4 ml. of this solution with 250 mg. of the uricase powder, borate buffer, etc., and continue with the color reaction as for the analysis of an unknown. If the uricase is active, no residual color will be obtained. The special lithium carbonate standard is unstable and must be made up fresh on the day of use.

*Standard Uric Acid Solution.* The Folin stock standard solution is used, containing 1 mg. of uric acid per ml., prepared as described on p. 560 in connection with the determination of uric acid in blood. Suitable dilutions of this stock standard are used in the preparation of the calibration curve, as described in the text. Dilute standards are unstable and must be prepared fresh on the day of use.

*Borate Buffer (pH 9.2).* Dissolve 12.4 g. of boric acid in 1 liter of 0.1 N sodium hydroxide solution.

*10 Per Cent Sodium Tungstate, 0.66 N Sulfuric Acid.* The same reagents used in the preparation of Folin-Wu blood filtrates (see p. 543).

acid. Both of these reagents are extremely poisonous; they should be handled with care, and always dispensed from burets. Immediately after the addition of the arsenophosphotungstic acid, dilute the contents of the flask to the 50-ml. mark with water and mix thoroughly. Allow to stand for exactly 30 minutes after so diluting (in serial analyses a suitable time schedule should be established), then determine the density of the unknown in a photometer at  $690\text{ m}\mu$ , setting the photometer to zero density with the blank.

(b) **RESIDUAL COLOR.** Place 5 ml. of the original undiluted urine in a small flask, add 10 ml. of water and a few drops of 0.04 per cent thymol blue solution as indicator. Titrate with 0.1 N sodium hydroxide solution to a definite blue tint. Record the amount of alkali required, and discard the mixture. Transfer a fresh 5-ml. portion of the urine to a 50-ml. volumetric flask, and add the predetermined amount of alkali (without indicator). Add 250 mg. of uricase powder, 5 ml. of borate buffer (pH 9.2), and wash down the sides of the flask with 10 ml. of water. Place in a water bath at  $45^{\circ}\text{C}$ . for 2 hours. Add 1 ml. of 10 per cent sodium tungstate and 1.5 ml. of two-thirds normal sulfuric acid. Dilute to 50 ml. with water, mix well, and pour onto a dry filter. Transfer 10 ml. of the filtrate to a 50-ml. volumetric flask, add 15 ml. of water, and continue with the addition of the color reagents and measurement exactly as described above for "Total Color" procedure. The same reagent blank may be used for setting the photometer to zero density, or a 5-ml. portion of water may be treated with uricase, buffer, etc., as described for the analysis of the urine, and the final solution after treatment with the color reagents used as a photometric blank.

#### CALCULATION.

a. *Total Color Value.* Determine the amount of uric acid in mg. equivalent to the photometer reading of the total color sample by reference to a calibration curve (see below). Multiply this by 5 (since the 10 ml. of urine diluted 1:50 represents 0.2 ml. of original urine) to obtain the uric acid content for the undiluted urine equivalent to the total color, in mg. per ml. (or g. per liter).

b. *Residual Color Value.* In a similar way, determine the uric acid content equivalent to the residual color; the value in mg. obtained from the calibration curve gives directly the residual color equivalent of the original urine, in mg. per ml., or g. per liter, since 10 ml. of urine diluted 1:10 are used.

c. *True Uric Acid Content.* Subtract the "residual color" value from the "total color" value, to obtain the true uric acid content of the urine:

$$\begin{array}{rcl} \text{Total Color} & - & \text{Residual Color} = \text{True uric acid content} \\ \text{(as uric acid)} & & \text{(as uric acid)} \quad \quad \text{(in g. per liter)} \end{array}$$

Multiply the result by the urine volume (expressed in liters) to obtain the uric acid content of the entire sample.

Other dilutions and aliquots than those specified may be used if the final colored solutions are either too light or too dark for accurate photometric measurement; in such case the calculations must be corrected accordingly.

The use of a calibration curve prepared from standard uric acid solutions is recommended because of the deviation from Beer's law shown by lower concentrations of uric acid. To prepare such a curve, proceed as follows: Dilute 1 ml. of the stock Folin uric acid standard (containing 1 mg. per ml.) to 100 ml. with water and mix, thus obtaining a solution containing 0.01 mg. of uric acid per ml. Measure aliquots of this dilute standard into 50-ml. volumetric flasks (preferably in duplicate) to give a series of solutions of known uric acid content covering the range of satisfactory photometric measurement (0.01 to 0.12 mg. for measurement at 2 cm. solution depth or its approximate equivalent, as with the Evelyn photometer; 0.02 to 0.24 mg. if 1-cm. cuvettes or

their equivalent are to be used). Include a blank flask containing water alone in the series. Adjust the volume in each flask to 25 ml. by adding water where necessary, then add 2.5 ml. of urea-cyanide solution to each flask. At timed (e.g., one-minute) intervals add 1 ml. of arsenophosphotungstic acid to a flask, dilute immediately to 50 ml. with water, and mix thoroughly. At the end of 30 minutes, set the photometer to zero density with the blank, and determine the density for each standard exactly 30 minutes after diluting and mixing. Plot the determined densities against the amount of uric acid present (in mg.) on cross-section paper, and draw a smooth curve to include the points.

In an analysis, the determined density of an unknown is translated into its equivalent uric acid value by reference to the curve. For accurate results the curve should be checked at intervals, particularly if new reagents are made up, and reconstructed if necessary. In an analysis, environmental and other conditions should reproduce as consistently as possible those prevailing at the time the curve was established. For further discussion concerning the validity and use of calibration curves in photometric analysis, see the section "Photometry" in Chapter 23, p. 512.

**Interpretation.** Results by the uricase method described here indicate that only 80 to 90 per cent of the color obtained by direct treatment of urine with uric acid color reagents may actually be due to uric acid; this discrepancy may be much greater if the diet contains significant amounts of the methyl xanthines (caffeine, theophylline, and theobromine, found in coffee, tea, and cocoa). In such instances, the uricase method appears to be even more specific for uric acid than the "isolation" procedures (see following method). For further aspects of interpretation, see under previous method.

**3. Colorimetric Methods of Folin:<sup>102</sup> Principle.** Phosphotungstic acid is reduced by uric acid with the production of a blue color which is compared with that produced with a standard solution of uric acid. Polyphenols also react, thus giving too high results, and amino acids decrease the color. The direct application of the reaction to urine is not therefore an accurate method but may be useful for many clinical purposes. The indirect method in which the uric acid is first separated by precipitation with silver nitrate is claimed to be an accurate method if conditions are strictly followed.

#### **Procedure.**

(a) **INDIRECT METHOD.** Half fill a 100-ml. volumetric flask with water. With a Folin-Ostwald pipet introduce 1 ml. of the urine. Add 10 ml. of the chloride-acetate solution<sup>103</sup> and then without shaking so as to avoid foaming, dilute to the mark with water and mix.

Transfer 5 ml. of the diluted urine to one 15-ml. centrifuge tube and 3 ml. plus 2 ml. of water to another. To each add 3 ml. of the silver nitrate solution

---

<sup>102</sup> Folin: *J. Biol. Chem.*, **101**, 111 (1933); **106**, 311 (1934).

<sup>103</sup> *Chloride-Acetate Solution.* A solution containing 1 per cent NaCl, 2 per cent cryst. sodium acetate, and 1 volume per cent of 99 per cent acetic acid.

*5 Per Cent Solution of Silver Nitrate.* This solution, even if perfectly clear when first prepared, may develop a slight color on standing. This color is most quickly produced by heating to 100° C. for 2 hours in a flask covered with a beaker. After cooling, add a few ml. of a solution containing 50 mg. of NaCl, shake thoroughly and filter through a double layer of quantitative filter paper until crystal clear. Thereafter the solution will remain perfectly colorless and need not be kept in brown bottles.

Other solutions are the same as those used in blood methods (see p. 560).

and centrifuge at once fairly rapidly for 4 to 5 minutes so as to get perfectly clear supernatant solutions. A few tiny flakes may float on the surface but these contain no uric acid. Decant and drain over a sink. It is permissible to let cold tap water rinse the mouths of the tubes during the draining. With a 25-ml. cylinder or a buret, to each tube add 10 ml. of the urea-cyanide solution (*poisonous!*). Stir immediately and simultaneously with glass rods until the two sediments have completely dissolved. Transfer the silver cyanide solutions to test tubes graduated at 25 ml. and rinse with exactly 5 ml. of water. Mix by whirling at an angle of about 60° until the solutions are visibly uniform. In another graduated test tube place 5 ml. of the standard uric acid solution containing 0.02 mg. of uric acid together with 10 ml. of the urea-cyanide solution and mix.

With a 10-ml. blood pipet add to each of the three tubes 4 ml. of the uric acid reagent and let stand for 20 minutes. Dilute to volume and mix. For colorimetric measurement, make the comparison between the standard and the unknown which is nearest to it in depth of color. When the standard is set at 20 mm., colorimetric readings between 35 mm. and 10 mm. are acceptable. For photometric measurement, only one unknown is necessary. Determine its density, and that of the standard, in a photometer at 660 m $\mu$ , setting the photometer to zero density with a blank prepared by treating 5 ml. of water with urea-cyanide and color reagent, etc., exactly as described for the preparation of the standard.

(b) DIRECT METHOD. Half fill a 100-ml. volumetric flask with water. With a Folin-Ostwald pipet introduce 1 ml. of urine, dilute to volume and mix. Introduce into test tubes graduated at 25 ml., 5 ml. of the diluted urine and 3 ml. of the diluted urine plus 2 ml. of water. To another graduated test tube add 5 ml. of the standard uric acid solution. Add 10 ml. of the urea-cyanide solution (*poisonous!*) to each, mix, and add 4 ml. of the uric acid reagent. Let stand for 20 minutes. Dilute to volume and mix. Continue with colorimetric or photometric measurement as described above for the indirect method.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.02 \times \frac{100}{v} = \text{Uric acid content of undiluted urine, in g. per liter}$$

$v$  is the volume of *diluted* urine (5 ml. or 3 ml.) used in an analysis. The same calculations are used for both indirect and direct methods.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.02 \times \frac{100}{v} = \text{Uric acid content of undiluted urine, in g. per liter}$$

The significance of  $v$  is the same as for colorimetric measurement. The conditions for satisfactory photometric measurement are the same as those given on p. 561 in connection with the determination of uric acid in blood, since the same standards and color reaction are used.

**Interpretation.** See previous methods.

**4. Folin-Shaffer Method: Principle.** Phosphates and some organic matter are removed by means of uranium acetate. The uric acid is precipitated as ammonium urate which is titrated with potassium permanganate.<sup>104</sup>

<sup>104</sup> Folin and Shaffer: *Z. physiol. Chem.*, 32, 552 (1901). This method was described in the 11th and previous editions of this book.

## PURINE BASES (INCLUDING URIC ACID)

**1. Krüger and Schmid's Method: Principle.** This method serves for the determination of both uric acid and the purine bases. The principle involved is the precipitation of both the uric acid and the purine bases in combination with copper oxide and the subsequent decomposition of this precipitate by means of sodium sulfide. The uric acid is then precipitated by means of hydrochloric acid and the purine bases are separated from the filtrate in the form of their copper or silver compounds. The nitrogen content of the precipitates of uric acid and purine bases is then determined by means of the Kjeldahl method (see p. 874) and the corresponding values for uric acid and purine bases calculated. For a study of this method as applied to the determination of purines in protein-free tissue extracts, on a microscale, see Hitchings and Fiske.<sup>105</sup>

**Procedure.** To 400 ml. of albumin-free urine<sup>106</sup> in a liter flask,<sup>107</sup> add 24 g. of sodium acetate, and 40 ml. of a solution of sodium bisulfite,<sup>108</sup> and heat the mixture to boiling. Add 40 to 80 ml.<sup>109</sup> of a 10 per cent solution of copper sulfate and maintain the temperature of the mixture at the boiling point for at least 3 minutes. Filter off the flocculent precipitate, wash it with hot water until the wash water is colorless, and return the washed precipitate to the flask by puncturing the tip of the filter paper and washing the precipitate through by means of hot water. Add water until the volume in the flask is approximately 200 ml., heat the mixture to boiling, and decompose the precipitate of copper oxide by the addition of 30 ml. of sodium sulfide solution.<sup>110</sup> After decomposition is complete, the mixture should be acidified with acetic acid and heated to boiling until the separating sulfur collects in a mass. Filter the hot fluid with the aid of a filter pump, wash with hot water, add 10 ml. of 10 per cent hydrochloric acid, and evaporate the filtrate in a porcelain dish until the total volume has been reduced to about 10 ml. Permit this residue to stand about 2 hours to allow for the separation of the uric acid, leaving the purine bases in solution. Filter off the precipitate of uric acid, using a small filter paper, and wash the uric acid, with water made acid with sulfuric acid, until the total volume of the original filtrate and the wash water aggregates 75 ml. Determine the nitrogen content of the precipitate by means of the Kjeldahl method (see p. 874), and calculate the uric acid equivalent.<sup>111</sup>

Render the filtrate from the uric acid crystals alkaline with sodium hydroxide, add acetic acid until faintly acid, and heat to 70° C. Now add 1 ml. of a 10 per cent solution of acetic acid and 10 ml. of a suspension of manganese dioxide<sup>112</sup> to oxidize the traces of uric acid which remain in the solution.

---

<sup>105</sup> Hitchings and Fiske: *J. Biol. Chem.*, **140**, 491 (1941).

<sup>106</sup> If albumin is present, the urine should be heated to boiling, acidified with acetic acid, and filtered.

<sup>107</sup> The total volume of urine for the 24 hours should be sufficiently diluted with water to make the total volume of the solution 1600 to 2000 ml.

<sup>108</sup> A solution containing 50 g. sodium bisulfite in 100 ml. water.

<sup>109</sup> The exact amount depending upon the content of the purine bases.

<sup>110</sup> This is made by saturating a 1 per cent solution of sodium hydroxide with hydrogen sulfide gas and adding an equal volume of 1 per cent sodium hydroxide. Ordinarily the addition of 30 ml. of this solution is sufficient, but the presence of an excess of sulfide should be *proved* by adding a drop of lead acetate to a drop of the solution. Under these conditions a dark brown color will show the presence of an excess of sodium sulfide.

<sup>111</sup> This may be done by multiplying the nitrogen value by three and adding 3.5 mg. to the product as a correction for the uric acid remaining in solution in the 75 ml.

<sup>112</sup> Made by heating a 0.5 per cent solution of potassium permanganate with a little alcohol until it is decolorized.

Agitate the mixture for 1 minute, add 10 ml. of the sodium bisulfite solution<sup>113</sup> and 5 ml. of a 10 per cent solution of copper sulfate, and heat the mixture to boiling for 3 minutes. Filter off the precipitate, wash it with hot water, and determine its nitrogen content by means of the Kjeldahl method (see p. 874). Inasmuch as the composition and proportion of the purine bases present in urine is variable, no factor can be applied. The result as regards these bases must therefore be expressed in terms of nitrogen.

Benedict and Saiki report cases in which the total purine nitrogen by this method was less than the uric acid nitrogen as determined by the Folin-Shaffer method. The inaccuracy was found to lie in the Krüger and Schmid method. To obviate this they advise the addition of 20 ml. of glacial acetic acid for each 300 ml. of urine employed, the acid being added before the first precipitation.

**Interpretation.** The amount of purine bases excreted by a normal man is small and variable. Values from 16 to 60 mg. have been found. The purine base nitrogen is of course only a fraction of this. The amount excreted is influenced by the diet somewhat in the same way as is the excretion of uric acid, being also increased in disorders associated with increased uric acid excretion such as leukemia. The purine bases form a higher percentage of the total purine excretion in the case of the monkey, sheep, and goat than in the case of man.

## 2. Hunter and Givens' Modification of the Krüger-Schmid Method:<sup>114</sup>

**Principle.** The Krüger-Schmid process is combined with the colorimetric method for uric acid (see p. 909).

**Procedure.** The first copper-purine precipitate as obtained in the Krüger-Schmid procedure is suspended in about 200 ml. of water, to which there is added about 1 ml. of concentrated hydrochloric acid. The mixture is vigorously boiled, whereupon the whole or greater part of the precipitate goes into solution. Removal of the copper is effected by treatment, while hot, with hydrogen sulfide and excess of the sulfide is completely expelled by renewed boiling. Filtration under suction, and thorough washing of flask and filter result in a filtrate which is perfectly clear and nearly colorless. This is concentrated if necessary, and made up to a convenient volume which must of course be sufficiently large to retain, when cool, the uric acid in solution. Of this an aliquot part is utilized directly for the colorimetric determination of uric acid. In the remainder the residual uric acid is destroyed and bases determined according to the regular Krüger-Schmid procedure. This modification is recommended particularly where the amount of uric acid present is minute.

## 3. Welker's Modification of the Methods of Arnstein and of Salkowski:

**Principle.** The phosphates are removed by treatment with magnesia mixture. The purine bases and uric acid are then thrown down as their silver salts and the nitrogen content of this precipitate determined.<sup>115</sup>

---

<sup>113</sup> To dissolve the excess of manganese dioxide.

<sup>114</sup> Hunter and Givens: *J. Biol. Chem.*, 17, 37 (1914).

<sup>115</sup> Dittman and Welker: *N. Y. Med. J.*, 89, 1134 (1909).

## ALLANTOIN

**1. Method of Larson:**<sup>116</sup> **Principle.** The urine is treated with phosphotungstic acid to remove interfering substances. Basic lead acetate is then added to remove excess phosphotungstic acid and residual interfering substances. Excess lead is removed by sulfuric acid and excess acid neutralized by sodium hydroxide. The solution is then boiled with Folin ammoniacal reagent and acid molybdate reagent added to the cooled solution. After proper dilution a colorimetric comparison is made against a 1-mg. allantoin standard.

**Procedure.** Transfer 1.5 g. of phosphotungstic acid<sup>117</sup> to a 50-ml. centrifuge tube and add 5 ml. of water. Rotate gently to insure solution; then add 5 ml. of animal urine. Centrifuge immediately, place the tube in a refrigerator for one-half hour, then centrifuge again until perfectly clear. The addition of a crystal of phosphotungstic acid should not cause further precipitation. Add 5 ml. of basic lead acetate solution which precipitates the excess phosphotungstic acid as well as the remaining interfering substances. Centrifuge the mixture, then treat with 5 ml. of 5 per cent sulfuric acid to remove the excess lead, and centrifuge until perfectly clear. Pipet 2 ml. of the resulting water-clear liquid into a Folin-Wu sugar tube, neutralize with 5 per cent sodium hydroxide, and then add 2 ml. of Folin ammoniacal copper reagent.<sup>118</sup> Place the tubes in a rapidly boiling water bath for 10 minutes, cool, then add 2 ml. of acid molybdate reagent.<sup>119</sup> Dilute the tubes to volume and read in a

<sup>116</sup> Larson: *J. Biol. Chem.*, **94**, 727 (1932). According to Young and Conway (*J. Biol. Chem.*, **142**, 839 (1942)), the Larson procedure, although giving reasonably good recovery of added allantoin, gives somewhat high results on urine compared to the procedure they describe, which is claimed to be more specific and satisfactory. For details, see the original article. For a photometric version of the Young-Conway procedure, and method for the determination of allantoin in blood, see Young, MacPherson, Wentworth, and Hawkins: *J. Biol. Chem.*, **152**, 245 (1944).

<sup>117</sup> *Phospho-24-tungstic Acid.* Dissolve 100 g. of  $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$  in about 100 ml. of water with the aid of heat. Add 10 ml. of 85 per cent  $\text{H}_3\text{PO}_4$  and then 80 ml. of concentrated  $\text{HCl}$ . Cool. After 4 hours or more, filter on a Buchner funnel and suck as dry as possible. Redissolve the precipitate in 120 ml. of  $\text{H}_2\text{O}$ , pour the solution into a liter separatory funnel, add about 90 ml. of ether, and then add 40 ml. of concentrated  $\text{HCl}$ . Shake. After standing a few minutes, there should be three layers of liquid. The lowest layer contains nearly all the complex acid. If there are only two layers, more ether must be added and the mixture shaken again. Transfer the lowest layer to another separatory funnel, add about 120 ml. of water, and shake vigorously; then add 50 ml. of ether and finally 50 ml. of concentrated  $\text{HCl}$ . After standing, the lowest layer, which should be perfectly clear, is transferred to a crystallizing dish. Add 30 ml. of  $\text{H}_2\text{O}$  and 1 drop of liquid bromine and evaporate on a steam bath. The solution should be greenish in color. If the slightest trace of dust or organic matter is present, a pinkish color develops; and 1 or 2 drops more of liquid bromine must be added to oxidize this foreign material.

Evaporate on the steam bath until crystals begin to form on the surface. Let stand overnight. The crystals obtained are sucked as dry as possible on a large Buchner funnel. After air-drying for one week, powder the crystals and keep in an amber glass container. This phosphotungstic acid should dissolve instantly to give a perfectly clear, practically colorless solution.

<sup>118</sup> *Folin Ammoniacal Copper Solution.* Dissolve 100 g. of ammonium sulfate in about 400 ml. of water and filter into a volumetric liter flask. 100 ml. of 10 per cent sodium hydroxide are then added, 12 g. of sodium tartrate, and finally a solution of 5 g. of copper sulfate. Dilute to volume and mix. This reagent will not give a blank for months, if kept in the dark in well-filled, tightly stoppered, amber glass bottles. The bottles should be of small volume.

<sup>119</sup> *Folin Acid Molybdate Reagent.* Prepare a stock solution of 30 per cent brominated sodium molybdate as follows: Dissolve 300 g. of sodium molybdate in water and make up to 1 liter. The solution is slightly turbid. Add 2 or 3 drops of liquid bromine and let stand

colorimeter against a 1-mg. allantoin standard.<sup>120</sup> Photometric data on this procedure are not available.

#### CALCULATION.

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 1 \times \frac{100}{5} = \text{mg. allantoin per 100 ml.}$$

**Interpretation.** Allantoin is found in only small amounts in human urine (35 to 45 mg. per day), and appears to be mainly, though not entirely, exogenous in origin. It forms, however, the principal end product of the purine metabolism of practically all mammals other than man and the anthropoid apes, with the notable exception of the pure-bred Dalmatian coach hound which excretes a considerable fraction of its purine nitrogen as uric acid. Thus over 90 per cent of the purine-allantoin nitrogen excretion of the dog, the cow, and the pig occurs as allantoin. In these animals its origin is from exogenous and endogenous purines, and its excretion is influenced by much the same factors as is that of uric acid in man. It appears to be entirely a waste product, since if injected into the blood of man or dogs it is excreted almost quantitatively in the urine.<sup>121</sup>

### HIPPURIC ACID

**1. Method of Griffith:<sup>122</sup> Principle.** Hippuric acid is extracted from urine with ether in a continuous extraction apparatus. The residue obtained by distilling off the ether is treated with bromine and sodium hypobromite to destroy traces of urea. Hippuric acid nitrogen is then determined in the residue by the Kjeldahl procedure.

In Quick's method<sup>123</sup> the hippuric acid is extracted in a similar manner, and the amino nitrogen determined by the formol titration (see p. 897). The older methods involved hydrolysis of the hippuric acid and titration of the liberated benzoic acid. These may give misleading results, however, because benzoic acid may be present also in the form of glucuronic acid monobenzoate (benzoyl glucuronic acid).

**Procedure.** Place 10 ml. of protein-free urine (containing not more than 150 mg. of hippuric acid) and 0.1 ml. of concentrated HCl in the extraction tube and 100 ml. of ether in the 500-ml. Kjeldahl flask. (The arrangement of the extraction apparatus is shown in Fig. 250.) Immerse the lower portion of the flask in a water bath heated to 60° to 70° C. and continue the extraction for one hour. Distil off the ether. To the dry residue in the flask add 5 ml. of sodium hypobromite<sup>124</sup> solution and shake one minute. Add 2 ml. of sulfuric acid (diluted 1:5). Mix thoroughly. Add 2 ml. of 25 per cent NaOH and 2 ml. of the hypobromite solution and shake 1 minute. Proceed with the determination of nitrogen in the flask by the Kjeldahl method.

overnight. Transfer 500 ml. of the clear supernatant liquid to a liter flask and add, with stirring, 225 ml. of 85 per cent phosphoric acid. Then add 150 ml. of cool sulfuric acid (25 volumes per cent). The bromine which is liberated is removed by aeration. Add 75 ml. of 99 per cent acetic acid, mix, and dilute to 1 liter.

<sup>120</sup> *Allantoin Standard.* Dissolve 100 mg. of allantoin in about 50 ml. of water with the aid of heat, but do not allow to boil. Cool, transfer to a 100-ml. volumetric flask, and dilute to volume. Cover with toluene. Such a standard will keep for about 2 weeks at room temperature without deterioration. Without toluene, a loss of 1 per cent of the allantoin is noted after standing 1 week. Givens reports a loss of 1.7 per cent after 90 days.

<sup>121</sup> Young, Wentworth, and Hawkins: *J. Pharmacol.*, **81**, 1 (1944).

<sup>122</sup> Griffith: *J. Biol. Chem.*, **69**, 197 (1926). Also private communication.

<sup>123</sup> Quick: *J. Biol. Chem.*, **67**, 477 (1926).

<sup>124</sup> Prepared by mixing equal volumes of 25 per cent NaOH and a solution containing 12.5 g. of bromine and 12.5 g. of sodium bromide dissolved in 100 ml. of water.

**CALCULATION.** If  $y$  represents the number of ml. of 0.1 N acid neutralized by ammonia in the Kjeldahl titration, then

$$y \times 1.4 \times \frac{179}{14} = \text{mg. hippuric acid in 10 ml. urine}$$

**Interpretation.** The average excretion of hippuric acid by a normal adult man is about 0.7 g. per day. The amount is increased by the ingestion of benzoic acid or fruits such as plums, prunes, and cranberries which contain, in addition to benzoic acid, certain other precursors of hippuric acid (quinic acid, etc.). It arises in part apparently from putrefaction products formed in the intestine. In herbivora it is often the most abundant nitrogenous constituent of the urine.

## 2. Hippuric Acid Test for Liver Function (Quick<sup>125</sup>):

**Principle.** If benzoic acid is ingested or injected, a major portion of it combines with glycine to form hippuric acid which is then excreted in the urine (for reactions, see p. 440). In man (but not necessarily in other animals) this synthesis appears to take place primarily in the liver. If the liver is damaged, the amount of hippuric acid excreted is diminished relative to that found normally. It is claimed that clinically the decrease in hippuric acid excretion under test conditions is fairly proportional to the extent of hepatic impairment.

**Procedure.** Just before the test, which is preferably given in the morning about 1 hour after a light breakfast (cereals or toast, and coffee, tea, or milk), the patient is instructed to empty his bladder as completely as possible, and the urine obtained is discarded. A dose of 6 g. of sodium benzoate dissolved in 30 ml. of water (flavored with oil of peppermint if desired) is then ingested,<sup>126</sup> followed by half a glass of water. More water may be taken during the test if necessary but excessive water intake should be discouraged in order to keep the urine volume down. A complete specimen of urine is collected each hour after the test dose, for 4 hours.

Measure the volume of each hourly specimen in a graduate. If a specimen volume exceeds 150 ml., it is advisable to acidify slightly with acetic acid and to concentrate the sample on a water bath to about 50 ml. Combine the four specimens in a graduated cylinder, measure the volume, and transfer to a beaker. Add solid ammonium sulfate in the proportion of 5 g. for each 10 ml. of urine, and stir to dissolve. Filter or centrifuge. To the clear filtrate or centrifugate in a beaker add sufficient concentrated hydrochloric acid (usually about 1 ml. is required) to render distinctly acid to Congo red or thymol blue (pH about 2).<sup>127</sup> Stir vigorously with a glass rod, scratching the sides of

FIG. 250. CONTINUOUS EXTRACTION APPARATUS (GRIF-FITH).

A, 500-ml. Kjeldahl flask; B, glass tube (420 × 15 mm.) with side opening; C, glass tube (400 × 6 mm.) with widened top and small openings at bottom; D, condenser.

<sup>125</sup> Quick: *Am. J. Clin. Path.*, **10**, 222 (1940). See also Weichselbaum and Probst: *J. Lab. Clin. Med.*, **24**, 636 (1938-1939); Hepler and Gurley: *ibid.*, **27**, 1593 (1941-1942).

<sup>126</sup> For details of the *intravenous* test, see Quick (*loc. cit.*).

<sup>127</sup> Indicator paper may also be used.

the beaker to promote crystallization, then place in the refrigerator or in ice water for 30 minutes. Filter off the crystalline hippuric acid by suction on a small Buchner funnel, and wash the precipitate with several small portions of ice-cold distilled water, using the wash water to complete the transfer of the crystals from the beaker to the Buchner funnel.

Quantitatively transfer the precipitate and filter paper to a beaker (a little water may be used to aid in the transfer), add sufficient water to cover, and heat to dissolve. Add a few drops of phenolphthalein solution and titrate with 0.5 N sodium hydroxide solution to a permanent pink. Record the buret reading.

CALCULATION. Each ml. of 0.5 N sodium hydroxide is equivalent to 0.0895 g. hippuric acid. Therefore:

$$\text{ml. 0.5 N alkali used} \times 0.0895 = \text{g. hippuric acid titrated}$$

To determine the amount of hippuric acid excreted, a correction for the solubility of the compound must be added. In the presence of ammonium sulfate as described, the solubility has been established as 0.001 g. per ml. of urine. If  $V$  is the total volume of urine in milliliters before adding the ammonium sulfate, the solubility correction is  $V \times 0.001$  g. Therefore:

$$\begin{aligned} (\text{ml. of 0.5 N alkali used} \times 0.0895) + (V \times 0.001) &= \text{g. hippuric acid excreted} \\ \text{G. hippuric acid} \times 0.68 &= \text{g. benzoic acid} \end{aligned}$$

**Interpretation.** Under the conditions of this test, the average healthy adult will excrete 3.0 to 3.5 g. (or even more) of benzoic acid in the form of hippuric acid. There is some indication that increased excretion above 3 g. is roughly proportional to body weight (or surface area) in normal individuals.<sup>128</sup> Any excretion of 2.7 g. or more is considered nonpathological. Marked diminution in output is found in various liver disorders. For further aspects of clinical interpretation, see texts on clinical diagnosis.

## LACTIC ACID

**Method of Friedemann and Graeser:**<sup>129</sup> **Principle.** By treatment with phosphoric acid and potassium permanganate, the lactic acid is converted to acetaldehyde.

The aldehyde is bound with sodium bisulfite.

The bound sulfite is titrated iodimetrically.

**Procedure.** A 10- to 25-ml. sample of urine is introduced into a 250-ml. volumetric flask, 10 ml. of 20 per cent  $\text{CuSO}_4\cdot 5\text{H}_2\text{O}$  and 10 ml. of a suspension of  $\text{Ca}(\text{OH})_2$  are added.<sup>130</sup> The suspension is diluted to the mark and filtered, an aliquot representing not more than 5 ml. of urine being used for analysis.

<sup>128</sup> Hepler and Gurley: *loc. cit.*

<sup>129</sup> Friedemann and Graeser: *J. Biol. Chem.*, **100**, 291 (1933). The authors describe adaptations of this method for blood (see p. 624), milk, culture media, and tissues.

<sup>130</sup> Special Reagents: *Calcium Hydroxide Suspension*. 1 kg. of fresh unslaked lime is slaked with water and immediately afterward sufficient water is added to bring the volume

Ten ml. of  $\text{H}_3\text{PO}_4\text{-MnSO}_4$  reagent and a pinch of finely powdered talc are placed in a 300-ml. Kjeldahl flask, followed by the sample of urine. About 85 ml. of water are added and the flask attached to the apparatus (see Fig. 251). Ten ml. of  $\text{NaHSO}_3$  solution are placed in the 150-ml. extraction flask (receiver). The microburner is adjusted to bring the solution to boiling in about 3 minutes. Addition of oxidizing agent is begun as soon as vapors appear in the condenser. The rate of addition is unimportant, but it is essential to have an excess of oxidizing agent throughout the distillation, as indicated by a brownish (not gray) color. It is best to add from 25 to 40 ml. over a 15-minute oxidation period. Shortly before the end of the oxidation the receiving flask is detached from the stopper and lowered. The glass tip is rinsed and the flask containing a total volume of 50 to 75 ml. is cooled prior to titration.

For the removal of excess bisulfite 1 ml. of starch solution is added, followed by a slight excess of the strong iodine solution which is immediately removed by the cautious addition of 0.1 N thiosulfate. The walls of the flask are now washed down by a thin stream of water after which the end point is adjusted to a faint blue with dilute iodine solution.

The flask is cooled and approximately 15 ml. of saturated  $\text{NaHCO}_3$  are added. The solution is titrated with dilute standard iodine solution which is run in rapidly so as to keep pace with the decomposition into aldehyde and

---

to approximately 5 liters. The suspension is thoroughly shaken, allowed to stand for a few seconds, and decanted from the coarser particles.

*Phosphoric Acid-Manganous Sulfate Reagent.* 100 g. of  $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$  are dissolved in about 500 ml. of warm water. To this are added 50 ml. of syrupy phosphoric acid (85 per cent, 15 M). The solution is cooled and diluted to a volume of approximately 1 liter.

*Oxidizing Agent.* To 10 ml. of 0.1 N  $\text{KMnO}_4$ , diluted to approximately 800 ml., are added 2 ml. of the  $\text{H}_3\text{PO}_4\text{-MnSO}_4$  reagent, stirring while adding. The volume is brought to about 1000 ml. and the solution is again well mixed. The reduction is complete in 5 to 10 minutes.

*Sodium Bisulfite.* 25 g. are dissolved in 2 liters of water. The solution should be kept in a stoppered bottle.

*Starch Indicator.* 5 g. of arrowroot starch are suspended in 10 to 20 ml. of cold water and poured into 500 ml. of boiling water; 500 ml. of hot water are added and boiling is continued for 15 minutes. The flask is covered with a beaker, cooled, and kept in the refrigerator. The supernatant clear solution only is used. The solution will keep several weeks if care is taken to avoid bacterial growth.

*Strong Iodine Solution.* 40 g. of iodine and 75 g. of KI are dissolved in a small quantity of water and the volume is brought up to about 2 liters.

*Standard Iodine Solution.* The weak iodine solutions (0.01 to 0.002 N) may be prepared either by dilution of a standard iodine solution or by liberation of iodine from 0.1 N iodate + KI. The latter method is preferred because of the permanence of iodate solutions. 0.1 N  $\text{KH}(\text{IO}_3)_2$  solution contains 3.2496 g. per liter. 0.1 N  $\text{KIO}_3$  contains 3.567 g. per liter. Five to 10 g. of c.p. KI, about 200 ml. of cool, distilled water, and 2 to 5 ml. of 5 N  $\text{H}_2\text{SO}_4$  are placed in a volumetric flask. Standard iodate is added and the volume is brought almost to the mark with cooled water. It is then warmed to 20° C. and the volume adjusted to the mark. Since iodine is volatile even from dilute solutions, they should be kept cool.

*Lactic Acid Standard.* Lithium lactate is preferred because this salt is anhydrous and not hygroscopic. It is prepared as follows:

U.S.P. lactic acid (85 per cent) is diluted with an equal volume of water and a few drops of phenol red indicator are added. Saturated (approximately 20 per cent) lithium hydroxide or  $\text{LiCO}_3$  (the former is preferred) solution is added to slight excess, as is indicated by the phenol red. The solution is heated to boiling and the alkali is again added to slight alkalinity. It is now cooled. Four volumes of 95 per cent alcohol are added and after cooling for some time, the mass of crystals is filtered off on a Buchner funnel and washed thoroughly with 95 per cent alcohol. This preparation is recrystallized from water and dried at 100° C.

9.60 g. of lithium lactate are transferred to a 1-liter volumetric flask. Enough  $\text{H}_2\text{SO}_4$  is added to bring the final concentration to 0.2 N when diluted to the mark. This 0.1 M lactic acid standard will keep for at least one year, provided it is kept away from strong light or stored in a refrigerator.

bisulfite. When this slows up, 1 ml. of 10 per cent  $\text{Na}_2\text{CO}_3$  is added until the end point persists for at least  $\frac{1}{2}$  minute.

Blank determinations should be run with filtrates prepared with the precipitating reagent and the  $\text{CuSO}_4$  and lime reagents.

CALCULATION. Each ml. of 0.01 N iodine solution used in the titration of bound sulfite is equivalent to 0.45 mg. of lactic acid.

**Interpretation.** The lactic acid concentration is variable, depending upon the volume, from 4 mg. in very dilute urine to as high as 25 mg. per 100 ml. in concentrated urine. These values are increased after severe exercise and probably in such pathological conditions as are accompanied

FIG. 251. APPARATUS FOR THE DETERMINATION OF LACTIC ACID (FRIEDEMANN AND GRAESER).

by deficient oxidative metabolism. For a discussion of lactic acid in the urine, see p. 812.

## CONJUGATED GLUCURONIC ACIDS

A satisfactory quantitative method which is applicable to the analysis of all conjugated glucuronic acids is not available. Quick<sup>131</sup> has described a method for menthol glucuronic acid in urine which has been extended, with slight modifications, to the determination of other conjugated glucuronic acids. It consists in extraction of the compound with ether, hydrolysis with dilute acid, and finally determination of the liberated glucuronic acid by a copper reduction method. A method for benzoyl glucuronic acid, similar to the above, was reported by Csonka.<sup>132</sup> Maughan, Evelyn,

<sup>131</sup> Quick: *J. Biol. Chem.*, 61, 667 (1924); 67, 477 (1926); 69, 549 (1926).

<sup>132</sup> Csonka: *J. Biol. Chem.*, 60, 545 (1924).

and Browne<sup>133</sup> have described a quantitative photometric version of the naphthoresorcinol test (see p. 843) which appears to give good results.

## GLUCOSE<sup>134</sup>

**1. Benedict's Method:**<sup>135</sup> *Principle.* Benedict's reagent for the estimation of reducing sugars contains potassium thiocyanate as well as copper sulfate, and in the presence of the former a white precipitate of cuprous thiocyanate is formed in reduction instead of the usual red precipitate of cuprous oxide. The small amount of potassium ferrocyanide also aids in keeping cuprous oxide in solution. As the precipitate formed is white the loss of all blue tint in the solution, indicating complete reduction of the copper, is readily observed. The alkali used is sodium carbonate, which has the advantage over hydroxides of being less likely to cause destruction of small amounts of sugar. The solution also has the great advantage of being stable for an indefinite length of time. The method is recommended for its simplicity and accuracy.

*Procedure.* The urine, 10 ml. of which should be diluted with water to 100 ml. (unless the sugar content is believed to be low, when it may be used undiluted), is placed in a 50-ml. buret and the volume adjusted to the zero mark. Twenty-five ml. of the reagent<sup>136</sup> is measured with a pipet into a porcelain evaporation dish or casserole (100 to 125 mm. in diameter), 20 g. of crystallized sodium carbonate (or one-half the weight of the anhydrous salt) is added, together with a small quantity of powdered pumice stone or talcum, and the mixture heated to boiling over a free flame and stirred with a glass rod to aid in dissolving the bulk of the carbonate. The diluted urine is now run in from the buret rather rapidly, until a chalk-white precipitate forms in noticeable amount and the blue color of the mixture begins to lessen perceptibly; after which the solution from the buret must be run in a few drops at a time, until the disappearance of the last trace of blue color, which marks the end point. The final color at the end point may be yellow or brown, owing to urinary pigments, but there should be no trace of blue (or green) color. The solution must be kept vigorously boiling and be stirred continuously throughout the entire titration. If the mixture becomes too concentrated during the process, water may be added from time to time to replace the volume lost by evaporation. Any material which dries out on the sides of the dish during the titration must be pushed back into the solution with the stirring rod before the end point is reached.

<sup>133</sup> Maughan, Evelyn, and Browne: *J. Biol. Chem.*, **126**, 567 (1938). See also Deichmann: *J. Lab. Clin. Med.*, **28**, 770 (1943).

<sup>134</sup> The method for sugar adopted by the Committee on Urinary Impairments of the Association of Life Insurance Medical Directors of America is given on p. 923.

<sup>135</sup> Benedict: *J. Am. Med. Assoc.*, **57**, 1193 (1911).

|                                                                  |            |
|------------------------------------------------------------------|------------|
| <sup>136</sup> Copper sulfate (crystallized) . . . . .           | 18.0 g.    |
| Sodium carbonate (crystallized, one-half the weight of the anhy- |            |
| drous salt may be used) . . . . .                                | 200.0 g.   |
| Sodium or potassium citrate . . . . .                            | 200.0 g.   |
| Potassium thiocyanate . . . . .                                  | 125.0 g.   |
| Potassium ferrocyanide (5 per cent solution) . . . . .           | 5.0 ml.    |
| Distilled water to make a total volume of . . . . .              | 1000.0 ml. |

With the aid of heat dissolve the carbonate, citrate, and thiocyanate in enough water to make about 800 ml. of the mixture and filter if necessary. Dissolve the copper sulfate separately in about 100 ml. of water and pour the solution slowly into the other liquid, with constant stirring. Add the ferrocyanide solution, cool and dilute to exactly 1 liter. Of the various constituents, the copper salt only need be weighed with exactness. Twenty-five ml. of the reagent are reduced by 50 mg. of glucose.

**CALCULATION.** The 25 ml. of copper solution is reduced by exactly 50 mg. of glucose. Therefore the volume run out of the buret to effect the reduction contained 50 mg. of the sugar. The formula for calculating the percentage of the sugar is the following:

$$\frac{0.050}{x} \times D \times 100 = \text{per cent in original sample, wherein } x \text{ is the number of ml. of the diluted urine required to reduce 25 ml. of the copper solution, and } D \text{ is the dilution of the urine (} D \text{ equals 1 for undiluted urine, 10 for urine diluted 1:10, etc.).}$$

In the use of this method chloroform must not be present during the titration. If used as a preservative in the urine it may be removed by boiling a sample for a few minutes, and then diluting to its original volume.

**Interpretation.** Glucose in the urine in amounts sufficient to be detected by the commonly employed qualitative tests (i.e., 0.1 to 0.2 per cent or more) ordinarily indicates a pathological condition, although it must be remembered that benign glucosuria is not uncommon (see p. 823 for further discussion), and that other reducing sugars (lactose, pentose) cannot be distinguished from glucose by the ordinary reduction tests, either qualitative or quantitative. Persistent glucosuria may indicate diabetes mellitus, a disorder in which the amount of sugar may rise as high as 10 per cent and averages 3 to 5 per cent. The volume of urine excreted per day is usually also large and the absolute sugar excretion may thus be very great (100 g. of glucose per day are not uncommon). The quantitative methods for the estimation of sugar in urine enable us to determine the severity of this disorder as well as to follow its course under treatment, etc.

**2. Sumner's Method:**<sup>137</sup> **Principle.** Urine is heated with a dinitrosalicylic acid reagent which is reduced by the sugar, and the resultant color is compared with standards. This is a rapid method, applicable to normal as well as glycosuric urine, but is not as precise as the more elaborate method of Shaffer and Hartmann described below.

**Procedure.** Pipet into a Folin-Wu blood-sugar tube 1 ml. of urine (diluted if necessary) and 3 ml. of the dinitrosalicylic acid reagent.<sup>138</sup> Mix and heat 5 minutes in boiling water. Cool 3 minutes in running water, dilute to 25 ml., mix and compare in a colorimeter with a standard glucose solution treated simultaneously in the same way. A concentration of 0.1 per cent glucose is satisfactory for the standard solution. If the color obtained with the urine is too dark, repeat the test using more dilute urine.

**CALCULATION.**

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{Dilution}}{10} = \text{per cent glucose}$$

**3. Folin-McEllroy-Peck Method: Principle.** The method is a titration procedure depending upon the use of an alkaline copper solution in which the cupric

<sup>137</sup> Sumner: *J. Biol. Chem.*, **65**, 383 (1925).

<sup>138</sup> To 10 g. crystallized phenol add 22 ml. 10 per cent NaOH. Dissolve in a little water and dilute to 100 ml. Weigh 6.9 g. sodium bisulfite and to this add 69 ml. of alkaline phenol solution. To this add a solution containing 300 ml. 4.5 per cent NaOH, 255 g. Rochelle salt ( $\text{NaKC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ ), and 880 ml. 1 per cent dinitrosalicylic acid. Mix and keep tightly stoppered in well-filled bottles. The reagent should keep for at least one year. Dinitrosalicylic acid may be obtained from the Eastman Kodak Co., Rochester, N. Y.

hydroxide is held in solution by means of phosphate instead of the customary tartrates, citrates, or glycerol. The method is applicable to the determination of lactose in milk.<sup>139</sup>

**4. Method of Shaffer and Hartmann:**<sup>140</sup> *Principle.* The sugar solution is boiled with Fehling's alkaline copper solution (as modified by Soxhlet) under the conditions prescribed in the standard method of Munson and Walker whose tables may therefore be used in the calculation of results. The residual cupric salt may then be converted into cuprous iodide with the liberation of an equivalent amount of iodine.  $2\text{Cu}^{++} + 4\text{I}^- \rightarrow 2\text{CuI} + \text{I}_2$ . Or the cuprous salt may be oxidized in the presence of a known amount of iodine.  $2\text{Cu}^+ + \text{I}_2 \rightarrow 2\text{Cu}^{++} + 2\text{I}^-$ . Iodine liberated, or excess iodine found in the second case may be titrated with sodium thiosulfate. In the titration of cuprous copper, oxalate is added to depress the ionization of the cupric salt. Shaffer and Hartmann prefer the cuprous titration.

*Procedure.* Pipet 25 ml. of each of the two Fehling's solutions<sup>141</sup> into a 300- or 400-ml. flask. Add 50 ml. or less of the (approximately neutral) sugar solution containing from 20 to 200 mg. of sugar, and water (if necessary) to make a total volume of 100 ml. Cover with a small inverted beaker and heat on an asbestos mat over a flame so adjusted as to bring the solution to boiling in 4 minutes. Boil 2 minutes. Stand the flask in the sink under running water till cool (3 to 4 minutes). Then use one of the two following procedures.

*Cuprous Titration.* Add 50 ml. (accurate pipet) or 25 ml. if but little cuprous oxide is present, of iodate-iodide solution,<sup>142</sup> followed by 15 to 17 ml. of 5 N  $\text{H}_2\text{SO}_4$ . The acid should be added from a cylinder or fast-flowing pipet in order that acidification of the whole solution may be accomplished promptly. Shake the solution gently for a few moments until the cuprous oxide has dissolved. The solution should become clear, but some cuprous iodide may separate. Add 20 ml. of saturated solution of potassium oxalate and rotate the flask until the cuprous iodide is *completely* dissolved.

Titrate with 0.1 N sodium thiosulfate (see Appendix) adding a few ml. of starch solution toward the end before the disappearance of the green color. Run a blank by boiling the Fehling's solution with 50 ml. of water instead of sugar solution.

*CALCULATION.* From the blank titration subtract the titration of the sugar determination, the remainder representing  $\text{I}_2$  required for the oxidation of the cuprous salt. Multiply by the copper factor of the thiosulfate (1 ml. of 0.1 N = 6.36 mg. of Cu), and find the amount of sugar equivalent to the copper by reference to Munson-Walker tables<sup>143</sup> or divide the amount of copper reduced by the corresponding ratio obtained from the glucose curve in Fig. 252.

*Cupric Titration.* To the cooled alkaline copper solution add 6 g. of KI and 25 ml. of 5 N  $\text{H}_2\text{SO}_4$ . Titrate with standard thiosulfate, adding starch

<sup>139</sup> Folin and Peck: *J. Biol. Chem.*, **38**, 287 (1919).

<sup>140</sup> Shaffer and Hartmann: *J. Biol. Chem.*, **45**, 365 (1921).

<sup>141</sup> *Fehling's Solutions (Soxhlet Modification).* (I) Dissolve 34.64 g.  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in water to make 500 ml. (II) Dissolve 173 g. Rochelle salt and 50 g. NaOH in water to make 500 ml.

<sup>142</sup> *Iodate-Iodide Solution.* Dissolve 5.4 g.  $\text{KIO}_3$  and 60 g. KI in water to which a small amount of alkali has been added and dilute to a liter.

<sup>143</sup> *Methods of Analysis of the Association of Official Agricultural Chemists*, 7th ed., Washington, D. C., 1950.

FIG. 252. COPPER: GLUCOSE RATIOS FOR FEHLING'S SOLUTION AND FOR THE MACRO COMBINED REAGENT, AND COPPER: LACTOSE RATIOS FOR FEHLING'S SOLUTION.

Divide the amount of reduced copper by its corresponding ratio as shown by the respective curves.

solution toward the end. The titration is subtracted from a similar blank determination on the Fehling's solution, the difference representing copper reduced by the sugar. For the cupric titration the copper solution must be measured accurately. Consult tables or chart (Fig. 252) for sugar values.

**5. Hanes' Modification of the Hagedorn-Jensen Method: Principle.** The Hagedorn-Jensen method (see Chapter 23) is modified so that it may be used for larger amounts of glucose (1 to 3 mg.). Maltose may also be determined in the presence of starch. Power and Wilder adapt the method to the determination of 1 to 50 mg. of glucose in urine. For accurate results the urine must be cleared with mercury. For an accuracy within 1 to 5 per cent on diabetic urines the uncleared urine may be used, a correction of 0.25 per cent glucose being subtracted.

**Procedure.** Into a test tube (1 × 7 in.) pipet 5 ml. of Solution A (alkaline ferricyanide).<sup>144</sup> Add 5 ml. of unknown solution (if necessary add water to make the 5 ml. volume). In another tube put 5 ml. of water and 5 ml. of Solution A. Incline the tube to mix in any drops of liquid adhering to the sides. Cover with glass bulbs (with about an inch of tubing left attached). Place for 15 minutes in a boiling water bath 2 to 3 in. deep. Cool for 3 minutes in cold running water.

Add 5 ml. of Solution B and then 3 ml. of Solution C, using rapid pipets which need not be precise. Run in thiosulfate to a pale yellow color, add a few drops of starch, and titrate to disappearance of the blue color. Subtract titration of unknown from titration of the blank. Convert result into ml. of 0.01 N thiosulfate. Consult Fig. 253 for amounts of glucose or maltose. In the presence of starch stir more vigorously and titrate more slowly. The maltose values are also easily calculated by multiplying the number of ml. of 0.01 N thiosulfate used by 0.414 mg. Invert sugar and thus indirectly sucrose may also be determined. The factor for invert sugar using a final volume of 15 instead of the usual 10 ml. is 0.347 and for sucrose 0.329. For a standard invert sugar solution dissolve 0.95 g. of sucrose in 150 ml. of water, add 30 ml. of 0.5 N HCl, heat to boiling, and boil 1 minute. Cool rapidly, add 30 ml. of 0.5 N NaOH, and dilute to 500 ml. 100 ml. will contain 0.2 g. of invert sugar. Other sugars may also be determined. The factor for fructose is 0.32, for ribose or an equimolecular mixture of glucose and galactose 0.38, arabinose 0.35, mannose and rhamnose 0.34, xylose 0.33, lactose and galactose 0.43.

**6. Benedict's Picrate Method** (ADOPTED BY THE COMMITTEE ON URINARY IMPAIRMENTS OF THE ASSOCIATION OF LIFE INSURANCE MEDICAL DIRECTORS OF AMERICA): **Principle.** The color produced by the reduction of picric acid (p. 67) is compared with permanent inorganic standards representing definite concentrations of sugar.

<sup>144</sup> **Solution A.** Dissolve 8.25 g. potassium ferricyanide and 10.6 g. anhydrous sodium carbonate in water to make 1000 ml. Store in an opaque bottle and keep 2 to 3 days before use. **Solution B.** Dissolve 12.5 g. KI, 25.0 g. zinc sulfate, and 125 g. NaCl in water to make 500 ml. Traces of iodine appear in the solution on storing. Remove by filtering through 2 thicknesses of filter paper. **Solution C.** Dilute 5 ml. of glacial acetic acid to 100 ml. **Starch.** Stir up 1 g. of Merck soluble starch with 20 ml. water, add to 60 ml. boiling water, boil 2 minutes, cool, and make up to 100 ml. Will keep for several months. **Sodium Thiosulfate.** An approximately N/75 solution used in a 10-ml. buret graduated in 0.02-ml. divisions. Dissolve 3.33 g. of the salt in 10 liters of boiled-out water. Keep in bottle protected by soda-lime tube and run into buret by siphon. Standardize each day at first, then every three to four days. Pipet 5 ml. 0.02 N KIO<sub>3</sub> solution (0.715 g. in 1000 ml.) into a tube. Add 5 ml. 2 per cent KI and 3 ml. 5 per cent acetic acid. Titrate using starch as indicator.

**Procedure.** Measure 1 ml. of urine into a test tube graduated at 25 ml. Add 3 ml. of picric acid solution (2 g. of pure dry picric acid per liter) and 0.5 ml. of 5 per cent NaOH. Add next 5 drops of 50 per cent acetone solution (prepared fresh each day by diluting acetone with an equal volume of water) and place the tube promptly in a boiling water bath. In 12 minutes remove

FIG. 253. CHART FOR SUGAR VALUES BY HANES' METHOD.

the tube, cool, and dilute the contents to 25 ml. Compare this colored solution with the permanent standards in tubes of the same dimensions, and estimate the amount of sugar. The permanent sugar standards are made as described below.

### PERMANENT SUGAR STANDARDS<sup>145</sup>

Put each standard in test tubes of the same diameter as used in sugar determination.

<sup>145</sup> Solutions needed.

**Ferric Chloride** (Merck's Analyzed).

Dissolve 200 g. ferric chloride ( $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ) in about 300 ml. distilled water, transfer to a 500-ml. volumetric flask, make up to volume with distilled water, and mix well. Filter through a dry filter paper.

**Cobalt Chloride** (analyzed grade).

Dissolve 150 g. cobalt chloride ( $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ ) in about 300 ml. distilled water, transfer to a 500-ml. volumetric flask, make up to volume with distilled water and mix well. Filter through a dry filter paper.

**Dilute Hydrochloric Acid.**

Dilute 5 ml. concentrated hydrochloric acid to 50 ml. with distilled water.

| <i>Sugar<br/>%</i> | <i>Ferric Chloride<br/>Solution<br/>ml.</i> | <i>Cobalt Chloride<br/>Solution<br/>ml.</i> | <i>Dilute Hydrochloric<br/>Acid<br/>ml.</i> | <i>Water</i>    |

| 0.3                | 22                                          | 22                                          | 8                                           |                 |
| 0.4                | 16                                          | 30                                          | 8                                           |                 |
| 0.5                | 14                                          | 40                                          | 8                                           |                 |

**7. Hawkins and Van Slyke Method:**<sup>146</sup> *Principle.* The time required for the urine to decolorize potassium ferricyanide solution is an index of the amount of reducing sugar present. Since normal constituents in concentrated urine may give reduction equivalent to as high as 0.4 per cent glucose, the method is regulated to determine reducing substances in concentrated urines in concentrations of 0.5 per cent and above, and in dilute urine in concentrations of 0.25 per cent and above.

*Procedure.* Dilute 1 ml. of urine to 50 ml. If urine is known to be high in sugar (over 3 per cent) dilute 1:100; if low in sugar, dilute 1:25. Albumin need not be removed. Pipet 2 ml. of diluted urine into a pyrex test tube (14 × 125 mm. outside diameter). Add 2 ml. of ferricyanide solution.<sup>147</sup> Mix. Immerse in a beaker of boiling water. A similar test tube containing water is immersed for comparison. Make a white background by pasting paper on the side of the beaker away from the observer. A casserole may be used instead of a beaker. Determine the time in seconds required for the last trace of yellow to disappear, preferably using a stop watch. From the chart, Fig. 254, obtain the percentage of sugar in the urine. The chart is for a dilution of 1:50. If a 1:25 dilution is used, divide the result obtained from the chart by 2; for a 1:100 dilution, multiply the result by 2.

**8. Fermentation Method: Principle.** This method consists in the measurement of the volume of carbon dioxide evolved when the dextrose of the urine undergoes fermentation with yeast. None of the various methods whose manipulation is based upon this principle is *absolutely* accurate. The method in which Einhorn's saccharometer (Fig. 15, p. 69) is employed is perhaps as satisfactory as any for clinical purposes.

*Procedure.* To about 15 ml. of urine in a mortar, add about 0.25 g. of active dry yeast and mix thoroughly. Transfer the mixture to the saccharometer,

<sup>146</sup> Hawkins and Van Slyke: *J. Biol. Chem.*, **81**, 459 (1929). For a similar procedure using smaller volumes of solution (and therefore with a slightly different calibration curve), which is also directly applicable to tungstic acid filtrates of blood, see Hawkins: *J. Biol. Chem.*, **84**, 69 (1929). A photometric adaptation of this procedure is described by Hoffman: *J. Biol. Chem.*, **120**, 51 (1937).

<sup>147</sup> *Potassium Ferricyanide Reagent.* Dissolve 75 g. of anhydrous potassium carbonate and 75 g. of potassium bicarbonate in about 750 ml. of water. Dissolve 1 g. of potassium ferricyanide in about 100 ml. of water. Add the ferricyanide solution quantitatively (rinsing with water) to the carbonate-bicarbonate solution in a 1-liter volumetric flask. Dilute to the mark with water and mix. Filter and store in a brown glass-stoppered bottle in the dark. This reagent appears to keep indefinitely. Of the various ingredients, only the ferricyanide need be weighed accurately.

being careful that the graduated tube is completely filled and that no air bubbles gather at the top. Allow the apparatus to stand in a warm place (30° C.) for 12 hours, and observe the percentage of dextrose as indicated by the graduated scale of the instrument. Both the percentage of dextrose and

FIG. 254. CHART OF URINE SUGAR VALUES FOR HAWKINS-VAN SLYKE METHOD.  
*J. Biol. Chem.*, 81, 459 (1929).

the number of cubic centimeters of carbon dioxide are indicated by the graduations on the side of the saccharometer tube. Controls should be run using normal urine and such urine to which sugar has been added.

**9. Polariscopic Examination.** Before subjecting urine to a polariscopic examination, the slightly acid fluid should be decolorized as thoroughly as possible by the addition of a little basic lead acetate. The urine should be well stirred and then filtered through a filter paper which has not been previously moistened. In this way a perfectly clear and almost colorless liquid is obtained.

In determining dextrose by means of the polariscope it should be borne in mind that this carbohydrate is often accompanied by other optically active substances, such as proteins, fructose,  $\beta$ -hydroxybutyric acid, and conjugate glucuronates which may introduce an error into the polariscopic reading; the method is, however, sufficiently accurate for practical purposes.

|                              | Specific Rotation                  |
|------------------------------|------------------------------------|
| Glucose                      | + 52.49                            |
| Maltose                      | +136.5                             |
| Isomaltose                   | + 68.0                             |
| Lactose                      | + 52.53                            |
| Fructose                     | - 92.25                            |
| $\beta$ -Hydroxybutyric acid | - 24.12                            |
| Conjugated glucuronic acids  | Levorotatory in<br>varying degrees |

For directions as to the manipulation of the polariscope, see p. 69.

The table gives the specific rotations of some physiologically important sugars as well as of certain other optically active substances

the possible presence of which must be borne in mind in determining glucose polarimetrically in urine.

## DETERMINATION OF SUGAR IN NORMAL URINE

**Principle.** Since the nature of normal urine "sugar" (i.e., reducing substances) is not definitely established, it is not possible to state which of the methods of determination is to be preferred. The methods involve removal of interfering substances and colorimetric determination of reducing power.

### Procedure.

(a) REMOVAL OF INTERFERING SUBSTANCES: METHOD OF FOLIN AND SVEDBERG.<sup>148</sup> To 5 ml. of urine in a 50-ml. Erlenmeyer flask add 5 ml. of 0.05 N oxalic acid, 10 ml. of water, and (last) 1.5 g. of Lloyd's alkaloidal reagent.<sup>149</sup> Shake gently for 4 minutes. Filter through a quantitative paper into another small flask containing 2 g. of Permutit. Shake 3 minutes. Decant.

(b) DETERMINATION OF SUGAR. Sugar may be determined in filtrates from treatment with Lloyd's reagent by one of the methods used for blood sugar<sup>150</sup> (see Chapter 23). The method of Sumner (see p. 920) is said to be applicable to urine without previous treatment. The urine may also be fermented and fermentable sugar determined by measurement of CO<sub>2</sub> given off or by difference. To 10 ml. of the filtrate from treatment with Lloyd's reagent add 3 ml. of a suspension of 1 cake of compressed yeast in 20 ml. of water. Keep at 37° C. for 40 minutes. Filter and determine sugar. Fermentable sugar is usually about 0.01 per cent (see Chapter 28). The urine may also be hydrolyzed and total sugar determined. To 8 ml. of urine filtrate add 1 ml. of 2.6 N H<sub>2</sub>SO<sub>4</sub> and heat in a boiling water bath for 75 minutes. Add 1 ml. of silica-free NaOH exactly equivalent to the acid added. Determine sugar by any of above methods.

## PROTEIN<sup>151</sup>

**1. Colorimetric Determination of Proteins (Method of Hiller, McIntosh, and Van Slyke):<sup>152</sup>** **Principle.** The protein is precipitated with trichloroacetic acid,<sup>153</sup> dissolved in NaOH solution, and copper ions added to give a biuret color which is compared with a standard.

**Procedure.** Measure 2 ml. of the urine (previously adjusted to a pH of about 7.4) into a centrifuge tube, add an equal volume of 10 per cent trichloroacetic acid solution, mix and centrifuge for 5 minutes. If the volume of the precipitate is less than 0.2 or more than 0.6 ml., repeat using more or less urine. Pour off the supernatant fluid. Dissolve the precipitate in about 3 ml. of 3 per cent NaOH and wash into a tube graduated at 10 ml. with portions of the 3 per cent NaOH until the volume is about 9 ml. Add 0.25 ml. of 20 per cent

<sup>148</sup> Folin and Svedberg: *J. Biol. Chem.*, **70**, 405 (1926). Hamilton (*J. Biol. Chem.*, **78**, 63 (1928)) omits Permutit but uses Lloyd's reagent extracted with concentrated HCl for 1 day, washed with water, and then extracted with concentrated HNO<sub>3</sub> for one day.

<sup>149</sup> Obtainable from Eli Lilly and Co., Indianapolis, Ind.

<sup>150</sup> See Folin: *J. Biol. Chem.*, **70**, 405 (1926); Benedict: *J. Biol. Chem.*, **68**, 766 (1926).

<sup>151</sup> The method for albumin adopted by the Committee on Urinary Impairments of the Association of Life Insurance Medical Directors of America is given on p. 929.

<sup>152</sup> Hiller, McIntosh, and Van Slyke: *J. Clin. Invest.*, **4**, 235 (1927).

<sup>153</sup> According to Beckman, Hiller, Shedlovsky, and Archibald (*J. Biol. Chem.*, **148**, 247 (1943)), from 4 to 20 per cent of the protein in proteinuria may not be precipitable by trichloroacetic acid. This may account for discrepancies in protein determination between methods involving trichloroacetic acid precipitation and those not involving such precipitation.

copper sulfate solution and dilute to 10 ml. with the NaOH. Mix by shaking. Let stand 10 minutes. Centrifuge and compare with a standard. For a standard measure 5 ml. of a biuret solution containing 13.33 mg. of biuret, equivalent to 12.3 mg. of protein, into a tube graduated at 10 ml. Add distilled water to 8 ml., 1 ml. of 30 per cent NaOH, 0.25 ml. of copper sulfate, and water to make 10 ml. Mix, let stand for 10 minutes, centrifuge, and compare in a colorimeter with the unknown, setting this standard at 15 mm.

For determining albumin add to 10 ml. of the urine, at pH 7.4, 10 ml. of 44 per cent sodium sulfate solution, mix well, and put in an incubator at 37° C. for three hours. Filter. Proceed as for total protein, using four times the volume. The globulin is estimated by difference.

CALCULATION. *For total protein:*

$$\frac{15}{R} \times \frac{12.3}{\text{ml. urine used}} = \text{g. protein per liter}$$

*For albumin:*

$$\frac{15}{R} \times \frac{12.3 \times 2}{\text{ml. filtrate used}} = \text{g. albumin per liter}$$

## 2. Folin's Gravimetric Method for the Determination of Protein in Urine:

**Principle.** The protein precipitated by heat and acetic acid is centrifuged, washed, dried, and weighed.

**Procedure.** Pipet 10 ml. of urine into an ordinary conical centrifuge tube, which has been previously weighed; add 1 ml. of 5 per cent acetic acid, and let stand for 15 minutes in a beaker of boiling water. At the end of this time remove the tube from the water bath, and centrifuge for a few minutes. Pour off the supernatant liquid, stir up the precipitate in the tube with about 10 ml. of boiling 0.5 per cent acetic acid, and again centrifuge. Remove the supernatant liquid from the precipitate in the tube, and wash once more, this time with 50 per cent alcohol. After centrifuging, pour off the supernatant alcohol and place the tube for 2 hours in an air bath at 100 to 110° C.; then cool in a desiccator, and weigh.

The precipitate may also be filtered off and washed on a small tared filter paper, then dried and weighed. In this case it is better to use a larger volume of urine. Instead of weighing, the nitrogen in the precipitate may be determined by the Kjeldahl method.<sup>154</sup>

CALCULATION. Multiply the weight of the precipitate in grams by 10 to obtain the percentage of protein present. If a volume other than 10 ml. of urine is used multiply by the appropriate volume factor.

**Interpretation.** The amount of albumin occurring in the urine is not necessarily an index of the severity or type of the disorder giving rise to it. Hence no significant figures can be given. Normal human urine probably contains a trace of albumin which is too slight to be detected or determined by the usual procedures. The determination of albumin may be of assistance in following the course of kidney disturbances, but the results can be interpreted only in the light of other clinical findings. (See discussion under "Albumin," p. 828.)

<sup>154</sup> In order to arrive at correct figures for the protein content, it is then only necessary to multiply the total nitrogen content by 6.25 (see p. 239). Correction should be made for the nitrogen content of the filter paper used unless this factor is negligible.

**3. Esbach's Method: Principle.** This method depends upon the precipitation of protein and measurement of its volume after settling. The apparatus used is Esbach's albuminometer (Fig. 255).

**Procedure.** In making a determination fill the albuminometer to the point *U* with urine, then introduce Esbach's reagent<sup>155</sup> (or 10 per cent trichloroacetic acid, as recommended by Quick) until the point *R* is reached. Now stopper the tube, invert it slowly several times in order to insure the thorough mixing of the fluids, and stand the tube aside for 24 hours. Creatinine, resin, acids, etc. are precipitated in this method, and for this and other reasons it is not so accurate as the coagulation method. It is, however, extensively used clinically. According to Sahli, Esbach's method is "accurate approximately to 1 part per 1000," whereas Pfeiffer claims it is not accurate for less than one-half or for more than 5 parts per 1000.

**CALCULATION.** The graduations indicate g. of protein per liter of urine. Thus a reading of 3 indicates 3 g. per liter, or 0.3 per cent protein.

**4. The Determination of Albumin** (METHOD ADOPTED BY THE COMMITTEE ON URINARY IMPAIRMENTS OF THE ASSOCIATION OF LIFE INSURANCE MEDICAL DIRECTORS OF AMERICA):

**Principle.** Clarified urine is treated with sulfosalicylic acid and the degree of turbidity produced is measured by comparison with artificial standards.

**Procedure.** Pipet 2.5 ml. of centrifuged urine into a test tube graduated at 10 ml. and add 3 per cent sulfosalicylic acid (30 g. in 1000 ml. of distilled water) to the 10-ml. mark. Invert the tube to mix, allow to stand 10 minutes, and compare the turbidity with the permanent turbidity standards. Record the value of the standard most closely matched, as the albumin content of the urine.

**Preparation of Permanent Albumin Standards.**<sup>156</sup> Dissolve 20 g. of gelatin (Super X brand in sheet form, Coignet Chemical Products Co., New York) in 120 to 140 ml. of distilled water at 45° to 55° C. and make up to 200 ml. Add about half the white of an egg and stir in. Heat in a water bath for at least 30 minutes after a temperature of 90° C. has been attained. Filter hot through a Whatman's No. 4 paper yielding a perfectly clear, slightly yellow solution. Immediately before using, add 0.3 ml. of formalin (40 per cent formaldehyde solution) to each 100 ml. of gelatin solution. Formazin, the material to be suspended in the gelatin, is made as follows: Dissolve 2.5 g. of urotropin in 25 ml. of distilled water at room temperature. Add to 25 ml. of 1 per cent hydrazine sulfate solution also at room temperature. Mix, stopper, and allow to stand at least 15 hours. Suspend the white amorphous precipitate uniformly by gently inverting the flask a few times. Add 14.5 ml. of the formazin suspension to 100 ml. of 10 per cent gelatin solution at

FIG. 255. ESBACH'S ALBUMINOMETER.

<sup>155</sup> See Appendix.

<sup>156</sup> These permanent standards were developed in the laboratories of the Metropolitan Life Insurance Company and the Mutual Benefit Life Insurance Company. For a detailed description of the preparation of these standards, see Kingsbury, Clark, Williams, and Post: *J. Lab. Clin. Med.*, **11**, 981 (1926).

45° to 55° C. (to which the correct amount of formalin has been added) and mix thoroughly. This produces a turbidity equivalent to that made by an albumin solution of 0.1 per cent, or one containing 100 mg. of albumin in 100 ml. when precipitated by 3 volumes of 3 per cent sulfosalicylic acid. Dilute this stock suspension as follows to make the remaining standards:

| <i>Stock Formazin Suspension Equivalent<br/>to 100 mg. Albumin per 100 ml.</i> | <i>10 % Clarified<br/>Gelatin</i> | <i>Value of Standard<br/>Made</i> |            |
|--------------------------------------------------------------------------------|-----------------------------------|-----------------------------------|------------|
|                                                                                |                                   | <i>%</i>                          | <i>mg.</i> |
| <i>ml.</i>                                                                     | <i>ml.</i>                        |                                   |            |
| 25.0                                                                           | 26                                | 0.05                              | 50         |
| 20.0                                                                           | 30                                | 0.04                              | 40         |
| 15.0                                                                           | 35                                | 0.03                              | 30         |
| 10.0                                                                           | 40                                | 0.02                              | 20         |
| 5.0                                                                            | 45                                | 0.01                              | 10         |
| 2.5                                                                            | 55                                | 0.005                             | 5          |

Pour each standard into a test tube of the same dimensions as those used in making the test with urine. Seal the tube with a waxed stopper and allow to cool to room temperature. In a short time the gelatin should solidify and after a few days cannot be melted at any room temperature. In extremely hot weather put the tubes in a cool place for a few days before any attempt is made to use them. Keep the standards in a well-lighted room. If in time they become greenish, they may be bleached by exposure to sunlight without changing their turbidimetric value. The standards may be checked against sheep serum standards of known protein content precipitated in the same manner as in the urine test. Standards older than 8 months should be replaced unless actual tests show that they have their original degree of turbidity. In the course of a year there may be only a very slight diminution in the turbidimetric value of the standards. There is no detectable change in 6 to 8 months.

## ACETONE BODIES

**1. Van Slyke's Methods:**<sup>157</sup> *Principle.* The method is based on a combination of Shaffer's oxidation of  $\beta$ -hydroxybutyric acid to acetone (p. 934), and Denigès' precipitation of acetone as a basic mercuric sulfate compound. Glucose and certain other interfering substances are removed by precipitation with copper sulfate and calcium hydroxide. Preservatives other than toluene or copper sulfate should not be used.

**Procedure: Removal of Glucose and Other Interfering Substances from Urine.** Place 25 ml. of urine in a 250-ml. measuring flask. Add 100 ml. of water, 50 ml. of copper sulfate solution,<sup>158</sup> and mix. Then add 50 ml. of 10 per cent

<sup>157</sup> Van Slyke: *J. Biol. Chem.*, 32, 455 (1917); 83, 415 (1929).

<sup>158</sup> Solutions Required. **20 Per Cent Copper Sulfate.** Dissolve 200 g.  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in water and make up to 1 liter.

**10 Per Cent Mercuric Sulfate.** Dissolve 73 g. pure red mercuric oxide in 1 liter of 4 N  $\text{H}_2\text{SO}_4$ .

**50 Volume Per Cent Sulfuric Acid.** Dilute 500 ml. sulfuric acid of specific gravity 1.835 to 1 liter with water. Concentration of  $\text{H}_2\text{SO}_4$  must be readjusted if necessary to make it 17.0 N by titration.

**10 Per Cent Calcium Hydroxide Suspension.** Mix 100 g. Merck's fine light reagent  $\text{Ca}(\text{OH})_2$  with 1 liter of water.

**5 Per Cent Potassium Bichromate.** 50 g.  $\text{K}_2\text{Cr}_2\text{O}_7$  dissolved in water and made up to 1 liter.

**Combined Reagents for Total Acetone Body Determination.** 1 liter of the above 50 per cent sulfuric acid, 3.5 liters of the mercuric sulfate, 10 liters of water.

calcium hydroxide suspension, shake, and test with litmus. If not alkaline, add more calcium hydroxide. Dilute to the mark and let stand at least one-half hour for glucose to precipitate. Filter through a dry folded filter. This procedure will remove up to 8 per cent of glucose. Urine containing more should be diluted enough to bring the glucose down to 8 per cent. The copper treatment is depended upon to remove interfering substances other than glucose, and should therefore never be omitted, even when glucose is absent. The filtrate may be tested for glucose by boiling a little in a test tube. A precipitate of yellow cuprous oxide will be obtained if the removal has not been complete. A slight precipitate of white calcium salts always forms, but does not interfere with the detection of the yellow cuprous oxide.

*Determination of Total Acetone Bodies (Acetone, Acetoacetic Acid, and  $\beta$ -Hydroxybutyric Acid).* Place in a 500-ml. Erlenmeyer flask 25 ml. of urine filtrate. Add 100 ml. of water, 10 ml. of 50 per cent sulfuric acid, and 35 ml. of the 10 per cent mercuric sulfate. Or, in place of adding the water and reagents separately, add 145 ml. of the combined reagents. Connect the flask with a reflux condenser having a straight condensing tube of 8 or 10 mm. diameter, and heat to boiling. After boiling has begun, add 5 ml. of the 5 per cent bichromate through the condenser tube. Continue boiling gently  $1\frac{1}{2}$  hours. The yellow precipitate which forms consists of the mercury sulfate-chromate compound<sup>159</sup> of acetone (total). It is collected in a Gooch or "medium density" alundum or fritted glass crucible, washed with 200 ml. of cold water, and dried for an hour at  $110^{\circ}$  C. The crucible is allowed to cool in room air (a desiccator is unnecessary and undesirable) and weighed. Several precipitates may be collected, one above the other, without cleaning the crucible. As an alternative to weighing, the precipitate may be dissolved and titrated as described below.

*Determination of Acetone and Acetoacetic Acid.* The acetone plus the acetoacetic acid, which completely decomposes into acetone and  $\text{CO}_2$  on heating, is determined without the  $\beta$ -hydroxybutyric acid exactly as the total acetone bodies, except that (1) no bichromate is added to oxidize the  $\beta$ -hydroxybutyric acid and (2) the boiling must continue for not less than 30 nor more than 45 minutes. Boiling for more than 45 minutes splits off a little acetone from  $\beta$ -hydroxybutyric acid even in the absence of chromic acid.<sup>160</sup>

*Determination of  $\beta$ -Hydroxybutyric Acid.* The  $\beta$ -hydroxybutyric acid alone is determined exactly as total acetone bodies except that the preformed acetone and that from the acetoacetic acid are first boiled off. To do this

---

<sup>159</sup> This contains about 77 per cent mercury and in the absence of chromate has approximately one of the following formulas:  $3\text{HgSO}_4 \cdot 5\text{HgO} \cdot 2(\text{CH}_3)_2\text{CO}$  or  $2\text{HgSO}_4 \cdot 3\text{HgO} \cdot (\text{CH}_3)_2\text{CO}$ .

<sup>160</sup> *Blank Determination of Precipitate from Substances in Urine Other than the Acetone Bodies.* The 25 ml. aliquot of urine filtrate is treated with sulfuric acid and water and boiled 10 minutes to drive off acetone. The residue is made up to 175 ml. with the same amounts of mercuric sulfate and sulfuric acid used in the above determinations, but without chromate, and is boiled under the reflux for 45 minutes. Longer boiling splits off some acetone from  $\beta$ -hydroxybutyric acid, and must therefore be avoided. The weight of precipitate obtained may be subtracted from that obtained in the above determination.

The blank is so small that it appears to be significant only when compared with the small amounts of acetone bodies found in normal or nearly normal urines. In routine analyses of diabetic urines it is not determined.

*Tests of Reagents.* When the complete total acetone bodies determination, including the preliminary copper sulfate treatment, is performed on a sample of distilled water instead of urine, no precipitate whatever should be obtained. This test must not be omitted.

the 25 ml. of urine filtrate plus 100 ml. of water are treated with 2 ml. of the 50 per cent sulfuric acid and boiled in the open flask for 10 minutes. The volume of solution left in the flask is measured in a cylinder. The solution is returned to the flask, and the cylinder washed with enough water to replace that boiled off and restore the volume of the solution to 127 ml. Then 8 ml. of the 50 per cent sulfuric acid and 35 ml. of mercuric sulfate are added. The flask is connected under the condenser and the determination is continued as described for total acetone bodies.

*Titration of the Precipitate in the Above Methods.* Instead of weighing the precipitate, one may wash the contents of the Gooch, including the asbestos, into a small beaker with as little water as possible, and add 15 ml. of normal HCl. The mixture is then heated, and the precipitate quickly dissolves. In case an alundum or glass crucible is used, it is set into the beaker of acid until the precipitate dissolves, and then washed with suction, the washings being added to the beaker. In place of using either a Gooch or alundum crucible, one may, when titration is employed, wash the precipitate without suction on a small quantitative filter paper, which is transferred with the precipitate to the beaker and broken up with a rod in 15 ml. of normal HCl.

In order to obtain a good end point in the subsequent titration it is necessary to reduce the acidity of the solution. For this purpose it has been found that the addition of excess sodium acetate is the most satisfactory means. Six to 7 ml. of 3 M acetate are added to the cooled solution of redissolved precipitate. Then the 0.2 M KI is run in rapidly from a buret with constant stirring. If more than a small amount of mercury is present, a red precipitate of  $\text{HgI}_2$  at once forms, and redissolves as soon as 2 or 3 ml. of KI in excess of the amount required to form the soluble  $\text{K}_2\text{HgI}_4$  has been added. If only a few mg. of mercury are present, the excess of KI may be added before the  $\text{HgI}_2$  has had time to precipitate so that the titrated solution remains clear. In this case not less than 5 ml. of the 0.2 M KI are added, since it has been found that the final titration is not satisfactory if less is present. The excess of KI is titrated back by adding 0.05 M  $\text{HgCl}_2$  from another buret until a permanent red precipitate forms. Since the reaction involved is  $\text{HgCl}_2 + 4\text{KI} = \text{K}_2\text{HgI}_4 + 2\text{KCl}$ , 1 ml. of 0.05 M  $\text{HgCl}_2$  is equivalent in the titration to 1 ml. of the 0.2 M KI.

In preparing the two standard solutions the 0.05 M  $\text{HgCl}_2$  is standardized by the sulfide method, and the iodine is standardized by titration against it. A slight error appears to be introduced if the iodide solution is gravimetrically standardized and used for checking the mercury solution, instead of vice versa.

In standardizing the mercuric chloride the following procedure has been found convenient: 25 ml. of 0.05 M  $\text{HgCl}_2$  is measured with a calibrated pipet, diluted to about 100 ml., and  $\text{H}_2\text{S}$  is run in until the black precipitate floculates and leaves a clear solution. The  $\text{HgS}$ , collected in a Gooch crucible and dried at  $110^\circ\text{C}$ ., should weigh 0.2908 g. if the solution is accurate.

Both by gravimetric analyses of the basic mercuric sulfate-acetone precipitate and by titration, the mercury content of the precipitate has been found to average 76.9 per cent. On this basis, each ml. of 0.2 M KI solution, being equivalent to 10.0 mg. of Hg, is equivalent to 13.0 mg. of the mercury acetone precipitate.

Titration is not quite so accurate as weighing, but, except when the amounts determined are very small, the titration is satisfactory.

CALCULATION. One mg. of  $\beta$ -hydroxybutyric acid yields 8.45 mg. of precipitate. One mg. of acetone yields 20.0 mg. of precipitate. One ml. of 0.2 M KI solution is equivalent to 13 mg. of precipitate in titration of the latter.

In order to calculate the acetone bodies as  $\beta$ -hydroxybutyric acid rather than acetone, use the above factors multiplied by the ratio of the molecular weights  $\frac{\beta\text{-acid}}{\text{acetone}} = \frac{104}{58} = 1.793$ . In order to calculate the acetone bodies in terms of molecular concentration, divide the factors in the table by 58. To calculate ml. of 0.1 M acetone bodies per liter of urine, use the above factors multiplied by 10,000/58 or 172.4.

SPECIAL FACTORS FOR CALCULATION OF RESULTS WHEN 25 ML. OF URINE FILTRATE, EQUIVALENT TO 2.5 ML. OF URINE, ARE USED FOR THE DETERMINATION

| <i>Determination Performed</i>    | <i>Acetone Bodies, Calculated as g. of Acetone per Liter of Urine, Indicated by:</i> |                               |

\* The "total acetone bodies" factor is calculated on the assumption that the molecular proportion of them in the form  $\beta$ -hydroxybutyric acid is 75 per cent of the total, which proportion is usually approximated in acetonuria. Because  $\beta$ -hydroxybutyric acid yields only 0.75 molecule of acetone, the factors are strictly accurate only when this proportion is present, but the error introduced by the use of the approximate factors is for ordinary purposes not serious. The actual errors in percentage of the amounts determined are as follows: molecular proportions of acetone bodies as  $\beta$ -acid 0.50, error 6.5 per cent;  $\beta$ -acid 0.90, error 3.8 per cent;  $\beta$ -acid 0.80, error 1.3 per cent.

**Interpretation.** Normal adults on a mixed diet excrete on the average 3 to 15 mg. of combined acetone and acetoacetic acid per day, and anything over 20 mg. is usually pathological. Usually about one-fourth of this total is acetone, although the proportion varies considerably. The amount is considerably increased in fasting and on a carbohydrate-free diet due to the development of ketosis. In severe diabetic ketosis values up to 6 g. per day or even higher may be noted. It is sometimes found in large amounts in intoxications associated with pregnancy. It may be found in increased amounts in the urine in a great variety of pathological conditions. Quantitative estimation enables us to follow the course of the ketosis. Ammonia excretion is also largely increased in these conditions, being used in the neutralization of the excess acids formed in the body. (See also Chapter 29.)

$\beta$ -Hydroxybutyric acid may occur in normal human urine to the extent of 20 to 30 mg. per day. In fasting or on a carbohydrate-free diet, very large amounts may be excreted (up to 20 g. per day). In severe diabetes mellitus the largest amounts are found, and excretions of 50 or even 100 g. or over per day have been noted. In this condition it is usually the most abundant of the acetone bodies making up from 60 to 80 per cent of the total. The ratio is, however, by no means constant, and it should be borne in mind that in rare cases large amounts of  $\beta$ -hydroxybutyric acid may be eliminated although the acetone excretion is very low. It is always present in the urine when large amounts of acetone are present.

A discussion of disturbance of acid-base equilibrium due to abnormal fat metabolism may be found on pp. 692 and 693.

**2. Method of Shaffer and Marriott:**<sup>161</sup> *Principle.* By this procedure the combined acetone and acetoacetic acid is determined in the same sample of urine used in the determination of  $\beta$ -hydroxybutyric acid. The preformed acetone and the acetoacetic acid are distilled off together as acetone and determined by the iodine titration method. The  $\beta$ -hydroxybutyric acid remains in the residue from distillation and is oxidized by means of potassium bichromate. The product of the oxidation is acetone which is distilled off and determined as such.

*Procedure: Determination of Acetone and Acetoacetic Acid.* Measure from 25 to 100 ml.<sup>162</sup> or more of urine (usually 50 ml.) with a pipet into a 500-ml. volumetric flask containing 200 to 300 ml. of water. Add basic lead acetate solution (U.S.P.) in volume equal to that of the urine used<sup>163</sup> and mix well. Add concentrated ammonium hydroxide in amount equal to about one-half that of the lead acetate solution. Dilute the contents of the flask to the mark with water, shake, and let stand for a few minutes. Then filter the liquid, preferably through a folded filter. Measure 200 ml. of the filtrate into a round-bottomed flask (800-ml. or liter Kjeldahl flasks are convenient), dilute with water to about 600 ml., and add 15 ml. of concentrated sulfuric acid and a little talc or a boiling stone. Distil until about 200 ml. of distillate have been collected. The tube of the condenser should dip beneath the surface of the water in the receiving flask so that no loss of acetone will occur. The distilling flask must also be fitted with a dropping tube or dropping funnel so water may be run in from time to time and the volume of liquid in the flask kept from becoming less than 400 to 500 ml. A good condenser should be used, but it is not necessary to cool the distillate in ice.

The distillate thus obtained is transferred to a second Kjeldahl flask and 10 ml. of 10 per cent NaOH added. It is then redistilled for about 20 minutes.<sup>164</sup> The second distillate is then titrated with standard iodine and thiosulfate solutions.

This is done by adding 10 to 25 ml. of 0.1 N iodine solution (0.02 N if the amount of acetone bodies as indicated by a qualitative test is small) and 10 ml. of strong NaOH (about 40 per cent). Let stand for 10 minutes. Add 18 ml. of concentrated HCl. Titrate with 0.1 N sodium thiosulfate solution to a pale yellow color, add a few ml. of soluble starch solution (see Appendix) and continue titration to disappearance of the blue color.

**CALCULATION.** Subtract the number of ml. of 0.1 N thiosulfate solution used from the volume of 0.1 N iodine solution employed. Since 1 ml. of the iodine solution is equivalent to 0.967 mg. of acetone, and since 1 ml. of the thiosulfate solution is equivalent to 1 ml. of the iodine solution, if we multiply the remainder from the above subtraction by 0.967 we will obtain the number of mg. of acetone and acetoacetic acid, expressed as acetone, in the volume of urine taken for analysis.

<sup>161</sup> Shaffer and Marriott: *J. Biol. Chem.*, **16**, 265 (1915).

<sup>162</sup> The amount used depends upon the expected yield of  $\beta$ -hydroxybutyric acid. In urines which give a strong ferric chloride reaction for acetoacetic acid, or when 5 to 10 g. or more of  $\beta$ -hydroxybutyric acid are expected, it is unnecessary to use more than 25 to 50 ml. of urine. However, in case only a trace of  $\beta$ -hydroxybutyric acid is expected, the volume should be much larger as indicated. Under all conditions, the amount specified is sufficient for duplicate determinations. It is desirable to use such a volume of urine as contains the proper amount of  $\beta$ -hydroxybutyric acid to yield 25 to 50 mg. of acetone.

<sup>163</sup> If the urine contains little or no sugar, only half the amount or less of lead acetate should be used.

<sup>164</sup> In many instances when a high degree of accuracy is not required, this redistillation may be omitted and the first distillate titrated directly. The results so obtained are slightly higher than those after redistillation from alkali. The object of the redistillation is to get rid of fatty acids, of which formic acid is one of the most troublesome.

**Determination of the  $\beta$ -Hydroxybutyric Acid.** The flask containing the residue from the first distillation above is used in the determination of the  $\beta$ -hydroxybutyric acid. A new receiver is arranged as before with the tip from the condenser dipping beneath the surface of the water. The distillation is then continued and water added whenever necessary to keep the volume between 400 and 600 ml. A dilute solution (1 per cent) of potassium bichromate is added during the distillation. At first 20 ml. of this 1 per cent solution are added slowly through the dropping tube and then 10-ml. portions every 15 to 20 minutes until the whole has been added.<sup>165</sup> Should the liquid become markedly green the bichromate must be added at correspondingly shorter intervals and in amount sufficient to maintain a slight red-yellow color of the chromic acid which may be detected even in the presence of the green. Continue the distillation with moderate boiling for from 2 to 3 hours. The distillate which should be collected in a liter flask to avoid transference is again distilled for about 20 minutes after adding 10 ml. of 10 per cent sodium hydroxide and 25 ml. of 3 per cent hydrogen peroxide. The flask must be heated cautiously until the peroxide has been decomposed. This final distillate is titrated with standard iodine and thiosulfate solutions in the usual manner and the result expressed as hydroxybutyric acid. One ml. of 0.1 N iodine solution is equivalent to 1.736 mg. of hydroxybutyric acid. About 10 per cent should be added to the results for  $\beta$ -hydroxybutyric acid as obtained by this method as the yield of acetone is only about 90 per cent of the theoretical. This error appears to be practically constant, so that satisfactory results may be obtained by correction.

**3. Method of Behre and Benedict, Modified by Behre:**<sup>166</sup> **Principle.** The acetone, preformed, from acetoacetic acid, and (after removal of interfering substances) from  $\beta$ -hydroxybutyric acid, is distilled from acid solution, and determined colorimetrically or photometrically by its reaction with salicylic aldehyde in alkaline solution. The colored product is dihydroxydibenzene acetone.

**Procedure.**<sup>167</sup>

**Determination of Acetone and Acetoacetic Acid, but Not  $\beta$ -Hydroxybutyric Acid.** To a 200- to 300-ml. distilling flask transfer a measured volume of urine (usually 15 to 30 ml.), and add 3 to 4 drops of 1:1 sulfuric acid. Add a few glass beads and connect immediately to a 200-mm. water-cooled con-

<sup>165</sup> From 0.5 g. to 1 g. of bichromate will usually be sufficient, and not more than 1 g. should be added unless the liquid turns green, indicating a great reduction to chromium sulfate. Very rarely 2 or 3 g. of bichromate may be necessary, especially if the sugar has not been completely removed.

<sup>166</sup> Behre and Benedict: *J. Biol. Chem.*, **70**, 487 (1926); Behre: *ibid.*, **136**, 25 (1940).

<sup>167</sup> Reagents Required: *Sulfuric Acid, 1:1*. Carefully pour 500 ml. concentrated sulfuric acid into 500 ml. water, with stirring. Cool, dilute to 1 liter, and mix.

*Salicylic Aldehyde*. Eastman's technical grade, or Eimer and Amend's "Acid Salicylous, Synthetic" are satisfactory.

*Saturated Potassium Hydroxide Solution*. Add an excess of solid reagent-grade potassium hydroxide to some water in a beaker. Stir to dissolve as completely as possible, allow to settle, and use the clear supernatant solution. The specific gravity should be 1.540.

*Aqueous Alcohol*. A 70 to 75 per cent solution of ethyl alcohol in water. Dilute 75 ml. 95 per cent ethyl alcohol to 100 ml. with water, and mix.

*Standard Acetone Solutions*. Dilute 5 ml. of freshly opened or well-kept c.p. acetone to 500 ml. with water, and mix. For approximate purposes, this may be assumed to produce a 0.78 to 0.79 per cent solution. For accurate work it should be standardized by iodimetric titration. Place 5 ml. acetone solution in a 250-ml. glass-stoppered flask, and add 25 ml. of normal sodium hydroxide solution, followed by 50 ml. (accurately measured) of 0.1 normal iodine solution. Add the iodine solution a little at a time, with mixing. Stopper and allow to stand 10 to 15 minutes. Add 25 to 30 ml. of normal sulfuric acid (there must

denser fitted with a delivery tube drawn out to a fine tip. An all-glass apparatus is preferred, the joints being lubricated with water; if this is not available, connections may be made with well-fitting cork (not rubber) stoppers. As receiver for the distillate, use a 15-ml. graduated centrifuge tube, so arranged that the enlarged portion of the delivery tube rests on the rim of the centrifuge tube, acting as a cover for it, and the fine tip of the delivery tube reaches just to the bottom of the receiver. Place a minimal amount of water in the receiver, to cover the tip outlet. Apply heat with a microburner to the contents of the distilling flask, slowly at first to prevent excessive bubbling in the receiver, and distil over a volume of distillate equal to one-third or more of the original volume. Remove the receiver, rinsing off the tip of the delivery tube with a little water in the process, measure the total volume in the receiver, or dilute with water to a definite volume, and mix by inversion.

For color development, transfer 0.1 ml. of salicylic aldehyde to a test tube graduated at 5 and 10 ml. Add 2 ml. of distillate, followed by 1.5 ml. of saturated potassium hydroxide solution from a buret with a fine glass tip. Mix the contents of the tube by several churning motions with a footed glass rod, leave the rod in the tube, and allow to stand 20 minutes at room temperature. Finally add either (A) water to the 10-ml. mark, or (B) aqueous alcohol to the 5-ml. mark, rinsing and removing the rod in the process. Mix by tapping or inversion. Choice between procedures A and B will depend largely upon the amount of acetone present; A gives less color than B, and is for larger amounts of acetone. This choice can usually be estimated roughly by inspection during the period of color development. For many purposes one procedure can be used consistently; both are described to permit the accurate covering of a wide range of acetone concentration.

For colorimetric measurement, compare the unknown in the colorimeter against a suitable standard acetone solution treated in the same way and at the same time as for the unknown.<sup>168</sup> For the preparation and choice of standards, see under "Calculation." For photometric measurement, determine the density in a photometer at 520  $m\mu$ , within 15 minutes after dilution by procedure A or 30 minutes after dilution by procedure B. Set the photometer to zero density with a blank prepared by treating 2 ml. of water by the same procedure as was used for the unknown.

**Determination of  $\beta$ -Hydroxybutyric Acid.** Glucose and other interfering substances are removed by the treatment with calcium hydroxide and copper sulfate as in the Van Slyke procedure, p. 930. All volumes may be reduced proportionately if advisable. If the urine is dilute, its volume may be increased in relation to the volume of the final mixture, twice the amount of copper sulfate (in 40 per cent solution) and calcium hydroxide being used. After standing for 30 to 45 minutes, the mixture is filtered, or centrifuged and

---

be an excess over the alkali present, to liberate all the iodine) and titrate the excess iodine with 0.1 normal sodium thiosulfate solution, using starch as indicator. Subtract the buret reading from 50, to obtain the ml. of iodine used up. One ml. 0.1 normal iodine is equivalent to 0.9675 mg. acetone.

From the standardized acetone solution, prepare by dilution a solution containing 1 mg. of acetone per ml. This *stock standard* will keep for about 1 month. Freshly prepared *dilute standards* containing 0.1, 1.0, and 5.0 mg. per cent are made from the stock standard by diluting 0.1 ml., 1.0 ml., and 5.0 ml. respectively to 100 ml. with water and mixing. Other concentrations (for preparing a photometric calibration curve) may be made similarly.

**Potassium Bichromate, 0.2 Per Cent.** Dissolve 2 g. reagent-grade potassium bichromate in water and dilute to 1 liter.

<sup>168</sup> Behre (*loc. cit.*) describes the preparation of "artificial standards" suitable for approximate clinical purposes.

filtered. Transfer an aliquot of the filtrate (the amount depending upon the  $\beta$ -hydroxybutyric acid content of the urine) to a distilling flask similar to that used for the acetone determination, but in addition fitted with a dropping funnel. Make up the volume in the flask to not less than 30 ml. by adding water if necessary, and acidify with three to four drops of 1:1 sulfuric acid. Distill off one-third or more of the original volume as described for the acetone determination, to get rid of preformed acetone and acetoacetic acid. Discard the distillate; it cannot be used for simultaneous acetone determination since some acetone is lost by the treatment with calcium hydroxide and copper sulfate. Place a 200-ml. round-bottomed flask in position as receiver for the distillate, closed and containing sufficient water to cover the tip of the delivery tube as described under "Determination of Acetone," above. Bring the residual solution in the flask (volume of approximately 20 to 60 ml.) to a boil, and add through the dropping funnel 15 ml. of 1:1 sulfuric acid and 10 ml. of 0.2 per cent potassium bichromate solution, by drops, during the first five minutes of distillation, followed by 25 ml. of bichromate during each of the next two five-minute periods. Regulate the rate of distillation so that 50 to 85 ml. of distillate are obtained in 15 minutes.

Measure the volume of distillate, or dilute to a known volume with water and mix, and determine the acetone content of a 2-ml. portion as described above.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times S \times \frac{\text{Distillate Vol.}}{2} \times \frac{100}{\text{Urine Vol.}} = \frac{\text{mg. acetone per}}{100 \text{ ml. urine}}$$

where  $S$  is the acetone content of the standard, in mg., and the volumes of distillate, and urine whose acetone is contained in the distillate, are measured in ml. The standard should have an acetone content approximating that of the distillate. If this is not known, or will vary widely from one unknown to another, a series of five standards may be prepared which will permit the accurate estimation of any concentration of acetone in the distillate from 0.05 to 200 mg. per cent (0.001 to 4.0 mg. per 2 ml.). First prepare dilute standard acetone solutions containing 0.1, 1.0, and 5.0 mg. per cent acetone, by dilution of the stock standard. Set up five test tubes, each containing 0.1 ml. of salicylic aldehyde. Add to each the amount of a particular standard as indicated in the table, followed by 1.5 ml. of potassium hydroxide solution and subsequent treatment for color development exactly as described for the analysis of an unknown. Dilute each standard after color development to the volume and with the solvent indicated in the table. The  $S$  value for each standard, to be used in the calculation, is given in the last column of the table.

| <i>Standard</i>                                      | <i>Final Volume<br/>After Color<br/>Development,<br/>and Solvent</i> | <i>S</i> |
|------------------------------------------------------|----------------------------------------------------------------------|----------|
| 1—1 ml. 0.1 mg. per cent acetone, + 1 ml. water..... | 5 ml., alcohol                                                       | 0.001    |
| 2—2 ml. 0.1 mg. per cent acetone.....                | 5 ml., alcohol                                                       | 0.002    |
| 3—2 ml. 1 mg. per cent acetone.....                  | 10 ml., alcohol                                                      | 0.010    |
| 4—2 ml. 1 mg. per cent acetone.....                  | 10 ml., water                                                        | 0.020    |
| 5—2 ml. 5 mg. per cent acetone.....                  | 10 ml., water                                                        | 0.100    |

Read the unknown against the nearest standard in the same solvent. If the unknown is known to come within the range of any one standard, naturally only that standard

need be prepared. If the color of the unknown in the alcohol solvent is more than twice that of Standard 3, or in the water solvent more than twice that of Standard 5, it may be diluted with the same solvent until approximate color match with a standard is obtained, and then read. Results in this event must be multiplied by the dilution. Dilution up to 200-ml. final volume is permissible.

For photometric measurement, the acetone content in the 2 ml. of distillate taken for analysis is established by reference to a calibration curve prepared previously from standard acetone solutions. The calculation is then:

$$\frac{\text{Mg. acetone in}}{2 \text{ ml. distillate}} \times \frac{\text{Distillate Vol.}}{2} \times \frac{100}{\text{Urine Vol.}} = \frac{\text{mg. acetone per}}{100 \text{ ml. urine}}$$

To prepare a calibration curve for procedure A (water solvent, 10 ml. volume), 2-ml. portions of standard acetone solutions containing from 0.0 to 0.16 mg. of acetone give a satisfactory curve relating density and concentration, at 520  $m\mu$  and 1 cm. solution depth (or its equivalent). For procedure B (alcohol solvent, 5 ml. volume) the corresponding range is 0.0 to 0.03 mg. of acetone. If the unknown is beyond the range of the curve, repeat the analysis using a smaller aliquot of distillate (or diluted distillate) made up to 2 ml. with water, and correct the calculations accordingly. In using a calibration curve for photometric measurement, the experimental conditions during an analysis (time of standing before and after dilution, temperature, etc.) should be uniform and should reproduce as far as possible those used when the curve was constructed. For accurate results the curve should be checked at intervals, particularly if new reagents are prepared, and reestablished if necessary.

Results obtained by the procedure in which  $\beta$ -hydroxybutyric acid is *not* determined (Determination of Acetone and Acetoacetic Acid) represent the preformed acetone present, as well as acetone equivalent to the acetoacetic acid present, which is decomposed into acetone during the analysis. In the  $\beta$ -hydroxybutyric acid analysis, results represent the *acetone equivalent* of the  $\beta$ -hydroxybutyric acid present. For factors used to obtain the content of  $\beta$ -hydroxybutyric acid itself, see previous methods.

## INDICAN

**Methods.** Indican (indoxylsulfuric acid) is usually determined by oxidation and condensation to form indigo or similar substances, followed by extraction with chloroform or other suitable solvents, and colorimetric or photometric estimation in terms of a standard. Earlier methods employed a standard solution of indigo. This type of standard has been criticized by Meiklejohn and Cohen,<sup>169</sup> who state that the final color intensity obtained from urine may be deeper than that corresponding to a saturated solution of pure indigo, in the same solvent. These authors describe a photometric modification of the method of Sharlit,<sup>170</sup> which appears to give satisfactory results, and which is based upon calibration of the photometer with standard indican solutions. In Sharlit's procedure, developed for visual colorimetry, standard indican solutions may also be used, but the author likewise describes an artificial standard containing cobalt sulfate, whose indican equivalence is defined. Kumon<sup>171</sup> has described a procedure claimed to be quite specific, based upon the

<sup>169</sup> Meiklejohn and Cohen: *J. Lab. Clin. Med.*, **27**, 949 (1941-1942). See also Townsend: *ibid.*, **23**, 809 (1937-1938).

<sup>170</sup> Sharlit: *J. Biol. Chem.*, **99**, 537 (1932).

<sup>171</sup> Kumon: *Z. physiol. Chem.*, **231**, 205 (1935).

color reaction between indican and ninhydrin. It is not felt practical to describe any of these procedures here, because of the difficulty of obtaining pure indican for standardization purposes.<sup>172</sup> The reader is referred to the original papers for details.

**Interpretation.** The daily excretion of indican ranges from 10 to 20 mg. per day in normal individuals.

Indican is apparently formed within the body from indole produced in the intestinal lumen by bacterial action; there is no good evidence that either indole or indican are intermediates in tryptophan metabolism by animal tissues. In normal individuals, variations in indican excretion appear to be dependent mainly upon the diet, a meat diet increasing excretion while a milk or carbohydrate diet decreases excretion. Pathologically the greatest increases are found in disorders involving increased putrefaction and stagnation of intestinal contents. Bacterial decomposition of body protein, as in gangrene, putrid pus formation, etc. gives rise to increases.

## PHENOLS

**Method of Volterra:**<sup>173</sup> **Principle.** The urine is distilled from slightly alkaline solution to obtain the free volatile phenols in the distillate. After acidification, a second distillate is obtained; this represents the conjugated volatile phenols present. Ether extraction of the remaining fluid separates the aromatic hydroxy acids from residual phenols. The significance of these various fractions is discussed under "Interpretation." Each fraction, after proper preparation, is treated with the phosphotungstic-phosphomolybdic acid color reagent of Folin and Ciocalteu and the resulting color compared with that obtained from a standard phenol solution.

### **Procedure.**<sup>174</sup>

(a) **FREE VOLATILE PHENOLS.** **Transfer 10 ml. of the well-mixed 24-hour sample of urine to a 250-ml. distilling flask fitted with a condenser. Add 150 to 175**

---

<sup>172</sup> For method of preparing indican from the urine of dogs fed indole, see Ellinger: *Z. physiol. Chem.*, **38**, 178 (1903).

<sup>173</sup> Volterra: *Am. J. Clin. Path.*, **12**, 525, 580 (1942).

<sup>174</sup> Reagents Required: *Silver Lactate Solution*. 3 per cent silver lactate in 3 per cent lactic acid.

*Colloidal Iron*. Fisher Scientific Company's "Dialyzed Iron, 5 Per Cent" is satisfactory.

*Acid Sodium Chloride Solution*. To 1 liter of a saturated solution of sodium chloride, add 10 ml. of concentrated hydrochloric acid.

*Phenol Reagent* (Folin and Ciocalteu: *J. Biol. Chem.*, **73**, 627 (1927)). Into a 1500-ml. Florence flask introduce 100 g. of sodium tungstate,  $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$ , 25 g. of sodium molybdate,  $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ , 700 ml. of water, 50 ml. of 85 per cent phosphoric acid, and 100 ml. of concentrated hydrochloric acid, and reflux gently for 10 hours. Add 150 g. of lithium sulfate, 50 ml. of water, and a few drops of bromine. Boil the mixture for 15 minutes without condenser, to remove excess bromine. Cool, dilute to 1 liter, and filter. The reagent should have no greenish tint. Protect from dust. Dilute a portion with an equal volume of water before use.

*Standard Phenol Solution*. Prepare and standardize a stock solution of phenol, containing 1 mg. of phenol per ml., as follows: Dissolve a little over 1 g. of crystallized phenol in a liter of 0.1 N hydrochloric acid. Transfer 25 ml. of this solution to a 250-ml. flask, add 50 ml. of 0.1 N sodium hydroxide, heat to 65° C., add 25 ml. of 0.1 N iodine solution, stopper the flask, and let stand at room temperature for 30 or 40 minutes. Add 5 ml. of concentrated hydrochloric acid and titrate the excess of iodine with 0.1 N thiosulfate solution. Each ml. of 0.1 N iodine solution used up corresponds to 1.567 mg. of phenol. On the basis of the result, dilute the remainder of the phenol solution with 0.1 N acid to give a solution containing 1 mg. of phenol per ml. This stock solution is quite stable. For a

ml. of water, followed by sufficient sodium bicarbonate solution to render the solution alkaline to litmus. Distil, collecting the distillate until 30 to 40 ml. have been obtained. Stop the distillation and measure the volume of distillate. Use a 10-ml. portion for the color reaction, as described below.

(b) CONJUGATED VOLATILE PHENOLS. When the contents of the distilling flask have cooled somewhat, add sufficient dilute sulfuric acid to render distinctly acid to Congo red, and start the distillation again. Collect 100 to 120 ml. of distillate, then test for completeness of distillation by collecting a separate 5-ml. portion of distillate and treat this by the phenol color reaction described below, using proportionately reduced amounts of reagents. If an evident color reaction is obtained in this test sample, add 50 to 100 ml. of water to the distilling flask and continue distillation until volatile phenols no longer distill over. Only in exceptional cases must more than about 150 ml. of distillate be obtained. Measure the volume of distillate, mix, and use a 10-ml. portion for the color reaction.

(c) TOTAL AROMATIC HYDROXY ACIDS. Transfer the acid solution in the distilling flask to a 250-ml. separatory funnel, using water for rinsing and dilution to about 100 ml., and shake for 3 minutes with 30 to 40 ml. of petroleum ether. Draw off the aqueous layer into a second separatory funnel (discard the petroleum ether layer) and shake twice with 30-ml. portions of ordinary ether, removing and combining the ether extracts, and saving the residual aqueous fluid. Wash the combined ether extracts by shaking with water, draw off the water, transfer the ether extract to an evaporating dish, and evaporate off the ether on a steam bath. Just before evaporation is complete, add about 5 ml. of water, and then complete the removal of the ether. Transfer the aqueous fluid remaining to a graduated cylinder and make up with rinsings to 10 ml. Mix, dilute 1 ml. to 10 ml. with water, and use this diluted portion for color development.

(d) RESIDUAL PHENOLS. Dilute the residue from the ether extraction to 200 ml. with water. To a 10-ml. portion, add 1.0 to 1.5 ml. of silver lactate solution, and one to two drops of colloidal iron. Shake, dilute to 20 ml. with water, allow to stand 15 minutes, and filter. To 10 ml. of filtrate add 1.0 to 1.5 ml. of acid sodium chloride solution, dilute to 20 ml. with water, mix, and filter. Use 10 ml. of filtrate for the color reaction.

**Color Reaction.** To 10 ml. of unknown in a test tube, add 0.5 ml. of diluted phenol reagent, followed by 2 ml. of 20 per cent sodium carbonate solution. Mix by shaking, and after 20 to 30 seconds place the tube in a boiling water bath for exactly 1 minute. Remove and cool in running cold water. Compare the color with that obtained by treating 10 ml. of standard phenol solution (containing 0.03 mg. of phenol) by the same procedure, at the same time.

#### CALCULATIONS.

*Volatile Phenols (Free or Conjugated):*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. phenol in Standard}}{\text{mg. phenol in Standard}} \times \frac{\text{ml. distillate}}{10} = \frac{\text{mg. phenol in 10 ml. urine}}{\text{mg. phenol in 10 ml. urine}}$$

Results on the distillate from (a) give the free volatile phenol content and from (b) the conjugated volatile phenols (both expressed as phenol). From the volume of the urine, the total output per 24 hours can be calculated.

---

working standard, dilute 0.3 ml. of the stock standard to 100 ml. with water and mix. This solution contains 0.03 mg. of phenol in 10 ml., and is made up fresh at the time of using.

*Aromatic Hydroxy Acids:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. phenol}}{\text{in Standard}} \times 10 = \frac{\text{mg. aromatic hydroxy acids}}{\text{(as phenol) in ml. urine used}}$$

Multiply results by 1.5 to express in terms of *p*-hydroxyphenylacetic acid instead of phenol. It may be necessary to dilute the 10-ml. aqueous solution of ether-soluble material, of which 1 ml. is used for analysis, to a greater volume to get color match with the standard, in which case the value 10 in the formula is replaced by the volume after dilution.

*Residual Phenols:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times \frac{\text{mg. phenol}}{\text{in Standard}} \times 80 = \frac{\text{mg. residual phenols (as phenol) in ml. urine used}}$$

**Interpretation.** Results on normal and pathological urine by this method indicate that free volatile phenols (phenol, *p*-cresol, etc.) are ordinarily present only in traces, if at all, and these findings are in agreement with the results of others (Deichmann and Shafer,<sup>175</sup> Schmidt<sup>176</sup>) using different methods. Conjugated phenols range in amount from 20 to 70 mg. per day normally, and do not appear to be significantly altered in amount by diet or fasting, at least in short experiments. Pathologically, increases in conjugated phenols have been noted in conditions associated with extensive tissue destruction and in intestinal obstruction. Ingestion of phenol or benzene likewise leads to increases. Aromatic hydroxy acids (*p*-hydroxyphenylacetic acid, *p*-hydroxyphenylpropionic acid, *p*-hydroxybenzoic acid, *p*-hydroxyphenyllactic acid, and possibly *p*-hydroxyphenylpyruvic acid) are excreted normally in amounts ranging from 50 to 90 mg. (as *p*-hydroxyphenylacetic acid) per day. Pathological variations have not been extensively studied. According to Schmidt (*loc. cit.*), about two-thirds of the total aromatic hydroxy acid excretion is normally in the free form and one-third in the conjugated form. The significance of the "residual phenol" analysis is obscure. Values ranging from 150 to 500 mg. per day are found normally, but it is generally recognized that many nonphenolic substances, such as imidazoles, etc., are included in this fraction, rendering interpretation difficult. Values for residual phenols as obtained by the method described here correspond roughly to the total phenol values of the admittedly nonspecific method of Folin and Denis.<sup>177</sup>

**SULFONAMIDES (SULFA DRUGS)**

**Method of Bratton and Marshall:**<sup>178</sup> **Principle.** The principle is the same as that applied to the determination of sulfonamides in blood (p. 657). The protein-free urine is treated with nitrous acid to diazotize any free sulfonamide present, excess nitrous acid is destroyed, and the diazotized sulfonamide is coupled with N-(1-naphthyl)-ethylenediamine to form a stable red color which is then compared with a standard treated in the same way. Total sulfonamide is determined after hydrolysis with acid. The difference between free and total sulfonamide represents acetylated sulfonamide.

<sup>175</sup> Deichmann and Shafer: *Am. J. Clin. Path.*, **12**, 129 (1942).

<sup>176</sup> Schmidt: *J. Biol. Chem.*, **145**, 533 (1942).

<sup>177</sup> Folin and Denis: *J. Biol. Chem.*, **22**, 205 (1915).

<sup>178</sup> Bratton and Marshall: *J. Biol. Chem.*, **128**, 537 (1939).

**Procedure.**<sup>179</sup> Transfer 1 ml. of urine to a 25-ml. volumetric flask and dilute to the mark with water. Mix, and place 2 ml. of the diluted urine in a small flask. From a buret add 30 ml. of water, followed by 8 ml. of 15 per cent trichloroacetic acid. Mix and filter.

**Free Sulfonamide.** Transfer a 10-ml. portion of the trichloroacetic acid filtrate to a small flask or wide test tube, and treat with nitrite, sulfamate, etc., exactly as described for a blood filtrate (p. 658).

**Total Sulfonamide.** Transfer a 10-ml. portion of filtrate to a test tube or other container graduated at 10 ml., and add 0.5 ml. of 4 N hydrochloric acid. Place in a boiling water bath for 1 hour, cool, and make up to 10 ml. with water. Continue with treatment with nitrite, sulfamate, etc., as for free sulfonamide.

Compare the final color obtained against a suitable standard as described for blood analysis, the same standards being satisfactory. If the urine is unusually low or high in sulfonamide content, the determination is repeated on a more satisfactory dilution of the sample. In every case, however, the final 10-ml. portion analyzed should contain 3 per cent trichloroacetic acid. The calculation is the same as for blood analysis, except that the dilution of the urine (i.e., in the present instance the dilution is 500) replaces the value 20 in the blood calculations. Either a colorimeter or a photometer may be used, as with blood.

The procedure as described provides for urine containing protein as well as protein-free urine. If the urine is known to be free from protein, the treatment with trichloroacetic acid may be omitted. The urine is diluted so as to contain from 1 to 2 mg. per cent of sulfonamide, and then 50 ml. of this diluted urine, plus 5 ml. of 4 N hydrochloric acid are diluted to 100 ml. with water. Free sulfonamide is determined on a 10-ml. portion of this final dilution as with a blood filtrate. Total sulfonamide is determined on a 10-ml. portion, heated without further addition of acid, made up to volume, and the analysis continued as above.

**Interpretation.** As with blood, the sulfonamide content of urine may vary between wide limits. The procedure as described is satisfactory for urines containing from 50 to 500 mg. per cent. If smaller or larger amounts than this are present, other suitable dilutions must be made.

Sulfonamides found in the urine may be either in the form of the free drug, its acetylated derivative,<sup>180</sup> or oxidized forms possibly combined with glucuronic acid.<sup>181</sup> Only the acetylated derivative does not respond to the colorimetric procedure; the difference between free and total sulfonamide therefore represents acetylated sulfonamide. The proportion of free drug to its various derivatives depends upon a number of factors, of which the nature of the sulfonamide itself is perhaps most important; sulfanilamide is relatively little acetylated as compared to sulfadiazine, for example. Clinically, the sulfonamide content of the urine is of importance in at least two respects; these include the possible formation of

---

<sup>179</sup> The reagents required are the same as those described on p. 658 for the determination of sulfonamides in blood.

<sup>180</sup> Marshall, Bratton, and Litchfield: *Science*, **88**, 597 (1938).

<sup>181</sup> Scudi: *Science*, **91**, 486 (1940); also Scudi and Jelinek: *J. Pharmacol.*, **81**, 218 (1944).

urinary calculi by the insoluble and precipitated drug, and the possibility of renal damage and hematuria associated with the deposition of crystalline sulfonamide or acetylsulfonamide in the renal tubules. Studies on these two possible manifestations of sulfonamide excretion have shown that the various sulfonamides and their derivatives differ significantly in their solubility in urine and in their propensity to precipitate out, either in the renal tubules or in the urine itself; in general, the therapy consists of maintaining an alkaline urine, since the compounds responsible are more soluble at alkaline reaction. Thus far, only the free drug and its acetylated product appear to be involved here; other excretory forms of the sulfonamides, where they have been recognized, are quite soluble.

## UROBILINOGEN

**Method of Wallace and Diamond:**<sup>182</sup> **Principle.** A series of dilutions of urine is carried to the point where the red color resulting from the reaction between urobilinogen and Ehrlich's aldehyde reagent is just discernible. This method is regarded as more accurate than the spectroscopic method of Wilbur and Addis.<sup>183</sup> A more extended, and probably more accurate, method for the determination of urobilinogens in urine and feces is described by Watson *et al.*<sup>184</sup> It has been shown that both mesobilirubinogen and stercobilirubinogen give the Ehrlich aldehyde reaction. Interfering substances can be extracted with petroleum ether.

**Procedure.** One ml. of Ehrlich's aldehyde reagent<sup>185</sup> is added to 10 ml. of undiluted urine and allowed to stand 1 to 3 minutes. An idea as to the quantity of urobilinogen is gained by noting the rapidity and intensity of color development. Dilutions are not carried out if the color remains a light red (normal values). For higher concentrations, prepare a series of dilutions of the urine from 1:10 to 1:200, or higher, as indicated by the preliminary test. Tap water may be used, but should not be too cold. Add 1 ml. of the reagent to each dilution and after 3 to 5 minutes note the highest dilution that shows a faint pink discoloration. Express the result in terms of this dilution. The test is best performed in daylight but in the absence of bright sunlight.

**Interpretation.** The appearance of the color in dilutions up to 1:20 may be regarded as normal. Constipation may produce a temporary rise in urobilinogen. This substance is believed to originate by reduction of the bile pigment. The latter may be extrahepatic as well as hepatic in origin (see p. 592). Excessive amounts of urobilinogen are, therefore, excreted in diseases of the liver and biliary tract, including toxemias of pregnancy, infectious diseases, and alcoholic intoxication, and in hemolytic diseases, including poisoning by lead, sulfonal, mushrooms, and hemolytic poisons in general.<sup>186</sup> It is claimed that urinary urobilinogen affords no accurate index to blood decomposition; according to Miller,

<sup>182</sup> Wallace and Diamond: *Arch. Internal Med.*, **35**, 698 (1925).

<sup>183</sup> Wilbur and Addis: *Arch. Internal Med.*, **13**, 235 (1914).

<sup>184</sup> Watson, Schwartz, Sborov, and Bertie: *Am. J. Clin. Path.*, **14**, 605 (1944); Watson and Hawkinson: *ibid.*, **17**, 108 (1947).

<sup>185</sup> See Appendix.

<sup>186</sup> Sulfonamides in the urine will interfere since they likewise react with Ehrlich's aldehyde reagent. If they are present, acidify the urine and shake with petroleum ether. Shake the petroleum ether extract with aqueous alkali and carry out the test on the final neutralized aqueous extract.

Singer, and Dameshek,<sup>187</sup> however, the fecal output of urobilinogen is of value in this connection.

## OXALIC ACID

Earlier methods for the determination of oxalic acid in urine were based on the precipitation of calcium oxalate from a large volume of urine. Difficulties in obtaining satisfactory checks were attributed to the effect of magnesium, phosphate, and sulfate ions upon the solubility and rate of crystallization of calcium oxalate. The following procedure is directed toward correcting the deficiencies in the older methods.

**Total Oxalic Acid (Method of Powers and Levatin<sup>188</sup>): Principle.** The urine is acid-hydrolyzed (to decompose any oxaluric acid) and the oxalic acid separated from interfering ions by extraction with ether. The extract is precipitated as calcium oxalate and dissolved in acid permanganate solution and back-titrated with thiosulfate.

**Procedure.** An all-glass continuous liquid-liquid extraction apparatus is used, as shown in Fig. 256. This consists of a 25 ml. test tube in which is

placed a funnel-shaped tube made from half a 25 ml. pipet having an over-all length of about 200 mm. The stem end is sealed and 4 holes punched through the sealed end with hot wire. The tube is suspended to an outer tube (25 × 300 mm.) by means of a nichrome wire around its lip or through a small hole near the top of the inner tube. This also serves to separate the cold-finger condenser slightly thus providing a vent.

Of the well-mixed 24-hr. urine sample (preserved if necessary with a few ml. of formaldehyde), transfer 25 ml. to a volumetric flask, add 1 ml. concentrated hydrochloric acid, mix by inversion and heat by immersion in boiling water for 30 minutes. Cool and filter.

Into the outside tube of the extraction apparatus place several glass beads, 2 ml. of water and 25 ml. of ether. Introduce 10 ml. of the acid-hydrolyzed urine filtrate into the inside tube and assemble the apparatus as shown in Fig. 256. Extraction may be carried out on an electric hot plate covered with an asbestos sheet in which a 1.5-cm. hole is cut, the walls of the extractor being thus protected from overheating and loss of ether. During

the extraction a good flow of cold water must be passed through the condenser and the heating regulated so that the ether drips at the rate of about

FIG. 256. ALL-GLASS CONTINUOUS LIQUID-LIQUID EXTRACTION APPARATUS.

Courtesy, Powers and Levatin.

<sup>187</sup> Miller, Singer, and Dameshek: *Arch. Internal Med.*, 70, 722 (1942).

<sup>188</sup> Powers and Levatin: *J. Biol. Chem.*, 154, 207 (1944).

100 drops per minute. If necessary, add a little more ether. (*Warning*—avoid getting ether vapors near hot plate!) Extract for 6 hours.

Disconnect the apparatus. Lift the inside tube, rinsing it down with 2 ml. of ethanol from a pipet before removing. Add 1 ml. of 2 per cent acetic acid to the contents of the outside tube, shake by twirling to mix the water and ether layers (the presence of water is necessary to avoid oxalic acid loss on evaporation to dryness) and drive off the ether by immersion in a water bath at 70° C. while continuously shaking.

Transfer the aqueous residue into a 15-ml. centrifuge tube by means of an aspirating device (see Fig. 183, p. 695). The tip of the centrifuge tube should be drawn out slightly to an inside diameter of 1 mm. so as to facilitate the handling of the small precipitate. Rinse down the walls of the outside tube with two 2-ml. portions of ethanol, transferring each rinsing to the centrifuge tube.

Add 5 ml. of 10 per cent calcium chloride to the contents of the centrifuge tube and stir with a gentle current of air introduced through a fine capillary tube. Overlay with 2 ml. of acid-ethanol solution (60 ml. ethanol, 10 ml. 2 per cent acetic acid, 20 ml. water) which prevents surface accumulation of the oxalate precipitate. Let stand overnight. Centrifuge at 2,000 r.p.m. for 30 minutes, decant, and invert on filter paper to drain. Rinse down the wall of the centrifuge tube with 2 ml. of acid-ethanol solution and thoroughly break up the precipitate with a fine glass rod. Remove the rod after rinsing it with 3 ml. of acid-ethanol solution. Centrifuge, decant, and drain as above. Drive off residual alcohol by heating in an oven or boiling water bath for a few minutes.

Add 1 ml. of 20 per cent sulfuric acid and 0.5 ml. of 1 per cent manganese sulfate. Break up the precipitate with a fine glass rod which is rinsed with a few drops of water before removal. Add exactly 3 ml. 0.01 N potassium permanganate. Stir with air current and let stand 8–10 minutes. Add 0.5 ml. of 10 per cent potassium iodide, mix by twirling, and follow with 4 drops of soluble starch solution (see Appendix) and 2 drops of a saturated solution of barium hydroxide. (The barium sulfate precipitate facilitates visualization of the end point of the titration.) Titrate the excess permanganate with 0.01 N sodium thiosulfate from a 5 ml. microburet. Read to nearest 0.01 ml.

A titration reagent blank should be run in parallel. For this purpose distilled water may be used in place of the oxalate solution.

#### CALCULATION.

In the following equation  $t$  is the ml. of 0.01 N thiosulfate used in the back titration,  $b$  is the ml. used in the reagent blank.

$$0.45(3 - t - b) \times \frac{26}{25} \times \frac{24\text{-hour volume}}{25} = \text{mg. total oxalic acid}^{189} \text{ in 24-hour urine}$$

**Interpretation.** From 15 to 50 mg. of oxalic acid is excreted by a normal adult on an ordinary mixed diet. It arises from oxalates of the food ingested and from fat and protein metabolism. It is increased by the ingestion of apples, grapes, cabbage, etc., although most of the ingested oxalate is destroyed. It is increased in disturbances of metabolism associated with decreased oxidation, according to certain observers. The term “oxaluria” has been largely a misnomer.

<sup>189</sup> Oxalic plus oxaluric acid. Even if preliminary acid hydrolysis were omitted, some of the oxaluric acid would be hydrolyzed at the temperature of the ether extraction.

SULFUR<sup>190</sup>

## GRAVIMETRIC PROCEDURES

**1. Total Sulfates (Folin's Method): Principle.** The sulfuric acid of the conjugated sulfates is set free by boiling with acid. The total sulfates are then precipitated with barium chloride.

**Procedure.** Place 25 ml. of urine in a 200- to 250-ml. Erlenmeyer flask, add 20 ml. of dilute hydrochloric acid<sup>191</sup> (1 volume of concentrated HCl to 4 volumes of water), and gently boil the mixture for 20 to 30 minutes. To minimize the loss of water by evaporation, the mouth of the flask should be covered with a small watch glass during the boiling process. Cool the flask for 2 to 3 minutes in running water, and dilute the contents to about 150 ml. by means of cold water. Add 10 ml. of a 5 per cent solution of barium chloride slowly, drop by drop, to the cold solution.<sup>192</sup> The contents of the flask should not be stirred or shaken during the addition of the barium chloride. Allow the mixture to stand at least 1 hour, then shake up the solution and filter it through a weighed Gooch crucible.<sup>193</sup>

Wash the precipitate of BaSO<sub>4</sub> with about 250 ml. of cold water, dry it in an air bath or over a very low flame, then ignite,<sup>194</sup> cool, and weigh.

**CALCULATION.** Subtract the weight of the Gooch crucible from the weight of the crucible and the BaSO<sub>4</sub> precipitate to obtain the weight of the precipitate. The weight of S in the volume of urine taken may be determined by means of the following proportion:

$$\text{Mol. wt. BaSO}_4 : \text{g. BaSO}_4 = \text{Mol. wt. S} : x(\text{g. S})$$

Representing the weight of the BaSO<sub>4</sub> precipitate by  $y$  and substituting the proper molecular weights, we have the following proportion:

$$233.43 : y = 32.06 : x(\text{g. S in the quantity of urine used})$$

Calculate the quantity of S in the 24-hour specimen of urine.

**Interpretation.** The total sulfate excretion (ethereal and inorganic sulfates) by a normal adult on a mixed diet is usually between 0.6 and

<sup>190</sup> Under this heading are described gravimetric and volumetric methods for sulfur in urine. A colorimetric procedure for inorganic sulfate has been described by Kahn and Leiboff: *J. Biol. Chem.*, **80**, 623 (1928). For turbidimetric methods, see Medes and Stavers: *J. Lab. Clin. Med.*, **25**, 624 (1939-1940); Treon and Crutchfield: *Ind. Eng. Chem., Anal. Ed.*, **14**, 119 (1942).

<sup>191</sup> If it is desired, 50 ml. of urine and 4 ml. of concentrated acid may be used instead.

<sup>192</sup> A dropper or capillary funnel made from an ordinary calcium chloride tube and so constructed as to deliver 10 ml. in 2 to 3 minutes is recommended for use in adding the barium chloride.

<sup>193</sup> If a Gooch crucible is not available, the precipitate of BaSO<sub>4</sub> may be filtered off upon a washed filter paper (Schleicher and Schüll's, No. 589, blue ribbon), and after washing the precipitate with about 250 ml. of cold water the paper and precipitate may be dried in an air bath or over a low flame. The ignition may then be carried out in the usual way in the ordinary platinum or porcelain crucible. In this case correction must be made for the weight of the ash of the filter paper used.

<sup>194</sup> Care must be taken in the ignition of precipitates in Gooch crucibles. The flame should never be applied directly to the perforated bottom or to the sides of the crucible, since such manipulation is invariably attended by mechanical losses. The crucibles should always be provided with lids and tight bottoms during the ignition. In case porcelain Gooch crucibles, whose bottoms are not provided with a nonperforated cap, are used, the crucible may be placed upon the lid of an ordinary platinum crucible during ignition. The lid should be supported on a triangle, the crucible placed upon the lid, and the flame applied to the improvised bottom. Ignition should be complete in 10 minutes if no organic matter is present.

2 g. S with an average of about 1.0 g. The sulfuric acid is derived but to a slight extent ordinarily from ingested sulfates, being mainly dependent on the sulfur of the protein metabolized, and will consequently vary widely with the level of protein metabolism. From 75 to 95 per cent of the total sulfur of the urine is ordinarily found as sulfate, the proportion being greatest on a high-protein diet. The sulfate excretion is increased in all conditions associated with increased decomposition of body protein as in acute fevers and decreased whenever there is a decrease in metabolic activity.

**2. Inorganic Sulfates (Folin's Method):** Place 25 ml. of urine and 100 ml. of water in a 200- to 250-ml. Erlenmeyer flask and acidify the diluted urine with 10 ml. of dilute hydrochloric acid (1 volume of concentrated HCl to 4 volumes of water). In case the urine is dilute, 50 ml. may be used instead of 25 ml. and the volume of water reduced proportionately. Add 10 ml. of 5 per cent barium chloride slowly, drop by drop, to the cold solution, and from this point proceed as indicated in the method under "Total Sulfates," above.

Calculate the quantity of inorganic sulfates, expressed as S, in the 24-hour urine specimen.

CALCULATION. Follow the directions given under Total Sulfates, above.

**Interpretation.** On an average, about 90 per cent of the total sulfates of the urine exists as inorganic sulfates, but the proportion of the sulfates existing in this form varies widely, being greater on a high protein diet than on a very low protein diet. The amount varies with the total sulfates (see above).

**3. Ethereal Sulfates (Folin's Method): Principle.** The inorganic sulfates are removed with barium chloride and the conjugated sulfates then determined after hydrolysis.

**Procedure.** Place 125 ml. of urine in an Erlenmeyer flask of suitable size, dilute it with 75 ml. of water, and acidify the mixture with 30 ml. of dilute hydrochloric acid (1 volume of concentrated HCl to 4 volumes of water). To the cold solution add 20 ml. of a 5 per cent solution of barium chloride, drop by drop.<sup>195</sup> Allow the mixture to stand about one hour, then filter it through a dry filter paper.<sup>196</sup> Collect 125 ml. of the filtrate and boil it gently for at least one-half hour. Cool the solution, filter off the precipitate of  $\text{BaSO}_4$ , wash, dry and ignite it according to the directions given on p. 946.

CALCULATION. The weight of the  $\text{BaSO}_4$  precipitate should be multiplied by 2 since only one-half (125 ml.) of the total volume (250 ml.) of fluid was precipitated by the barium chloride. The remaining calculation should be made according to directions given under "Total Sulfates," above.

Calculate the quantity of ethereal sulfates, expressed as S, in the 24-hour urine specimen.

---

<sup>195</sup> See footnote 192, p. 946.

<sup>196</sup> This precipitate consists of the inorganic sulfates. If it is desired, this  $\text{BaSO}_4$  precipitate may be collected in a Gooch crucible or on an ordinary quantitative filter paper and a determination of inorganic sulfates made, using the same technique as that suggested above. In this way we are enabled to determine the inorganic and ethereal sulfates in the same sample of urine.

**Interpretation.** The excretion of ethereal sulfates (expressed as S) varies ordinarily from 0.04 to 0.1 g. per day comprising from 5 to 15 per cent of the total sulfur excretion. The absolute amount of ethereal sulfate increases with increase in the protein of the diet and particularly with increase of putrefactive processes in the intestine or elsewhere. The amount excreted cannot, however, be taken as an index of the extent of intestinal putrefaction.

**4. Total Sulfur<sup>197</sup> (Benedict's Method<sup>198</sup>): Principle.** The urine is evaporated and ignited with a solution of copper nitrate and potassium chlorate. Organic matter is thus destroyed and all unoxidized sulfur is oxidized to the sulfate form and can be readily precipitated with barium chloride in the usual manner. The method is very convenient and accurate.

**Procedure.** Ten ml. of urine is measured into a small (7 to 8 cm.) porcelain evaporating dish and 5 ml.<sup>199</sup> of Benedict's sulfur reagent<sup>200</sup> is added. The contents of the dish are evaporated over a free flame which is regulated to keep the solution just below the boiling point, so that there can be no loss through spattering. When dryness is reached the flame is raised slightly until the entire residue has blackened. The flame is then turned up in two stages to the full heat of the bunsen burner and the contents of the dish thus heated to redness for 10 minutes after the black residue (which first fuses) has become dry. This heating is to decompose the last traces of nitrate (and chlorate). The flame is then removed and the dish allowed to cool more or less completely. Ten to 20 ml. of dilute (1:4) hydrochloric acid are then added to the residue in the dish, which is then warmed gently until the contents have completely dissolved and a perfectly clear, sparkling solution is obtained. This dissolving of the residue requires scarcely 2 minutes. With the aid of a stirring rod the solution is washed into a small Erlenmeyer flask,<sup>201</sup> diluted with cold, distilled water to 100 to 150 ml., 10 ml. of 10 per cent barium chloride solution added drop by drop, and the solution allowed to stand for about an hour. It is then shaken up and filtered as usual through a weighed Gooch crucible. Controls should be run on the oxidizing mixture.

**CALCULATION.** Follow directions given under "Total Sulfates," p. 946. Calculate the quantity of sulfur, expressed as S, in the 24-hour urine specimen.

**Interpretation.** The total sulfur excretion averages about 1.0 g. per day, expressed as S. It runs more or less parallel with the decomposition

<sup>197</sup> For determination of total sulfur in other biological material, see the method of Stockholm and Koch (p. 643). See also Pollock and Partansky: *Ind. Eng. Chem., Anal. Ed.*, 6, 330 (1934).

<sup>198</sup> Benedict: *J. Biol. Chem.*, 6, 363 (1909).

<sup>199</sup> If the urine is concentrated, the quantity should be slightly increased.

<sup>200</sup> Crystallized copper nitrate, sulfur-free or of known sulfur content. . . . . 200 g.  
Sodium or potassium chlorate. . . . . 50 g.  
Distilled water to. . . . . 1000 ml.  
Denis suggested the use of the following solution:  
Copper nitrate. . . . . 25 g.  
Sodium chloride. . . . . 25 g.  
Ammonium nitrate. . . . . 10 g.  
Water to make. . . . . 100 ml.

The procedure is the same as above except that 25 ml. of urine and 5 ml. of reagent are taken.

<sup>201</sup> Sometimes the porcelain glaze cracks during heating, in which case the solution should be filtered into the flask.

of endogenous and exogenous protein and a definite ratio between the excretion of total N and total S might be expected; however, no constant value can be given. See "Total Sulfates, p. 946."

**5. Total Sulfur (Osborne-Folin Method<sup>202</sup>): Principle.** This method depends on the destruction of organic matter by means of sodium peroxide. It is employed particularly for the determination of sulfur in foods and feces. Benedict's procedure (see above) is simpler and fully as satisfactory for urine.

## VOLUMETRIC PROCEDURES

**6. Volumetric Determination of Ethereal and Inorganic Sulfates and Total Sulfur (Fiske's Modification of the Method of Rosenheim and Drummond): Principle.** The sulfates of the urine are precipitated by means of benzidine solution, the precipitate of benzidine sulfate being filtered off and the sulfuric acid of the compound titrated with 0.02 N NaOH, using phenolsulfonephthalein (phenol red) as an indicator. This is possible because the benzidine is a very weak base and its sulfate readily dissociates. It is necessary that excess of HCl be avoided in the precipitation process. For critical studies of this procedure, see Owen<sup>203</sup> and McKittrick and Schmidt.<sup>204</sup> Kahn and Lieboff<sup>205</sup> have described a colorimetric method for sulfate based on diazotization of the benzidine sulfate and coupling with phenol in alkaline solution.

### Procedure.

(a) REMOVAL OF PHOSPHATE. This step is necessary for the highest accuracy, especially where the proportion of phosphorus to sulfur may be high, as in half-hourly specimens of urine. For 24-hour specimens where the highest accuracy is not desired it may be omitted.

Transfer to a 100-ml. volumetric flask enough urine (usually 10 to 20 ml.) to contain about 10 to 20 mg. of sulfur as sulfate. Dilute to about 50 ml. with water. Add one drop of phenolphthalein solution and then concentrated ammonium hydroxide drop by drop to a faint pink color. Add 10 ml. of 5 per cent ammonium chloride and about 1.5 g. of finely powdered magnesium carbonate. Make to mark, stopper, mix thoroughly by shaking for 1 minute, and let stand for 30 minutes. Using a dry filter, filter into a dry flask. This filtrate is used for the three following determinations.

(b) INORGANIC SULFATE. Pipet 5 ml. of the filtrate into a large pyrex test tube with flaring lip. Add 2 drops of a 0.04 per cent alcoholic solution of bromophenol blue and 5 ml. of water. Add approximately N HCl until the last trace of blue disappears and the solution is yellow. Add 2 ml. of benzidine solution.<sup>206</sup> Let stand for 2 minutes. Add 4 ml. of 95 per cent acetone and let stand for 10 minutes. Prepare a thin mat of paper pulp in a filtration tube (see Fig. 257).<sup>207</sup> This mat should first be washed with water and then sucked dry. Filter off benzidine sulfate with very gentle suction. Wash down the

<sup>202</sup> Described in the eleventh and earlier editions of this book.

<sup>203</sup> Owen: *Biochem. J.*, **30**, 352 (1936).

<sup>204</sup> McKittrick and Schmidt: *Arch. Biochem.*, **6**, 411 (1945).

<sup>205</sup> Kahn and Lieboff: *J. Biol. Chem.*, **80**, 623 (1928).

<sup>206</sup> Made by shaking 4 g. of benzidine in about 150 ml. of water in a 250-ml. flask, adding 50 ml. of approximately N HCl, shaking until dissolved, and diluting to mark. Filter if necessary.

<sup>207</sup> Made from glass tubing of 15 mm. diameter shrunk at one end to leave an opening 3 mm. in diameter, cut to a length of 7 cm., and flanged at the cut end. A somewhat elongated tip is desirable.

sides of the test tube with 1 ml. of 95 per cent acetone, transferring to filtration tube. Wash twice more with 1 ml. and finally with 5 ml. of acetone. Add about 2 ml. of water and poke the mat with a wire out through the bottom of the tube into the pyrex test tube, rinsing the wire with a few drops of water. Add 2 to 4 drops of 0.05 per cent water solution of phenol red. Titrate with 0.02 N NaOH (prepared from 0.1 N NaOH by dilution) the solution being kept

FIG. 257. FILTRATION TUBE FOR SULFUR DETERMINATION (FISKE).<sup>196</sup>

hot. At the beginning of the titration the filter tube is kept suspended in the mouth of the test tube and the alkali run through the filter tube to dissolve adherent sulfate. Rinse the inner tube with 2 to 3 ml. of water, heat the solution to boiling so that the tube is further washed with condensed steam, and finally rinse the inner tube with a few ml. more of water and remove. Titrate to a definite pink color that remains after boiling.

**CALCULATION.** The sulfate titrates like free sulfuric acid. One ml. 0.02 N NaOH is equivalent to 0.32 mg. S. Multiply the buret reading by 0.32 to get mg. inorganic S in 5 ml. filtrate.

(c) **TOTAL SULFATE (INORGANIC AND ETHEREAL).** To 5 ml. of filtrate in a 100-ml. beaker add 1 ml. of approximately 3 N HCl. Heat on a water bath to dryness and for 10 minutes longer. Transfer to a pyrex tube with lip using five 2-ml. portions of water, add 2 ml. of benzidine solution, and proceed as in the method for inorganic sulfate. The calculation is the same.

(d) **ETHEREAL SULFATE.** Subtract inorganic from total sulfate. The difference is ethereal sulfate.

(e) **TOTAL SULFUR.** Transfer approximately 0.25 ml. of Benedict's sulfur reagent (see p. 948) and 5 ml. of filtrate to a small evaporating dish (6 cm.). Evaporate carefully to dryness on wire gauze or hot plate. Gradually increase heat, finally igniting at red heat for 2 minutes over free flame. Let cool for 5 minutes. Add 1 ml. of 3 N HCl and evaporate to dryness at low heat. The mixture will turn from green to brown. Transfer to a pyrex tube with a lip with the aid of five 2-ml. portions of water. Add 1 drop of N HCl and 2 ml. of benzidine solution. Complete the determination as in the methods above but in place of the first 1-ml. portion of acetone, in washing use 2 ml. of 50 per cent acetone. The calculation is the same as above.

(f) **NEUTRAL SULFUR.** Subtract from the total sulfur the total sulfate as determined above. The difference is neutral or unoxidized sulfur.

**Interpretation.** The neutral sulfur of the urine is made up of cystine and related substances, thiocyanate, oxyproteic acids, etc. It makes up ordinarily from 5 to 25 per cent of the total sulfur of the urine, or on the average 0.08 to 0.16 g. per day calculated as S. The absolute amount is fairly constant for a given individual through wide variations of protein intake, indicating that its origin is mainly endogenous, that is, that it arises principally from the decomposition of tissue protein. On this account the percentage of the total sulfur excretion existing in the neutral form may rise to 25 per cent on a very low protein diet and decrease to 5 per cent on a high-protein diet, the absolute amount remaining nearly constant. In fasting, percentages as high as 70 have been noted. In many disorders, as tuberculosis, cancer, cystinuria, etc., the amount may be relatively and in some cases absolutely increased, but no fixed relations have been determined for the various conditions.

## PHOSPHORUS

**1. Determination of Inorganic Phosphate (Method of Fiske and Subba-Row<sup>208</sup>): Principle.** Phosphate reacts with molybdic acid to form phosphomolybdic acid. On treatment with 1,2,4-aminonaphtholsulfonic acid, phosphomolybdic acid is selectively reduced<sup>209</sup> to produce a deep blue color ("molybdenum blue"), which is probably a mixture of lower oxides of molybdenum. This color is then compared in a colorimeter or photometer with that obtained from a suitable standard phosphate solution treated in the same way.

**Procedure.**<sup>211</sup> Measure into a 100-ml. volumetric flask enough urine<sup>212</sup> to contain between 0.2 and 0.8 mg. of inorganic phosphorus (usually 1 or 2 ml.). Add water to bring the total volume to about 70 ml., followed by 10 ml. of Molybdate I reagent. Mix by gently shaking and add 4 ml. of aminonaphtholsulfonic acid reagent. Again mix, dilute to the mark with water, mix several times by inversion, and allow to stand 5 minutes.

At the same time, transfer to a similar flask 5 ml. of standard phosphate solution, containing 0.4 mg. of phosphorus, 65 ml. of water, and the same reagents that were added to the urine sample, mixing as above. Dilute to the mark with water, mix well by inversion, and allow to stand 5 minutes. For photometric measurement, prepare a blank solution by treating 70 ml. of water in a 100-ml. flask with the same reagents that are used for the standard and unknown, dilute to the mark with water, and mix by inversion.

For colorimetric measurement, match the standard against itself at 20 mm. and compare the unknown against the standard. For photometric measurement, determine the density of the standard and of the unknown in a photometer at 660 to 720 m $\mu$ , setting the photometer to zero density with the blank.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 0.4 = \frac{\text{mg. inorganic phosphate (as P)}}{\text{in the volume of urine used}}$$

An unknown reading between 5 and 40 mm. is acceptable with the standard at 20 mm.; if the unknown reads outside this range, repeat the analysis on a smaller or larger volume of urine. Results are usually expressed in terms of grams (or mg.) of inorganic P per 24-hour volume of urine.

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 0.4 = \frac{\text{mg. inorganic phosphate (as P)}}{\text{in the volume of urine used}}$$

<sup>208</sup> Fiske and SubbaRow: *J. Biol. Chem.*, **66**, 375 (1925).

<sup>209</sup> Various other reducing agents have been proposed (see discussion on p. 630), of which stannous chloride has perhaps found most favor. A method using stannous chloride has been suggested.<sup>210</sup> Stannous chloride has the advantage of being more stable than aminonaphtholsulfonic acid solution, and of giving a more intense color, thus permitting the use of smaller volumes of urine. This latter appears to be of little value in urine analysis, and a disadvantage of stannous chloride is that the color produced changes in intensity on standing and may not obey Beer's law, thus requiring careful technical control, particularly in photometric measurement.

<sup>210</sup> Youngburg and Youngburg: *J. Lab. Clin. Med.*, **16**, 158 (1930).

<sup>211</sup> The reagents required, and the standard phosphate solution, are described on p. 631 in connection with the determination of blood inorganic phosphate.

<sup>212</sup> If albumin is present and the addition of molybdate produces a turbidity, treat the urine with 4 volumes of 10 per cent trichloroacetic acid, stopper, shake and filter, and repeat the determination using 2 to 10 ml. of filtrate. If very low in phosphate so that more than 10 ml. of filtrate must be used, follow the method for blood filtrates (see p. 631).

In a 1-cm. cuvette, and at 660  $m\mu$ , the density of the standard is approximately 0.500 (see Fig. 166, p. 632). Under these conditions, up to 0.8 mg. of phosphorus may be accurately determined. If larger amounts are present, or if a deeper cuvette is used, the determination is carried out on a smaller portion of urine (and standard, if necessary) and the calculations are corrected accordingly.

**Interpretation.** The excretion of phosphoric acid is extremely variable but on the average the total output for the 24 hours is about 1.1 g. expressed as P, mainly in the form of phosphates. The greater part of the phosphate excretion arises from the ingested food, either from the pre-formed phosphates or more especially from the organic combinations as phospho- and nucleoproteins. The excretion is consequently very largely dependent upon the phosphorus content of the diet. Some of the phosphoric acid results from the breakdown of the tissues of the body, and this endogenous phosphoric acid excretion is increased in conditions of increased metabolism as in fevers. The findings in pathological conditions have been somewhat contradictory due to lack of control of diet. The so-called "phosphaturias" nearly always represent decreased acidity and not increased phosphate content of the urine. Such conditions are, however, significant as indicating a possible tendency to the formation of phosphatic calculi.

**2. Total Phosphates (Uranium Acetate Method): Principle.** Standard uranium acetate is run into a measured quantity of urine until all of the phosphate has been precipitated as insoluble uranium phosphate. An excess of uranium is indicated by a reddish coloration with potassium ferrocyanide. This method is accurate and gives practically the total phosphorus of urine inasmuch as the latter exists generally almost entirely as phosphates.

**Procedure.** To 50 ml. of urine in a small beaker or Erlenmeyer flask add 5 ml. of a special sodium acetate solution<sup>213</sup> and heat the mixture to the boiling point. From a buret, run into the hot mixture, drop by drop, a standard solution of uranium acetate<sup>214</sup> until a precipitate ceases to form and a drop of the mixture when removed by means of a glass rod and brought into contact with a drop of a solution of potassium ferrocyanide<sup>215</sup> on a porcelain test tablet produces instantaneously a brownish-red coloration. Take the buret reading and calculate the P content of the urine under examination.

**CALCULATION.** Multiply the number of ml. of uranium acetate solution used by 0.002 to determine the number of grams of P in the 50 ml. of urine used. To express the

<sup>213</sup> The sodium acetate solution is prepared by dissolving 100 g. of sodium acetate in 800 ml. of distilled water, adding 100 ml. of 30 per cent acetic acid to the solution, and making the volume of the mixture up to 1 liter with water.

<sup>214</sup> *Uranium Acetate Solution.* Dissolve about 35.0 g. of uranium acetate in 1 liter of water with the aid of heat and 3 to 4 ml. of glacial acetic acid. Let stand a few days and filter. Standardize against a phosphate solution containing 0.002 g. of P per ml. For this purpose dissolve 13.480 g. of pure air-dry sodium ammonium phosphate ( $\text{NaNH}_4\text{HPO}_4 + 4\text{H}_2\text{O}$ ) in water to make a liter. To 20 ml. of this phosphate solution in a 200-ml. beaker add 30 ml. of water and 5 ml. of sodium acetate solution (see above) and titrate with the uranium solution to the correct end-reaction as indicated in the method above. If exactly 20 ml. of uranium solution are required 1 ml. of the solution is equivalent to 0.002 g. of P. If stronger than this, dilute accordingly and check again by titration.

<sup>215</sup> A 10 per cent solution of potassium ferrocyanide is satisfactory. Cochineal in 30 per cent alcohol may be used as an indicator. It is added directly to the urine after the uranium acetate titration produces no further precipitate. A green color is the end reaction. The use of cochineal is more convenient but rather less accurate than the procedure involving the use of the ferrocyanide.

result in percentage of P, multiply the value just obtained by 2, e.g., if 50 ml. of urine contained 0.074 g. P, it would be equivalent to 0.148 per cent.

**3. Total Phosphorus: Principle.** Although urine phosphorus exists almost entirely as inorganic phosphate and the determination as such is usually sufficient, a strictly total phosphorus determination requires the destruction of organic matter. This is brought about by heating with sulfuric acid and hydrogen peroxide. The determination is otherwise the same as for the colorimetric determination of inorganic phosphate.

**Procedure.** Place sufficient urine to contain between 0.2 and 0.8 mg. of total phosphorus (usually 1 to 2 ml.) in a large pyrex test tube (200 by 25 mm.), add 10 ml. of 5 N sulfuric acid (or 5 ml. of 10 N acid), and a quartz chip to prevent bumping. Heat over a microburner or on an electric hot plate until the water has been driven off and a dark brown fluid remains. Add 30 per cent hydrogen peroxide<sup>216</sup> by drops as necessary to complete oxidation of organic matter and leave a colorless solution, heating to boiling momentarily between drops. The hydrogen peroxide should be allowed to drop directly into the tube contents and not run down the sides of the tube. When oxidation is complete, cool slightly, add 2 to 3 ml. of water, and boil for two to three minutes to ensure hydrolysis of meta- or pyrophosphate. Cool, and transfer quantitatively with rinsings to a 100-ml. volumetric flask. Make up to about 70 ml. with water and add 10 ml. of a 2.5 per cent solution of ammonium molybdate in water. Mix and add 4 ml. of the aminonaphtholsulfonic acid reagent used for the determination of inorganic phosphate (p. 951). Dilute to 100 ml. with water and mix. The remaining procedure (including standard and calculations) is exactly as described for the determination of inorganic phosphate.

**4. Total Phosphorus (Neumann's Procedure): Principle.** The organic matter is destroyed by digestion with a mixture of sulfuric and nitric acids or some other oxidizing agent. The phosphorus is then precipitated as the phosphomolybdate and determined gravimetrically or volumetrically.

**Preparation of the Solution.** Pipet 10 ml. of urine (or an amount of substance containing about 10 mg. of P) into a Kjeldahl flask. Add 10 ml. of a mixture of equal parts of concentrated  $\text{H}_2\text{SO}_4$  and concentrated  $\text{HNO}_3$ . Digest over a low flame until red fumes cease to come off. If the mixture darkens due to the charring action of the sulfuric acid, add nitric acid from a separatory funnel a few drops at a time and continue the digestion. When the mixture remains clear on evaporation to the point where white sulfuric fumes come off, the digestion is completed by heating for 10 to 15 minutes longer. Cool and transfer the solution to a 400-ml. Erlenmeyer flask with the aid of enough water to make a total volume of about 75 ml.<sup>217</sup>

Instead of oxidizing the material as described above, it may be ignited with magnesia to destroy organic matter. About 2 g. of the solid substance or 25 ml. of urine (previously evaporated nearly to dryness) are mixed with a little more than an equal bulk of magnesium oxide in a porcelain dish of about 30-ml. capacity. Five ml. of magnesium nitrate solution (see Appendix) are added and the mixture heated very gently at first, then gradually to bright

<sup>216</sup> Merck's Blue Label or "Special" Reagent is satisfactory.

<sup>217</sup> In the case of urine it is possible to neutralize this acid solution with ammonia, make it acid with acetic acid, and titrate with uranium acetate as in the preceding method.

redness. The mixture is cooled and transferred with water to a 250-ml. flask. An excess (20 to 30 ml.) of HCl are added and the mixture boiled a few minutes. Remove from the flame and add at once enough barium chloride solution to precipitate any sulfate present. Cool, make to mark, filter, and take an aliquot for analysis.

**Precipitation of the Phosphomolybdate.** Neutralize the solution with ammonia, make slightly acid with nitric acid, and add 15 g. of ammonium nitrate in substance (or 25 ml. of a 60 per cent solution). Heat on a water bath to 60° to 65° C. (not higher) and add 30 to 40 ml. of molybdate solution,<sup>218</sup> stir and let stand for about 15 minutes at 60° to 65°. Filter at once through a small paper,<sup>219</sup> washing the precipitate twice by decantation with 1 per cent potassium nitrate solution, using about 25 ml. each time, stirring up the precipitate well in each case, and allowing to settle. Transfer the precipitate to the filter and wash with 1 per cent potassium nitrate solution until two fillings of the filter (collected separately) do not greatly diminish the color produced with phenolphthalein by 1 drop of the standard alkali.

**Titration of the Phosphomolybdate.** Transfer the precipitate and filter back to the original beaker and dissolve in a small excess of 0.2 N NaOH (about 2 to 3 ml. more than required to completely dissolve the yellow precipitate). Add about 100 ml. of boiled and cooled water and a few drops of phenolphthalein as an indicator (a red color should be observed indicating excess of NaOH) and titrate the excess of NaOH with 0.1 N acid.

**CALCULATION.** Divide the ml. of 0.1 N acid used by 2 and subtract from the ml. of 0.2 N NaOH used. This gives the ml. of 0.2 N NaOH required. Multiply by 0.270 (the equivalent of 1 ml. 0.2 N NaOH in P) to obtain the number of mg. P in 10 ml. of the urine analyzed. Calculate the daily output of P in this case from the 24-hour volume.

**Interpretation.** Nearly all of the phosphorus of the urine exists as inorganic phosphates. Consequently the total phosphorus of urine varies in the same way as total phosphates. A small portion of the phosphorus of the urine may exist in organic combination, though not in a reduced form. This organically bound phosphate may amount to from 1 to 4 per cent of the total phosphorus excretion. Little is known with regard to the compounds in which it occurs. Some glycerophosphoric acid may occur either free or as lecithin.

**Gravimetric Modification.** The phosphorus may be determined somewhat more accurately by substituting a gravimetric procedure for the above titration. In this case the washed phosphomolybdate precipitate is dissolved on the filter paper with ammonium hydroxide and hot water to make a volume of not more than 100 ml. Nearly neutralize with HCl, cool, and add about 10 ml. of magnesia mixture (see Appendix) from a buret. Add slowly (about 1 drop per second), stirring vigorously. After 15 minutes add 12 ml.

<sup>218</sup> Made by adding 5 ml. of concentrated HNO<sub>3</sub> to 100 ml. of the ordinary molybdate solution (see Appendix).

<sup>219</sup> It is better to use a special filter tube of about 1¼ inches diameter (similar to a Gooch filtering tube) in which is placed a perforated porcelain plate 1⅛ inches in diameter, covered with a layer of asbestos ⅛ inch thick. Filtration is carried out with suction and is very rapid. Ordinary Gooch crucibles lined with asbestos may also be used but are not so satisfactory. The asbestos used should be specially prepared (see Appendix). For a good discussion of the details of procedure and sources of error of this volumetric method, see Hibbard: *J. Ind. Eng. Chem.*, 5, 998 (1913).

of ammonium hydroxide solution (sp. gr. 0.90). Let stand for some time (2 hours is usually enough), then filter and wash the precipitate with 2.5 per cent ammonia until practically free from chlorides. Ignite to whiteness or to a grayish-white ash and weigh. Multiply the weight of magnesium pyrophosphate thus obtained by 0.279 to get the weight of P.

CALCULATION. Calculate as explained above.

## CHLORIDES

**1. Volhard-Arnold Method: Principle.** The urine is acidified with nitric acid and the chlorides precipitated with a measured excess of standard silver nitrate solution. The silver chloride formed is filtered off and in the filtrate the excess silver nitrate is titrated back with standard ammonium thiocyanate solution. Ferric ammonium sulfate is used as an indicator. A red color due to the formation of ferric thiocyanate indicates that an excess of thiocyanate is present and that the end point has been reached.

**Procedure.** Place 10 ml. of urine in a 100-ml. volumetric flask, add 20 to 30 drops of nitric acid (sp. gr. 1.2) and 2 ml. of a cold saturated solution of ferric alum. If necessary, at this point a few drops of 8 per cent solution of potassium permanganate may be added to dissipate the red color. Now slowly run in a known volume of the standard silver nitrate<sup>220</sup> solution (20 ml. is ordinarily used) in order to precipitate the chlorine and insure the presence of an excess of silver nitrate. The mixture should be continually shaken during the addition of the standard solution. Allow the flask to stand 10 minutes, then fill it to the 100-ml. graduation with distilled water and thoroughly mix the contents. Now filter the mixture through a dry filter paper, collect 50 ml. of the filtrate, and titrate it with standardized ammonium thiocyanate solution.<sup>221</sup> The first permanent tinge of red-brown indicates the end point. Take the buret reading and compute the weight of sodium chloride in the 10 ml. of urine used.

CALCULATION. The number of ml. of ammonium thiocyanate solution used indicates the excess of standard silver nitrate solution in the 50 ml. of filtrate titrated. Multiply this reading by 2, inasmuch as only one-half of the filtrate was employed, and subtract this product from the ml. silver nitrate (20 ml.) originally used, in order to obtain the ml. of silver nitrate utilized in the precipitation of the chlorides in the 10 ml. of urine employed.

To obtain the weight in g. sodium chloride in the 10 ml. of urine used, multiply the ml. of the standard silver nitrate solution actually utilized in the precipitation, by 0.010. If it is desired to express the result in percentage of sodium chloride, move the decimal point one place to the right; for results in terms of grams of sodium chloride per liter of urine, move the decimal point two places to the right.

---

<sup>220</sup> Standard silver nitrate solution may be prepared by dissolving 29.061 g. of silver nitrate in 1 liter of distilled water. Each ml. of this solution is equivalent to 0.010 g. of sodium chloride or to 0.006 g. of chlorine.

<sup>221</sup> This solution is made of such a strength that 1 ml. of it is equal to 1 ml. of the standard silver nitrate solution used. To prepare the solution dissolve 13 g. of ammonium thiocyanate,  $\text{NH}_4\text{SCN}$ , in a little less than a liter of water. In a small flask place 20 ml. of the standard silver nitrate solution, 5 ml. of the ferric alum solution, and 4 ml. of nitric acid (sp. gr. 1.2), add water to make the total volume 100 ml., and thoroughly mix the contents of the flask. Now run in the ammonium thiocyanate solution from a buret until a permanent red-brown tinge is produced. This is the end-reaction and indicates that the last trace of silver nitrate has been precipitated. Take the buret reading and calculate the amount of water necessary to use in diluting the ammonium thiocyanate in order that 10 ml. of this solution may be exactly equal to 10 ml. of the silver nitrate solution. Make this dilution and titrate again to be certain that the solution is of the proper strength.

In a similar manner the weight or percentage of chlorine may be computed using the factor 0.006 instead of 0.010.

To express results in terms of milliequivalents of chloride per liter of urine, multiply the ml. standard silver nitrate required for the chloride in 10 ml. of urine by the factor 17.1.

Calculate the quantity of sodium chloride and chlorine in the 24-hour urine specimen.

**Interpretation.** From 10 to 15 g. of chlorine, expressed as sodium chloride (170 to 250 milliequivalents of chloride), are excreted per day, on the average, by normal adults. The amount is, however, closely dependent upon the chloride content of the food ingested. In fasting, the chloride excretion falls rapidly to a very minimal quantity. On high water ingestion it is increased. In pneumonia and certain other acute infectious diseases the excretion of chlorides may be markedly diminished, particularly during the periods in which exudates are forming. In convalescence and with resolution of the exudates the chlorine excretion rises again. A decrease has also been noted in nephritis associated with edema.

**2. Volhard-Harvey Method: Principle.** This procedure<sup>222</sup> differs from the Volhard-Arnold method in that the excess of silver nitrate is titrated directly without filtering and hence in the presence of the silver chloride. The procedure is thus more rapid but the end point is more difficult to determine, and the results are not so exact. It is therefore not recommended.

**3. Method of Sendroy (Modified by Van Slyke and Hiller):<sup>223</sup> Principle.** This is an application to urine of the blood-chloride method described on p. 627. The urine is shaken with solid silver iodate; chloride present forms insoluble silver chloride and an equivalent amount of soluble iodate. After removing insoluble material, the iodate in solution is converted to free iodine, which is then titrated with standard thiosulfate. The method is recommended because of its simplicity and accuracy.

**Procedure.<sup>224</sup>** Treat 1 ml. of urine with 25 ml. of phosphoric-tungstic acid reagent and shake with silver iodate, exactly as described for the analysis of 1 ml. of plasma or serum on p. 628. After filtration or centrifugation, treat 10 ml. of the filtrate or centrifugate with sodium iodide and titrate the liberated iodine with 0.02308 N thiosulfate solution, likewise as described on p. 628.

**CALCULATION.** The thiosulfate is of such strength that, at the dilution of urine employed, 1 ml. is equivalent to 10 milliequivalents of chloride per liter of urine. Therefore,

Ml. 0.02308 N thiosulfate required  $\times 10$  = milliequivalents chloride per liter urine

One milliequivalent of chloride equals 0.0585 g. of sodium chloride.

If the chloride content of the urine is so low that less than 5 ml. of thiosulfate are required for the titration, repeat the analysis, using 5 ml. of urine and 25 ml. of phosphoric-tungstic acid reagent. Shake with iodate and titrate a 10-ml. portion of filtrate as before, and calculate as follows:

Ml. 0.02308 N thiosulfate required  $\times 2.31$  = milliequivalents chloride per liter urine

Multiply the result by 0.0585 to express in terms of g. sodium chloride per liter.

**Interpretation.** See above.

<sup>222</sup> Harvey: *Arch. Internal Med.*, 6, 12 (1910).

<sup>223</sup> See footnote 209, p. 627.

<sup>224</sup> Reagents Required: See method for blood chlorides, p. 627.

## FLUORINE

**Determination of Fluoride (Method of Icken and Blank):<sup>225</sup> Principle.**

Fluoride ions react quantitatively to form a complex with thorium alizarin lake, resulting in a bleaching of the color. The residual intensity is read spectrophotometrically and interpolated on a reference curve derived from standard sodium fluoride solutions. The determination of fluorides in urine is preceded by the separation of phosphates and sulfates (by distillation from perchloric acid<sup>226</sup>) and of chlorides (by precipitation with silver sulfate<sup>227</sup>).

**Procedure.** (a) ISOLATION OF FLUORIDES.<sup>228</sup> Evaporate to dryness an aliquot of a 24-hour specimen of urine, containing from 100 to 200  $\mu\text{g}$ . fluorine (usually about 200 ml.), by adding it in small portions to 25 ml. of a suspension of calcium hydroxide<sup>229</sup> in a platinum dish or crucible. Dry thoroughly under an infrared lamp, then char slowly and finally ignite in a muffle oven at 600° C. until all traces of organic matter disappear.

Cool and wet the ash with 10 ml. distilled water. Dissolve the ash in a minimum quantity of perchloric acid,<sup>230</sup> keeping the dish covered with a watch glass. Rinse down the cover with a little water and transfer the solution through a funnel to a suitable distillation apparatus, e.g., a constant-temperature still.<sup>231</sup> Rinse the dish and the funnel with perchloric acid, using 20 ml. for all the above mentioned operations. Add to the mixture in the still a quantity of crystalline silver sulfate equivalent to the content of chlorides, previously determined on a separate aliquot of the urine by one of the methods described under "Chlorides." Connect the still to a steam generator and steam-distil, collecting about 200 ml. of distillate.

Evaporate to dryness and ignite the distillate as previously described, using an amount of the calcium hydroxide suspension sufficient to assure alkalinity. Dissolve the ash in perchloric acid and transfer to the still, which has been washed with hot 10 per cent NaOH and thoroughly rinsed with distilled water. Add to the solution in the still 200–500 mg. crystalline silver sulfate to precipitate the remaining traces of chlorides. Repeat the steam distillation and collect the distillate in a 150 ml. volumetric flask to which a few drops of *p*-nitrophenol indicator<sup>232</sup> and a few drops of 0.05 N KOH have been added. Keep the distillate alkaline at all times by dropwise addition of 0.05 N KOH. So regulate this addition of alkali that the distillate is neutralized as it approaches the mark.

<sup>225</sup> Icken and Blank: *Anal. Chem.*, **25**, 1741 (1953).

<sup>226</sup> Willard and Winter: *Ind. Eng. Chem., Anal. Ed.*, **5**, 7 (1936).

<sup>227</sup> McClure: *Ind. Eng. Chem., Anal. Ed.*, **11**, 171 (1939).

<sup>228</sup> Association of Official Agricultural Chemists: *Official Methods of Analysis* (1950), with minor modifications.

<sup>229</sup> *Calcium hydroxide suspension.* Carefully slake *ca.* 56 g. of low fluorine CaO with 250 ml. distilled water, and add slowly and with stirring 250 ml. of 60 per cent HClO<sub>4</sub>. Add a few glass beads and boil down to copious fumes of acid. Cool, add 200 ml. of H<sub>2</sub>O and boil down again. Repeat diluting and boiling down once more. Cool, dilute, and filter through fritted glass filter if precipitate of SiO<sub>2</sub> has appeared. Pour solution, with stirring, into 1 l. of 10 per cent NaOH solution, allow precipitate to settle. Siphon off the supernatant liquid. Remove sodium salts by washing and centrifuging 5 times. Finally shake precipitate into suspension and make to 2 liters. Preserve in paraffined bottles. Shake suspension well before using.

<sup>230</sup> *Perchloric acid.* Dilute 60 per cent HClO<sub>4</sub> with 3 volumes of distilled water and boil down to original volume. Avoid active fuming. Repeat and preserve in pyrex glass bottle.

<sup>231</sup> Huckabay, Welch, and Metler: *Anal. Chem.*, **19**, 154 (1947).

<sup>232</sup> *p*-Nitrophenol indicator: 0.5 per cent alcoholic solution.

(b) **DETERMINATION OF FLUORIDES.** Pipet standard solutions of sodium fluoride<sup>233</sup> containing 0, 10, 20, 30, 40, 50 and 500  $\mu\text{g.}$  of fluoride ion, and an aliquot of the final distillate containing from 0 to 50  $\mu\text{g.}$  of fluoride ion, into 50 ml. volumetric flasks. Add 10 ml. of the thorium-alizarin reagent<sup>234</sup> to each flask. Make the flasks to volume with distilled water, stopper, shake, and allow to stand for 2 hours. Determine the light absorbance of the standards at a wavelength of 525  $\text{m}\mu$  by means of a spectrophotometer equipped with 10-mm. Corex cells. Set the instrument for 100 per cent transmittance with the 500  $\mu\text{g.}$  standard. Plot the reference curve. Determine the light absorbance of the sample and read the fluoride content from the reference curve.

**CALCULATION.**

$a$  = ml. of urine taken for analysis

$b$  = ml. of final distillate taken for the spectrophotometric determination

$c$  =  $\mu\text{g.}$  fluoride in aliquot " $b$ " (from reference curve)

$$\frac{c \times 150}{a \times b} = \text{mg. F}^- \text{ per liter urine}$$

**Interpretation.** The amount of fluorine in urine is influenced by the fluoride content of the diet or water supply and is therefore a criterion of fluorine exposure and absorption. In areas where dental fluorosis (mottled enamel) is prevalent an average concentration of 3 mg. F per liter of urine has been reported as compared with a "normal" value of 1 mg. per liter.<sup>235</sup> Two populations whose water supplies contained 0.06 and 1.36 parts per million (mg. per liter) of fluoride respectively, (the latter by fluoridation) showed mean urine fluoride levels of  $0.06 \pm 0.13$  and  $1.12 \pm 0.56$  mg. F per liter and blood levels of 0.4 and 4.0  $\mu\text{g.}$  per 100 ml., respectively.<sup>236</sup> Fluoride is eliminated not only via urine and feces, but also by insensible and sensible perspiration. No significant retention was noted when the daily intake was below 5 mg., the data suggesting this to be the approximate limit.<sup>237</sup>

## TOTAL FIXED BASE

**Method of Fiske:**<sup>238</sup> **Principle.** The fixed bases sodium, potassium, calcium, and magnesium are converted into sulfates and the combined sulfuric acid titrated by the benzidine method.

<sup>233</sup> *Sodium fluoride standard solution:* The sodium fluoride content of a commercial sodium fluoride c.p. powder is determined by precipitation as  $\text{CaF}_2$  (cf. Scott, W. W., *Standard Methods of Chemical Analysis*, Vol. I, 4th ed., p. 226, 1925). 2.2105 g. sodium fluoride (100 per cent basis) are dissolved in distilled water in a 1-l. volumetric flask and made to volume. (0.5 ml. = 500  $\mu\text{g. F}^-$ .) Ten ml. of this solution are diluted to 1 l. with distilled water to give the final standard solution (1 ml. = 10  $\mu\text{g. F}^-$ ).

<sup>234</sup> *Thorium-alizarin reagent:*

10 ml. 0.1 N hydrochloric acid.

10 ml. 1 per cent hydroxylamine hydrochloride.

40 ml. 0.1 per cent aqueous alizarin sodium monosulfonate.

40 ml. 0.05 per cent thorium nitrate,  $\text{Th}(\text{NO}_3)_4 \cdot 4\text{H}_2\text{O}$ .

The components are added in the sequence listed. The reagent is prepared fresh from stock solutions.

<sup>235</sup> Greenwood: *Physiol. Revs.*, **20**, 582 (1940).

<sup>236</sup> Smith, Gardner, and Hodge: *J. Dent. Res.*, **29**, 596 (1950).

<sup>237</sup> McClure, Mitchell, Hamilton, and Kinsner: *J. Ind. Hyg. Toxicol.*, **27**, 159 (1945).

<sup>238</sup> Fiske: *J. Biol. Chem.*, **51**, 55 (1922). See also method of Stadie and Ross: *J. Biol. Chem.*, **65**, 735 (1925) and comment of Brown and Shohl: *J. Biol. Chem.*, **91**, 745 (1931). A simple and accurate method for the determination of total fixed base by electrolysis is described by Consolazio and Talbot: *J. Biol. Chem.*, **132**, 753 (1940).

**Procedure.** Measure into a large-lipped test tube (200 by 20 mm.) a sample of urine containing preferably between 10 and 25 mg. of NaCl but not more than 5 mg. of inorganic phosphorus. Add 1 ml. of approximately 4 N sulfuric acid and 0.5 ml. of concentrated nitric acid, and boil down until white fumes appear. If the residue does not soon become colorless after this stage has been reached, cool slightly, add a few more drops of nitric acid, and continue the heating. When the remaining drop of sulfuric acid has become clear and colorless, let cool for a few minutes, and wash into a test tube which is marked at 25 ml., with four 2-ml. portions of water. Add a drop of saturated alcoholic solution of methyl red. Neutralize with powdered ammonium carbonate until the color of the indicator just begins to change, and restore the pink color by adding 4 N sulfuric acid 1 drop at a time. Heat to boiling and add more acid to restore the pink color if this is necessary. Add a 10.5 per cent solution of ferric chloride crystals in 0.2 N HCl in the proportion of 0.1 ml. for each mg. of inorganic phosphorus present, shake and run in 1 ml. of a 5 per cent solution of ammonium acetate. Add sufficient water to make the total volume 10 or 11 ml., heat again to boiling, and dilute to the 25-ml. mark with cold water. Insert a rubber stopper and mix by inverting a few times. Filter at once through a dry 9-cm. ashless paper into a dry test tube. Keep the filter nearly filled with liquid as long as possible and collect only 20 ml. Stopper the tube containing filtrate and cool. The phosphate has now been removed.

Transfer 5 ml. of filtrate to a small platinum dish, add 1 ml. of approximately 4 N sulfuric acid, and evaporate on the water bath until nearly dry. Place the dish on a metal triangle and heat cautiously at first over a microburner, gradually raising the flame until fumes have ceased to come off. Let cool, sprinkle over the residue a little powdered ammonium carbonate, and ignite again, finally raising the flame to its maximum and moving the triangle about until each part of the dish has been momentarily subjected to a dull red heat. When the dish has cooled, add 2 ml. of water. Agitate until the residue has dissolved, using a rubber-tipped rod to assist in solution if necessary. Transfer the contents of the dish to a large-lipped pyrex test tube, rinsing four times with 2-ml. portions of water. Determine the sulfate according to the benzidine method (see p. 949).

**CALCULATION.** An aliquot of one-fifth of the original urine was used for the determination and 0.02 N NaOH in the titration. Therefore the titration reading is equivalent to the number of ml. of 0.1 N fixed base in the sample of urine used. Subtract a correction of 1 per cent for the contraction of the warm solution during the filtration stage. Results are usually expressed in terms of milliequivalents of total fixed base per liter; this is obtained by dividing by 10 the number of ml. of 0.1 N base per liter.

**Interpretation.** The total fixed base excretion, combining as it does the sodium, potassium, calcium, and magnesium excretions, will be influenced by factors affecting any of these. In acidosis, volatile base (ammonia) plays a large part in neutralization but the fixed base excretion is also increased in varying degrees.

## CALCIUM

**Determination of Calcium (Method of Shohl and Pedley<sup>239</sup>): Principle.** The urine is oxidized with ammonium persulfate. Calcium is precipitated as oxalate

<sup>239</sup> Shohl and Pedley: *J. Biol. Chem.*, 50, 537 (1922). For references to various other procedures upon which the determination of calcium may be based, see the section on blood-calcium methods in Chapter 23, p. 644.

and titrated with potassium permanganate. The method is more rapid than the gravimetric.

**Procedure.** To 100 ml. of unfiltered urine in a 250-ml. Erlenmeyer flask add 5 ml. of concentrated  $\text{HNO}_3$  or  $\text{H}_2\text{SO}_4$  and one spoonful (containing 3 to 4 g.) of ammonium persulfate. Insert a funnel in the flask to prevent spattering. Boil and keep near the boiling point on a hot plate or over a low flame for 1 hour or until reduction of the persulfate is complete, as evidenced by an absence of frothing when the flask is agitated. The solution at this point is pale green in color. Add 10 ml. of 2.5 per cent oxalic acid. Cool to room temperature. Neutralize with ammonium hydroxide, using one drop of methyl red as an indicator. Cool to room temperature. If the color is now red, add a few drops of ammonia to bring to intermediate color between red and yellow (pH 4.8 to 5.2). Let stand overnight. Filter. Whatman No. 50 hardened filter paper 12.5 cm. is satisfactory. Wash precipitate and flask three times with distilled water,<sup>240</sup> filling the filter two-thirds full each time and allowing to drain. Break a hole in the filter paper and wash back the precipitate into the original flask, first with distilled water and then with hot dilute sulfuric acid, bringing the volume to about 100 ml. Add 10 ml. of concentrated sulfuric acid and heat to  $70^\circ$  to  $80^\circ$  C. Titrate with 0.05 N potassium permanganate, taking as an end point the first color that persists 15 to 30 seconds. One ml. 0.05 N  $\text{KMnO}_4$  is equivalent to 0.0010 g. Ca.

**Interpretation.** The average urinary excretion of calcium by normal adults lies between 0.1 to 0.3 g. (expressed as Ca) per day. This corresponds to 5 to 15 milliequivalents of calcium ion. Calcium excretion in the urine is dependent very largely upon the amount of calcium in the diet. From 10 to 40 per cent of the ingested calcium ordinarily is excreted by this channel, the greater part being eliminated by the feces. The proportion is dependent particularly on the amount of calcium in the food. If the calcium ingestion is very high, the per cent of the total excretion taking place by way of the kidneys will be low, and *vice versa*. As excretion takes place by way of the intestine as well as by the kidneys, no conclusions can be drawn from urinary analyses alone. The excretion of calcium may be greatly increased in certain bone disorders as osteomalacia. In others, as in rickets, the urinary excretion may be very low. For further discussion, see p. 820.

The calcium content of the urine is of clinical significance in connection with the formation of certain calcium-containing stones. According to Shorr,<sup>241</sup> measures designed to decrease the amount of calcium (and of phosphate) in the urine, or to increase the solubility of calcium as by promoting the urinary excretion of citrate (which forms a soluble complex with calcium) should prove to be of value in the management of nephrolithiasis due to stones of the calcium-carbonate and calcium-phosphate types.

## CALCIUM AND MAGNESIUM

**McCrudden's Methods: Principle.** Urine contains magnesium, phosphates, and a small amount of iron, each of which will interfere with the accurate determination of its calcium content if proper conditions of acidity are not maintained during the

<sup>240</sup> See footnote 249, p. 645.

<sup>241</sup> Shorr: *J. Urol.*, 53, 507 (1945).

precipitation. In the following method the proper acidity is attained through the use of sodium acetate and hydrochloric acid, and this with slow addition of the ammonium oxalate reduces the danger of occlusion of magnesium oxalate, calcium phosphate, or ferric phosphate in the calcium oxalate precipitate.

The calcium oxalate precipitate is either ignited and weighed as CaO or determined volumetrically by titration with potassium permanganate. Magnesium is determined in the filtrate from the calcium determination after destruction of the organic matter. It is determined in the usual way by ignition of the magnesium ammonium phosphate precipitate and weighing as the pyrophosphate.

For colorimetric adaptations of these classical methods for calcium or magnesium, reference should be made to the procedures described for blood in Chapter 23.

**Calcium: Gravimetric Procedure.** If the urine is alkaline, make it neutral or slightly acid and filter. Take 200 ml. of the filtered urine for analysis. If it is only faintly acid to litmus paper, add 10 drops of concentrated hydrochloric acid (sp. gr. 1.20). If the urine is strongly acid, it may be made just alkaline with ammonia and then just acid with hydrochloric acid, after which the 10 drops of concentrated hydrochloric acid are added. Then add 10 ml. of 2.5 per cent oxalic acid. Run in slowly with stirring 8 ml. of 20 per cent sodium acetate. Allow to stand overnight at room temperature or shake vigorously for 10 minutes. Filter off the precipitate of calcium oxalate on a small paper, and wash free from chlorides with 0.5 per cent ammonium oxalate solution. The precipitate may then be dried, ignited to constant weight, and weighed as calcium oxide, or it may be manipulated volumetrically as described below.

**Volumetric Procedure.** If free from uric acid, the calcium oxalate precipitate may be washed three times with distilled water, filling the filter about two-thirds full and allowing it to drain completely before adding more. A hole is made in the paper and the calcium oxalate washed into a clean flask. The volume of the fluid is brought up to about 50 ml. and 10 ml. of concentrated sulfuric acid added. Titrate with standard potassium permanganate solution to a pink color which endures for at least a minute.

**CALCULATION.** In the gravimetric procedure, convert the weight of CaO into terms of Ca by multiplying by 0.715. In the volumetric procedure, one ml. of 0.1 N permanganate solution is equivalent to 2.0 mg. of Ca. Calculate the daily output of calcium.

**Magnesium: Gravimetric Procedure.** Transfer the filtrate from the determination of calcium as above to a porcelain dish, add about 20 ml. of concentrated nitric acid, and evaporate to dryness. Heat the residue over a free flame until the ammonium salts are destroyed and the residue fuses. After cooling, take the residue up with water and a little hydrochloric acid and filter if necessary. Dilute to about 80 ml., nearly neutralize with ammonia, and cool. Add a slight excess of sodium acid phosphate and then ammonia drop by drop with constant stirring until the solution is alkaline, and then add enough more slowly with constant stirring to make the solution contain one-fourth its bulk of dilute ammonia (sp. gr. 0.96). Allow to stand overnight. Filter and wash free from chlorides with alcoholic ammonia solution (1 part alcohol, 1 part dilute ammonia, 3 parts water). The precipitate with filter paper is incinerated slowly and carefully with a good supply of air to prevent reduction, in the usual manner, and ignited and weighed as the pyrophosphate.

**CALCULATION.** To obtain the weight of Mg, multiply the weight of magnesium pyrophosphate by 0.2184.

**Interpretation.** The daily excretion of magnesium by way of the urine usually amounts to between 0.05 and 0.2 g. (expressed as Mg). This amount corresponds to 4 to 20 milliequivalents of magnesium ion per day. The amount depends mainly upon the diet. Usually less than 50 per cent of the excreted magnesium is eliminated by the kidneys, the major portion passing out in the feces. The proportion varies, however, and it is impossible to draw any conclusions from the urinary output alone. There may be a retention of magnesium in certain bone disorders accompanying a loss of calcium—in osteomalacia, for example. Thus the excretions of calcium and magnesium do not necessarily run parallel.

**Determination of Calcium in Ash of Foods or Feces.**<sup>242</sup> Ignite the material in a crucible to a white ash and dissolve the ash with the aid of a little hydrochloric acid. Bring the volume of the ash solution to 75 to 150 ml. Make just alkaline with strong ammonia added drop by drop (using litmus paper or alizarin as an indicator). Add concentrated HCl drop by drop until just acid to litmus. Then add 10 drops of concentrated HCl (sp. gr. 1.20) and 10 ml. of 2.5 per cent oxalic acid. Either of two procedures may then be followed. (a) The solution is boiled until the precipitated calcium oxalate is coarsely crystalline, and then an excess of 3 per cent ammonium oxalate is slowly added to the boiling solution and the boiling continued until any further precipitate is coarsely crystalline. (If but little calcium is present, nothing will precipitate at this point and it is not necessary to add oxalate.) Or (b) the flask closed with a rubber stopper is shaken vigorously for 10 minutes. An excess of 3 per cent ammonium oxalate is then added. Cool to room temperature. Add 8 ml. of 20 per cent sodium acetate solution. (In case of ash of feces add 15 ml.) The solution may either be (a) allowed to stand overnight or (b) stoppered and vigorously shaken for 10 minutes. The calcium oxalate is filtered off on a small ash-free paper and washed free from chlorides with 0.5 per cent ammonium oxalate solution. Either of two procedures may next be followed: (a) The precipitate and filter are dried, and burned in a platinum or porcelain crucible to constant weight as CaO. (b) The precipitate is washed three times with cold distilled water, as given under the method for urine and the oxalate titrated with potassium permanganate.

Magnesium is determined in the filtrate from calcium just as given above.

## SODIUM AND POTASSIUM

**Determination of Combined Sodium and Potassium.**<sup>243</sup> From 50 to 100 ml. of urine, depending upon the specific gravity, are oxidized in a Kjeldahl flask with nitric and sulfuric acids as in the Neumann procedure for total phosphorus (see p. 953). To remove the sulfuric acid as completely as possible, transfer with the aid of a little water to a platinum dish<sup>244</sup> and evaporate to dryness over a free flame. (The alkalies are in the form of sulfate and do not

<sup>242</sup> For another procedure for the determination of calcium in tissues and other biological materials, see p. 648 (Corley and Denis: *J. Biol. Chem.*, **66**, 601 (1925)). For determination of Ca, Mg, and P in materials such as hay and cow feces which contain much acid-insoluble material, see Morris, Nelson, and Palmer: *Ind. Eng. Chem., Anal. Ed.*, **3**, 164 (1931).

<sup>243</sup> For a method for direct quantitative determination of sodium, potassium, calcium, and magnesium in urine and feces, see Tisdall and Kramer: *J. Biol. Chem.*, **48**, 1 (1921). The flame photometer (see p. 530) of Barnes, Richardson, Berry, and Hood (*Ind. Eng. Chem., Anal. Ed.*, **17**, 605 (1945)) is being successfully used in many laboratories for the simple and accurate separate determination of urinary sodium and potassium.

<sup>244</sup> Wilson (*J. Biol. Chem.*, **50**, 301 (1922)) suggests the use of inexpensive tin dishes instead of platinum.

volatilize.) Dissolve the residue in hot water with the aid of a little dilute hydrochloric acid. Heat to boiling and add barium chloride solution until no more precipitate forms. While still hot, add an excess of ammonia and ammonium carbonate. The barium chloride precipitates the sulfates and part of the phosphates: the ammonia in the presence of excess barium precipitates the rest of the phosphates, and the carbonate precipitates the calcium and most of the magnesium, as well as the excess barium. Filter and wash the precipitate well with hot water containing a few drops of ammonia. Evaporate the filtrate and washings to dryness and heat the residue to dull redness for a moment. Redissolve in water and treat again with ammonia and ammonium carbonate to remove any remaining alkaline earth metals. Filter and wash as before. Transfer the filtrate and washings to a weighed platinum dish, add a few drops of hydrochloric acid, and evaporate to dryness. Heat the residue gently to remove ammonium salts and then to dull redness for a moment. Desiccate and weigh. Reheat to constant weight which represents the combined chlorides of sodium and potassium. The reagents used in the determination must be tested and found free from alkali metals or a correction made for the alkali metals present in the reagents used. The sodium is determined by difference after potassium has been estimated by the method given below.

**Potassium.** Dissolve the alkali chlorides from the preceding determination in a little water and add a slight excess of 10 per cent platinic chloride over that necessary to precipitate all of the alkali present calculated as sodium chloride (about 17 ml. being required for each gram of sodium chloride). Evaporate to a syrupy consistency on the water bath and add about 50 ml. of 80 per cent alcohol. Stir occasionally for a few minutes. This operation must be carried out in the absence of ammonia vapors. Filter through a weighed Gooch crucible, washing the precipitate with 80 per cent alcohol first thoroughly by decantation and then on the filter, for some time after the filtrate is colorless. Dry at  $110^{\circ}$  to  $115^{\circ}$  C. and weigh.

**CALCULATION.** Multiply the weight of potassium platinic chloride by 0.1608 to obtain the amount of K present. Express as KCl by using instead of this factor the factor 0.3067. Subtract from the weight of total alkali chlorides as determined in the preceding method, the weight of potassium chloride as calculated and obtain the amount of sodium chloride present. To convert sodium chloride into sodium, multiply by 0.3934. To express the sodium (or potassium) content in terms of milliequivalents, divide the weight of NaCl (or KCl) in grams by 0.05845 (or 0.07455).

**Interpretation.** The average alkali excretion of an adult on a mixed diet is about 1 to 3 g. of potassium expressed as K (40 to 65 milliequivalents), and 3.0 to 5 g. of sodium expressed as Na (130 to 200 milliequivalents). The ratio of Na to K is thus about 5:3. Both the ratio and the absolute amounts of these elements excreted are, however, largely dependent upon the salt content of the diet. The urine during fasting contains more potassium than sodium salts, because of the noningestion of sodium chloride and the accompanying destruction of potassium-containing body tissues. The excretion of the bases, particularly K, may be increased in fevers and in acidosis.

## IRON

**Methods of Elvehjem and Kennedy.** The urine is ashed, the ash dissolved, and the iron present determined colorimetrically as thiocyanate.

**Procedure.** Evaporate and ash 100 ml. of urine and carry out iron determination according to Elvehjem or Kennedy (see p. 656).

## IODINE

**Method of Von Fellenberg:**<sup>245</sup> **Principle.** For discussion of the principle, see the original articles. McCullagh<sup>246</sup> has suggested a simpler procedure for iodine determinations in blood and other materials. Chaney's method<sup>247</sup> for protein-bound iodine is described on p. 661.

**Procedure.** To 10 to 40 ml. of urine add 1 to 3 ml. of a saturated solution of iodine-poor  $K_2CO_3$  and evaporate in a low iron dish (about 10 cm. diameter). Heat gently without igniting, moisten with water, and ignite, not bringing the bottom of the dish to redness. Extract the charred mass with a little water and filter. Ignite the paper and residue, then add the filtrate (only faintly yellow) and a few drops of 10 per cent  $NaNO_3$ , and complete ignition. The residue should be pure white. Extract four times with 2 to 3 ml. of alcohol. Evaporate the alcoholic solution in a gold or platinum dish (about 6 cm. diameter) on a water bath to dryness, after adding a few drops of saturated  $K_2CO_3$  solution. Ignite gently. Extract again with 95 per cent alcohol and evaporate and ignite, this time adding no  $K_2CO_3$ . The bottom of the dish must not turn red. Dissolve the residue in 0.3 ml. of water and titrate iodine according to the method of McCullagh<sup>246</sup> or according to the procedure of v. Fellenberg.<sup>248</sup> The amount of iodine eliminated in 24 hours may be from 10 to 200  $\mu g$ .

## TESTS FOR KIDNEY EFFICIENCY

### 1. Blood-Urea Clearance (*Method of Möller, McIntosh, and Van Slyke*):<sup>249</sup>

**Principle.** Urea is normally filtered through the renal glomeruli and only partly re-absorbed in the tubules. The blood-urea clearance test is a measure of the efficiency with which the kidney excretes urea. Results are expressed either in terms of the volume of blood in ml. which is completely cleared of urea per minute, or more commonly as the percentage of the average normal value which this volume represents. The necessary data include the concentration of urea in blood and urine and the volume of urine excreted in unit time.

**Procedure.** The patient is permitted to eat a moderate meal (usually breakfast) without coffee. Vigorous exercise is avoided and after breakfast the patient is kept at rest during the 2-hour test period. At the beginning of the test period, the bladder is emptied and the urine discarded. The patient is given a glass of water to drink, and the urine is collected in two succeeding periods of one hour each. At the beginning of the second period, the patient is given another glass of water, and a sample of blood is drawn for urea determination. At the close of the test, the volumes of urine passed during each period are accurately measured in graduated cylinders, and the urea content of each determined separately.

The two collection periods need not be exactly one hour long, but may be longer if convenient. It is important, however, that the *time* of the period be accurately known, to the nearest minute, and that the entire volume of urine formed during this period be obtained, since only in this way can the volume of urine flow per minute be calculated. The two periods serve as checks on one another; if results calculated on the basis of each separate period differ significantly, error is indicated. If the urine volume is less than 25 ml. per hour, the sample is discarded.

**CALCULATION.** The *maximum clearance* ( $C_m$ ) indicates the maximum efficiency of urea excretion with high urine volumes and is calculated if the urine volume observed in an adult, or if the corrected volume  $V \times \frac{1.73}{\text{sq. m. surface area}}$  in a child, exceeds 2 ml. per minute. The *standard clearance* ( $C_s$ ), or the efficiency with which the kidneys excrete urea when the urine volume is at the average normal level of 1 ml. per minute, is calculated if the urine volume, corrected in the case of a child, is less than 2 ml. per minute. Both clearances are best calculated in percentage of the average normal  $C_s$  or  $C_m$ .

$$\text{Percentage of average normal } C_m = \frac{100 UV}{75B} = 1.33 \frac{UV}{B}$$

$$\text{Percentage of average normal } C_s = \frac{100 U \sqrt{V}}{54B} = 1.85 \frac{U \sqrt{V}}{B}$$

$U$  = Urea concentration of urine (mg. urea N per 100 ml.)

$B$  = Urea concentration of blood (mg. urea N per 100 ml.)

$V$  = ml. urine excreted per minute

<sup>249</sup> Möller, McIntosh, and Van Slyke: *J. Clin. Invest.*, **6**, 427 (1928). See also Van Slyke and Cope: *Proc. Soc. Exptl. Biol. Med.*, **29**, 1169 (1932).

The following table is convenient in calculating standard clearance. It gives values of  $\sqrt{V}$ .

| $V$<br><i>ml. per<br/>minute</i> | $\sqrt{V}$ | $V$<br><i>ml. per<br/>minute</i> | $\sqrt{V}$ | $V$<br><i>ml. per<br/>minute</i> | $\sqrt{V}$ | $V$<br><i>ml. per<br/>minute</i> | $\sqrt{V}$ |
|----------------------------------|------------|----------------------------------|------------|----------------------------------|------------|----------------------------------|------------|
| 0.2                              | 0.45       | 0.7                              | 0.84       | 1.2                              | 1.10       | 1.7                              | 1.30       |
| 0.3                              | 0.55       | 0.8                              | 0.89       | 1.3                              | 1.14       | 1.8                              | 1.34       |
| 0.4                              | 0.63       | 0.9                              | 0.95       | 1.4                              | 1.18       | 1.9                              | 1.38       |
| 0.5                              | 0.71       | 1.0                              | 1.00       | 1.5                              | 1.23       | 2.0                              | 1.42       |
| 0.6                              | 0.78       | 1.1                              | 1.05       | 1.6                              | 1.27       | 2.1                              | 1.45       |

**Interpretation.** In patients with diminishing renal function, the blood-urea clearance shows evidence of diminution sooner than does the blood-creatinine content, the blood-urea content considered without relation to urea excretion, or the phenolsulfonephthalein excretion. The blood-urea clearance usually falls below 50 per cent of normal values before any of the other three show abnormality. Only after the blood-urea clearance indicates less than 20 per cent of normal renal function are all values for blood urea, creatinine, and phenolsulfonephthalein found outside the limits of normal variation. The maximum clearance is normally about 40 per cent greater than the standard clearance, the mean values being 75 ml. (variations 64 to 99 ml.) of blood per minute for the maximum and 54 ml. (variations of 40 to 68 ml.) for the standard. The method is based on the view that with abundant urine the urea excretion per minute equals the urea contained in a constant volume of blood.

**2. Phenolsulfonephthalein Test: Principle.** This test for renal function was devised by Rowntree and Geraghty. It depends upon the injection into the tissues of a dyestuff which is eliminated rapidly by the normal kidneys, and can be easily estimated quantitatively in the urine.

This dyestuff, phenolsulfonephthalein, is nonirritative to the body either when taken by mouth or when injected into the tissues, so that it does no harm to an already weakened kidney.

The patient upon whom the test is to be performed is given 300 to 400 ml. of water 20 to 30 minutes previously, in order to assure a free flow of urine. Just before the start of the test, the bladder is emptied and the urine discarded.

**Procedure.** One ml. of a solution containing 6 mg. of phenolsulfonephthalein<sup>250</sup> per ml. is injected intramuscularly in the lumbar region, the time of injection being noted. The patient is then catheterized and the urine as it forms thereafter allowed to drop into a beaker containing 2 drops of 25 per cent NaOH. The appearance of a red color in the alkalinized urine indicates beginning excretion of the drug, the normal time being within 5 to 10 minutes after its injection. Urine is now collected in one-hour samples. In

<sup>250</sup> This solution is prepared by adding 0.6 g. of phenolsulfonephthalein and 0.84 ml. of 2 N NaOH to enough 0.75 per cent NaCl solution to make 100 ml. This gives the monosodium or acid salt which is slightly irritant locally when injected. It is necessary to add two to three drops more 2 N NaOH which changes the color to a Bordeaux red. This preparation is nonirritant. Suitable preparations of the dye in sterile ampuls may be obtained from pharmaceutical supply houses.

patients with obstruction to the flow of urine from the bladder, the retention catheter is stoppered and the urine drawn off at the end of each hour. Other patients may simply be allowed to urinate at the hourly periods.

To each hour sample of urine is added 25 per cent NaOH, drop by drop, until the maximum intensity of color appears. This color will remain constant for an indefinite period of time. Each sample is then placed in a 1000-ml. volumetric flask and diluted to the mark with distilled water.

Compare the color intensity of each sample either colorimetrically or photometrically against a standard. To prepare the standard, place a sufficient amount of the phenolsulphonephthalein solution to contain 3 mg. of the dye (i.e., one-half of the amount administered) in a beaker, dilute with a little water, and add 25 per cent NaOH dropwise to maximum color intensity. Transfer quantitatively to a 1000-ml. volumetric flask, dilute to the mark with water, and mix.

For colorimetric comparison, match the unknowns against the standard in the usual way. It is convenient to set the standard at 10 mm. For photometric measurement, determine the densities of standard and unknown in a photometer at 520  $m\mu$ , setting the photometer to zero density with water.

CALCULATION. *For colorimetric measurement:*

$$\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 50 = \text{per cent of administered dye in sample}$$

*For photometric measurement:*

$$\frac{\text{Density of Unknown}}{\text{Density of Standard}} \times 50 = \text{per cent of administered dye in sample}$$

**Interpretation.** The amount of the drug eliminated normally is 40 to 60 per cent during the first hour and 20 to 25 per cent during the second hour, or a total of 60 to 85 per cent for two hours. The amount of the drug excreted has been found to be independent of the quantity of urine obtained. Ordinarily, two one-hour samples are sufficient; in case of delayed excretion the collection of hourly samples may be continued until practically all of the drug has been recovered in the urine.

If it is desired to test the function of each kidney separately, ureteral catheterization must be resorted to, the experiment otherwise being performed as above described.

The phenolsulfonephthalein test may be used to indicate the amount of derangement in quantitative functional disturbance of the kidneys, as in chronic interstitial and chronic parenchymatous nephritis or uremia.

It is claimed that the rate of excretion of phenolsulfonephthalein is affected by certain extrarenal factors; namely, the albumin and hydrogen-ion concentrations of the blood.

**3. Mosenthal Test for Kidney Function:**<sup>251</sup> **Principle.** The patient under examination is placed for a day on a more or less definite diet.<sup>252</sup> The urine is collected

<sup>251</sup> Mosenthal: *Boston Med. Surg. J.*, **170**, 245 (1914); *Ohio State Med. J.*, **18**, 348 (1922).

<sup>252</sup> A diet suitable to ordinary hospital conditions is given by Kahn: *Functional Diagnosis*, p. 260, New York, W. F. Prior Co., 1920. It is not essential, as was formerly believed, to prescribe a diet abundant in diuretic foods or beverages, since ordinary foods contain sufficient diuretic materials for the proper carrying out of the test. In private practice it is only necessary that the patient eat three full meals a day and record the approximate quantities—1 cup of coffee, 2 slices of toast, 2 tablespoonfuls of oatmeal, etc.

in six two-hour periods during the day and one 12-hour night period. These urine specimens are analyzed for volume, specific gravity, total nitrogen, and chlorides.

**Procedure.** On the day of the test have the patient empty the bladder at 8 A.M. and start the diet for the day which, if desired, may contain approximately 13 to 14 g. of nitrogen, 8 to 9 g. of salt, 1700 to 1800 ml. of fluid, and considerable purine material in meat, soup, tea, and coffee.<sup>253</sup> No solid food nor fluid of any kind must be taken between meals and *especial care must be observed that nothing is eaten or drunk after the evening meal.* The meals should start at 8 A.M., 12 noon, and 5 P.M.

Collect the urine punctually at the end of every 2-hour period until 8 P.M., and place in separate bottles. Collect the night urine from 8 P.M. to 8 A.M. of the following day in another bottle. Measure the volume of each specimen of urine and determine in each case the specific gravity, total nitrogen, and total chlorides.

**Interpretation.** The test is of particular value apparently as giving earlier indications of diminished kidney efficiency than is true of some other tests used. It is sometimes difficult to interpret the results obtained in terms of renal involvement because of the influence of possible extra-renal factors. In general, however, the normal response is one in which the specific gravity figures vary at least 9 points (less if too little water is taken) from the highest to the lowest and the volume of the *night* urine is 400 ml.<sup>254</sup> or less. If the percentage of nitrogen and sodium chloride in the night urine or in the highest of any of the day specimens is 1 per cent, a normal condition is indicated. Values under 1 per cent, however, may or may not be abnormal.

| Time of Day          | Urine |         | Sodium Chloride |       | Nitrogen |       |
|----------------------|-------|---------|-----------------|-------|----------|-------|
|                      | Ml.   | Sp. gr. | Per Cent        | G.    | Per Cent | G.    |

When kidney function becomes involved, the first signs are usually demonstrated in the night urine. The quantity becomes increased and

<sup>253</sup> See footnote 252.  
<sup>254</sup> This represents the usual normal limit. Volumes in excess of 750 ml. are distinctly abnormal, whereas volumes between 400 and 750 ml. are of doubtful significance.

the specific gravity and the nitrogen concentration are lowered. One or all of these changes from the normal may occur. In severe cases of chronic nephritis an advanced degree of functional inadequacy of the kidney is indicated by a markedly fixed and low specific gravity, a diminished output of both salt and nitrogen, a tendency to total polyuria, and a night urine showing an increased volume, low specific gravity, and low concentration of nitrogen. Such functional pictures are, however, not confined to nephritis. They are found frequently in many other conditions: pyelitis, cystitis, hypertrophied prostate, marked anemia, pyelonephritis, polycystic kidney, and diabetes insipidus. The table above taken from Mosenthal shows the response of a normal individual.

**4. Other Methods.** Inulin is filtered through the glomeruli and neither excreted nor reabsorbed by the tubules. This is the basis for an inulin-clearance test for renal (glomerular) function.<sup>255</sup>

The *p*-aminohippuric acid (PAH) clearance test is employed as an index of renal blood flow since this compound is filtered through the glomeruli and excreted via the tubules.<sup>256</sup>

Other kidney function tests based on dye excretion rates or on concentration and dilution efficiencies have been proposed.

## Isotopes

The chemical properties of the several elements depend upon the number and configuration of the unit negative charges, or *electrons*, which surround the nuclei of their atoms. The number of such planetary electrons in the neutral atom of any given element is equal to the number of *protons*, each having a unit positive charge, in the nucleus of that atom. An element is characterized by a fixed and definite *atomic number* of protons in the nuclei of its atoms, balanced by an equal number of planetary electrons.

All atomic nuclei, with the single exception of the nucleus of ordinary hydrogen, contain one or more *neutrons* in addition to protons. The mass number of the neutron (1.00896) is almost identical with that of the proton (1.00813), based upon the arbitrary designation of 16 for the mass number of the commonest variety of oxygen. The number of neutrons in the nuclei of the atoms of a given element is not necessarily fixed, but may vary within narrow limits. Therefore the atoms of most elements contain nuclei with different numbers of neutrons, and consequently of different mass numbers. Each such atomic species, with a specific mass number as well as a specific atomic number, is called an *isotope*.

The complete symbol for any isotope includes the chemical symbol of the element preceded by the atomic number written as a subscript and followed by the mass number written as a superscript. Thus ordinary oxygen would be written  ${}_8\text{O}^{16}$ , ordinary carbon as  ${}_6\text{C}^{12}$ , and ordinary hydrogen as  ${}_1\text{H}^1$ . These elements also have less abundant isotopes such as  ${}_8\text{O}^{17}$ ,  ${}_8\text{O}^{18}$ ,  ${}_6\text{C}^{13}$ ,  ${}_1\text{H}^2$ , and  ${}_1\text{H}^3$ . Since the atomic number is implicit in the chemical symbol, it is more common practice to omit the subscript and simply write  $\text{O}^{16}$ ,  $\text{C}^{12}$ ,  $\text{H}^1$ ,  $\text{O}^{17}$ ,  $\text{O}^{18}$ ,  $\text{C}^{13}$ ,  $\text{H}^2$ , or  $\text{H}^3$  for the isotopes mentioned in the previous sentences. An equally logical but less often used system is to give the two numbers, omitting the chemical symbol.

Most elements exist in nature as mixtures of isotopes. The table on p. 971 lists the isotopes of the elements of major physiological significance. The proportions of the several isotopes in a naturally occurring sample of an element are, as a general rule, constant regardless of the source of the material. For example, the percentage of  $\text{O}^{17}$  is the same in atmospheric oxygen and in oxygen obtained by decomposition of ocean water or of silicate or carbonate rocks. Most of the naturally occurring isotopes listed in the table are stable, which means that they do not exhibit radioactivity as a result of spontaneous nuclear decay.

For any given element, with its fixed number of protons, there exists only a limited number of possible isotopes, each with its specific number of neutrons. Of these isotopes, still fewer possess stable nuclei. Among certain elements, usually those containing an odd number of protons, only one of the possible isotopes is stable. Sodium, phosphorus, and iodine are examples of such elements with only one stable isotope. Elements whose nuclei contain an even number of protons are likely to have more than one stable isotope. Tin, for example, has 10. As atomic nuclei increase in size and complexity, the proportion of neutrons required to maintain stability also increases. From the table on p. 971 we can see that iron (atomic number 26) requires 30 neutrons to stabilize its most common isotope; the neutron-proton ratio is 1.15. Iodine (atomic number 53) has for its stable isotope a neutron-proton ratio of 1.40, while the most complex of all stable elements is bismuth (atomic number 83), whose 126 neutrons give it a neutron-proton ratio of 1.52.

All nuclei more complex than that of bismuth, and many that are less complex, are unstable and undergo spontaneous changes in neutron-proton composition. Such changes constitute *radioactivity* and may occur in one or more of three ways:

*Alpha particles*, each consisting of 2 protons and 2 neutrons, may be emitted, resulting in a loss of 4 in mass number and of 2 in atomic number.

*Beta particles*, which are high-speed electrons, may be emitted, causing a gain of 1 in atomic number by the change of a neutron into a proton, and no change in mass number.

*Gamma rays*, which are electromagnetic radiations comparable to x-rays but more energetic and penetrating, may be emitted and cause no change in mass or atomic number. The production of  $\gamma$  rays, and the high velocities at which  $\alpha$  and  $\beta$  particles travel, are evidence of the release of *nuclear energy* previously stored in the bonds between protons and neutrons. Such nuclear energy is of an order of magnitude sufficient to permit its evaluation in terms of mass, according to the relationship demonstrated by Einstein, that  $9 \times 10^{20}$  ergs of energy are equivalent to 1 gram of mass.

When these energetic radiations impinge upon surrounding atoms or molecules, they not only produce chemical changes by altering the configuration of planetary electrons, but they also cause changes in nuclear structure, transmuting one element into another. The cyclotron and the atomic pile are devices for the production of high-energy radiations in high concentrations. By their use, radioactive isotopes can be prepared in useful quantities. Radioactive isotopes are now known for every chemical element. Both types of isotopes, stable and radioactive, have been useful in biological investigation. The two types require different procedures for their utilization and have different applicabilities. Each type will be considered separately.

## RADIOACTIVE ISOTOPES

Radioactive isotopes differ with regard to availability, half-life, and type of radiation emitted. Availability now appears to be largely a matter of technical development. The type of radiation emitted (kind and

intensity) influences the sensitivity and methods of measurement. The half-life of a radioactive element is the time required for one-half of the atoms to disintegrate. Isotopes with a very short or very long half-life are of less value than those with a half-life of the order of weeks or months. A short half-life means that too great a proportion of the original material will have lost its activity (and original chemical nature) during the time required for transport after preparation to the place of use, and for the manipulative details of an experiment. A very long half-life means that a high proportion of the isotope must be incorporated into a compound if accurate radioactivity measurements are to be made.

In contrast to the ordinary radioactive half-life defined in the preceding paragraph, we sometimes speak of the *biological half-life*, which is the time taken for a radioactive element within the body of a given organism to lose half of its activity. Elements which are firmly fixed in the body, such as plutonium in bone, have a biological half-life comparable to the ordinary half-life. Excretion of other radioactive elements causes a loss in total body radioactivity frequently more significant than the loss by radioactive decay.

**Measurement of Radioactivity.** Most methods for the measurement of radioactivity depend upon the fact that energetic  $\alpha$  or  $\beta$  particles can convert atoms or molecules of a gas to positive ions by displacing electrons from them. Each positive ion so formed is paired either with the free detached electron or with a negative ion formed by the union of the electron with another neutral atom or molecule. The number of such ion pairs formed per centimeter of the path of a particle is called its *specific ionization*. Gases can also be ionized by  $\gamma$  rays, which detach high velocity electrons from atoms or molecules in their path. These secondary electrons in turn produce ion pairs.

The *ionization chamber* can be used for the measurement of any type of ionizing radiation, but is particularly adaptable to  $\alpha$  particle counting. In its simplest form, an ionization chamber consists of two parallel conducting plates, usually about 1 cm. apart, mounted in a chamber containing a suitable gas, with provision for maintaining a potential difference across the plates and for measuring the current flow through the circuit. The radioactive material can be placed on the lower plate or alternatively the  $\alpha$  particles may enter the chamber through a thin window of mica. No current flows unless ionization of the gas is produced, when positive and negative ions will travel towards the oppositely charged plates. Within the range of voltage across the plates suitable for the individual instrument (usually 100 to 500 volts), every ion formed reaches the plates and causes an electrical impulse. The instrument is designed to take advantage of the high specific ionization of  $\alpha$  particles and to minimize the disadvantage of their short range. The ionizing chamber is usually used in connection with an amplifier and a mechanical counter, or a counting-rate meter. A *scaler* is a device used with mechanical counters to cut down, by a predetermined factor, the number of electrical impulses recorded. A *pulse analyzer* or "kicksorter" differs from a scaler in that it transmits only stronger impulses, eliminating the weak effects of  $\beta$  and  $\gamma$  radiation, and may also assort the transmitted impulses

according to strength and allot them to different counting circuits. In counting mixed radiations,  $\alpha$  particles may be screened out by a thin sheet of aluminum, and both  $\alpha$  and  $\beta$  particles by a thin sheet of lead.

In *proportional counters* the applied voltage is increased to a range (500 to 800 volts) where the electrons liberated in the primary ionization are given sufficient velocity to cause secondary ionization with formation of more electrons, which in turn are speeded up in the high-potential field, and so on. This results in a self-amplification of impulses known as the *Townsend cascade*, or *Townsend avalanche*. The degree of such self-amplification depends upon the applied voltage.

The Geiger-Müller counter utilizes a still higher voltage (800 to 1500 volts) with a greater degree of self-amplification and only minimal variation with small changes in applied voltage. The cascades produced under these conditions are likely to continue for some time after the entry of the initiating ionizing radiation, and so may merge with the impulses from subsequent rays or particles. To resolve individual impulses, some form of quenching is necessary, which may be internal by the use of polyatomic organic gases, or external by the use of resistances. An adequately quenched Geiger-Müller counter will resolve individual particles at rates less than 5000 per second. The probability of two or more impulses occurring during an interval too short for resolution can be calculated—the *coincidence correction*—for a given tube and a given counting rate. Geiger-Müller counters have been designed for all types of ionizing radiations, but are most suitable for  $\beta$  particles and  $\gamma$  rays.

*Scintillation counters* utilize the flashes of light produced, chiefly by  $\alpha$  particles, upon impact of the radiation upon zinc sulfide and certain other substances. The photomultiplier tube is used in counting circuits based on this principle. Still other types of counters are actuated by the change in electrical conductivity of certain crystals when exposed to ionizing radiations.

The activity of any radioactive source can be expressed in *curies*. The curie was originally defined as the quantity of radon in radioactive equilibrium with one gram of radium. It is now defined by the approximate equivalent,  $3.7 \times 10^{10}$  disintegrations per second. A millicurie, therefore, describes a radioactive source with  $3.7 \times 10^7$ , and a microcurie such a source with  $3.7 \times 10^4$  disintegrations per second. Another unit, the *rutherford*, defines the quantity of radioactive material that decays at a rate of  $10^6$  disintegrations per second. Note that these units refer to disintegrations, and not to particles or rays emitted. From measurements of radiation per unit time, expression of the results in curies or rutherfords requires a calculation of disintegrations per unit time utilizing the decay scheme (which may be quite complex) of the radioactive element in question. By measuring the ionization produced by any  $\gamma$  ray emitter, its source strength can be expressed in *roentgens per hour at one meter* (see p. 976) without knowledge of the disintegration scheme.

*Radioautography* is a method for detecting and measuring radioactive substances by the effect of their radiations upon the silver bromide of photographic emulsions. The action of light and of ionizing radiations upon the emulsion is comparable in that electrons are transferred from

bromide ions to silver ions, with formation of metallic silver—the latent image—around which the silver produced by further reduction in the developing process precipitates. A *radioautograph* is therefore produced by placing the radioactive material in close contact with a photographic emulsion. Light must of course be excluded, and direct chemical action of

the specimen upon the photographic emulsion may be obviated by interposing a thin layer of celloidin. Following adequate exposure, the photographic emulsion is developed, fixed, washed, and dried in the manner customary for ordinary photographic negatives. In histological studies, it is advantageous to have stained section and radioautograph superimposed for observation. Several techniques for this purpose have been described.<sup>1</sup> Figure 258 shows by radioautographs the comparative secre-

tory activity of the sublingual and the submaxillary glands in newborn rats.

**Biological Effects of Ionizing Radiations.** The unit in which exposure to x-rays or to  $\gamma$  rays is measured is the *roentgen*. The roentgen ( $r$ ) is defined as the quantity of x-rays or  $\gamma$  rays which will produce, by ionization, 1 electrostatic unit of electricity of either sign in 1 ml. of dry air measured under standard conditions of temperature and pressure. A more convenient equivalent definition for the roentgen is the amount of x-rays or  $\gamma$  rays which must be absorbed by 1 g. of air to cause it to gain 83.8 ergs of energy.

To include other types of ionizing radiations, such as  $\alpha$  and  $\beta$  particles, the *roentgen equivalent physical* or *rep* is defined as the quantity of ionizing radiation of any kind which, if absorbed by the soft tissues of the body, causes an energy gain per gram of tissue equivalent to that caused by 1  $r$  of x-rays or  $\gamma$  rays.

Since the absorption of 1 rep of one type of radiation might have a biological effect quite different quantitatively from that of 1 rep of another type, the *roentgen equivalent man* or *rem* is defined as the quantity of radiation of any type which produces the same amount of damage in man upon absorption as 1  $r$  of x-rays or  $\gamma$  rays. For x-rays,  $\gamma$  rays, and  $\beta$  particles, 1 rep equals approximately 1 rem, but for  $\alpha$  particles, 1 rep equals 10 to 20 rem.

The combined experience and experiments of medical radiologists and of the physicists charged with the protection of workers handling radioactive materials has led to the tentative conclusion that the *total permissible dose* of all kinds of ionizing radiation is 0.3 rem per week over the whole body. In defining this dose, it is understood that very concentrated whole body exposure for short times is dangerous even within the limits of the permitted amount per week. Larger doses, up to 1.5 rem per week, may be permitted if exposure is limited to hands and forearms.

Neutrons are emitted at high velocity from atomic explosions and in nuclear reactors. Such "fast neutrons" possess high energies but limited powers of penetration. When fast neutrons interact with tissue, they are first slowed down by collisions with nuclei, predominantly those of hydrogen, which are thereby detached from their molecules and stripped of orbital electrons. In this manner, fast neutrons are actually ionizing radiations. When the velocity of the neutrons is cut down by repeated collisions, the neutrons may be captured by ordinary atomic nuclei, bringing about nuclear transformations. Neutron capture may result in the ejection from the nucleus of energetic protons, or in the emission of  $\gamma$  rays accompanying the formation of deuterium in the case of hydrogen, and in other instances the formation of radioactive isotopes. All of these nuclear transformations are further sources of ionizing radiation, which are spoken of collectively as *induced radioactivity*.

Since water is the substance present in greatest amount in the majority of living cells and organisms, the effect of ionizing radiations upon water is of considerable importance. Detachment of an electron from water leaves a positive water ion ( $\text{H}_2\text{O}^+$ ) which can react with an intact water molecule to yield a hydrated hydrogen ion and a free hydroxyl radical.<sup>2</sup>

<sup>2</sup> Weiss: *Nature*, 153, 748 (1944).

The detached electron can also react with a water molecule, yielding a hydroxyl ion and a hydrogen atom:

The ions react together to form water molecules again. Some of the hydrogen atoms unite to form hydrogen molecules. Some of the free hydroxyl radicals unite to form hydrogen peroxide. A hydrogen atom may unite with a hydroxyl radical to form water. Thus radiation of pure water forms hydrogen and hydrogen peroxide.

If the water contains dissolved oxygen, it will combine with hydrogen atoms, increasing the yield of hydrogen peroxide, and forming perhydroxyl radicals:

Among the substances which have been shown to diminish the destructive effect of ionizing radiations upon solutions of enzymes or upon living cells, cysteine and other substances containing the sulfhydryl group are noteworthy. The sulfhydryl group can reduce hydroxyl radicals, hydrogen peroxide, and perhydroxyl radicals,<sup>3</sup> thus removing from aqueous solutions these products of ionizing radiation. The other product, hydrogen atoms, is removed indirectly through the formation of perhydroxyl radicals (in the presence of dissolved oxygen, see equation above).

The lethal effects of radiation result chiefly from the destruction of the more susceptible cells (all types of blood and epithelial cells) and the failure to form new cells to replace them. Death after a single heavy exposure is usually delayed weeks or months, during which time blood cell counts fall and ulcerations of epithelia develop. The symptoms which appear promptly after heavy irradiation—the *initial radiation response* or *radiation sickness*—do not necessarily indicate a lethal exposure. Gastrointestinal upset and lowered blood pressure may occur even after heavy x-ray dosage within the therapeutic range, particularly if applied to the abdomen. Possible mechanisms to explain this prompt reaction are the liberation of VDM (to be discussed later) and direct effects of radiation on the autonomic nervous system. The damaging effects of ionizing radiations upon tissues can be demonstrated histologically.<sup>4</sup> The clearest results are obtained in specimens prepared by freezing-drying, then cut and mounted dry. Vacuoles appear within the cell nuclei of tissues which have been subjected to radiation. In cells such as lymphocytes, which are sensitive to radiation, the vacuoles distend and eventually rupture the nucleus. In more resistant cells, the vacuoles formed are smaller, and are later extruded through the nuclear membrane without necessarily destroying the cell.

The well-recognized *genetic effect* of sublethal exposures to ionizing radiations is an increase in the rate of occurrence of mutations. It has not been definitely established whether this effect is chemical (upon the

<sup>3</sup> Swallow: *J. Chem. Soc.*, 1334 (1952).

<sup>4</sup> Warren, Holt, and Sommers: *Am. J. Clin. Path.*, **22**, 411 (1952).

nucleoprotein molecule) or mechanical (upon the chromosome). The genetic effect of radiations has been shown to be cumulative, depending more upon the total radiation received by the experimental plant or animal than upon the intensity of the radiation. Data relating amount of radiation to genetic effects in man are not available. Sterility can be produced by ionizing radiations in sublethal doses.

The amount of energy expended in producing the lethal effects of ionizing radiation in living cells is very small, less than one-millionth of the cell's normal daily expenditure of energy in metabolic processes.<sup>5</sup> It is therefore evident that damage to key substances, such as enzymes or nucleic acids, by ionization must be postulated to explain the destructive action of relatively minute amounts of energy. Sulfhydryl enzymes are particularly susceptible to inactivation by radiation, even *in vitro*.<sup>6</sup> One chemical mechanism by which tissue damage from radiation is known to take place is the formation of peroxides. Two-thirds of the total biological effect of exposure of *Paramecium aurelia* to x-rays could be attributed to peroxide formation in the medium, since it could be abolished by catalase and could be duplicated by adding  $H_2O_2$  to the medium without radiation.<sup>7</sup>

Ionizing radiation also brings about the release within the circulating blood of a toxic substance which causes severe peripheral vasodepression. The behavior of this substance is like that of a similar substance liberated in traumatic shock. This substance was first designated simply as VDM (vasodepressor material), but was later identified as ferritin. By several criteria based upon physiological action, ferritin and the VDM of irradiated animals are identical.<sup>8</sup> A vasoexcitor material which has not been identified chemically, has been reported in situations of reversible shock and in animals that survived into the second week following irradiation.

**Radioactive Tracers.** Physiological chemists have repeatedly sought a means of placing an identifying tag or label upon a particular sample of a foodstuff, drug, or intermediate and following it through its metabolic transformations in a living organism. Knoop used such a tracer in his studies of fatty-acid oxidation when he substituted the phenyl group on the omega carbon atom of fatty acids. Elaidic acid, the *trans* isomer of oleic acid, has been similarly used. In both these instances, the pathway of the tracer substance was found to be not identical in all metabolic sequences with that of the natural substance under investigation.

The use of tracer substances identical with the corresponding natural substances except for one or more radioactive isotopic atoms in the molecule has obviated this difficulty. The tagged atoms can be identified by their radioactivity, whatever the compounds may be into which they are introduced by metabolic activities. Such tracer substances can be prepared by ordinary chemical synthesis, or in some instances more efficiently by biosynthesis, using as starting material radioactive isotopes obtained by the use of the cyclotron or the nuclear reactor. The fundamental

<sup>5</sup> Hempelmann, Lisco, and Hoffman: *Ann. Internal Med.*, **36**, 279 (1952).

<sup>6</sup> Barron, Dickman, Muntz and Singer: *J. Gen. Physiol.*, **32**, 537 (1949).

<sup>7</sup> Kimball and Gaither: *Proc. Soc. Exp. Biol. Med.*, **80**, 525 (1952).

<sup>8</sup> Haley: *Trans. N. Y. Acad. Sci.*, Ser. II, **14**, 303 (1952).

postulate in metabolic studies with radioactive tracers is that the chemical changes undergone by the radioactively tagged molecule during its metabolism are the same as those of the corresponding untagged natural substance. This postulate is valid if, and only if, two important experimental conditions are maintained: (a) radioactivity must be kept at a level low enough not to cause disturbance of cell metabolism, as for example by inactivation of enzymes; and (b) the tracer substance must be given in amounts not large enough to exceed physiological concentrations in the organism. The latter condition can be purposely waived if the study involves the effects of unusual concentrations or unphysiological substances.

Hevesy<sup>9</sup> made the first biological application of radioactive tracers. He followed the absorption and distribution of lead in plants with thorium B (in modern terms,  $\text{Pb}^{212}$ ), a naturally occurring radioactive isotope of lead. The choice of available radioactive isotopes at that time was, of course, extremely limited. Currently the nuclear reactor and the cyclotron make available a large number of radioactive isotopes of elements significant in biology. The radioactive isotopes most useful in present metabolic studies are  $\text{C}^{14}$ ,  $\text{H}^3$ ,  $\text{P}^{32}$ ,  $\text{Na}^{24}$ ,  $\text{I}^{131}$ ,  $\text{Fe}^{55}$ ,  $\text{Fe}^{59}$ ,  $\text{S}^{35}$ , and  $\text{Co}^{60}$ . Procurement of radioactive isotopes for experimental work requires the authorization of the Atomic Energy Commission. No useful radioactive isotopes exist for two very important elements, oxygen and nitrogen. Tracer work with these elements must therefore be done with the stable isotopes,  $\text{O}^{18}$  and  $\text{N}^{15}$ .

Although samples of pure radioactive isotopes can be isolated (with considerable difficulty), the material used for preparations of tracer substances is almost invariably a mixture of the desired radioactive isotope with stable isotopes of the same element. The *specific activity* of a sample is defined as the number of atoms of the specified radioactive isotope divided by the total number of atoms of the same element. (Unfortunately, the term *specific activity* is also used to mean curies per gram of the element specified. The reader must distinguish these two different quantities by the units used.)

An important consideration enters here into the interpretation of results obtained with labeled organic molecules. If the isotopic element is in a labile position—i.e., if it can enter readily into exchange reactions with the solvent or with other elements in the molecule—interpretation is obscured. For example, an organic acid labeled with deuterium in the ionizable portion of the carboxyl group may exchange with the nonisotopic hydrogen of water present to render the labeling valueless as a means of identifying the compound:

Thus a stably bound isotope is of more value in this connection than a labile one, and due consideration must be given to this fact. It should be pointed out that some positions in organic molecules are stable *in vitro* but may become labile *in vivo*. Thus the  $\alpha$ -amino nitrogen of an amino

<sup>9</sup> Hevesy: *Biochem. J.*, **17**, 439 (1923).

acid may be stable, but may become detached by metabolic processes so that the remainder of the molecule is no longer identifiable in terms of isotope content:

Thus, although this type of labeling permits following the course of the nitrogen metabolism, it is valueless as a guide to what happens to the remainder of the molecule after deamination; for this purpose, the carbon chain should contain isotopic carbon, preferably in as many positions as possible, or stably bound deuterium may be present.

Measurements of blood volume and extracellular fluid volume have long been made by nonisotopic dilution methods involving the injection of some substance foreign but harmless to the body. A known amount was injected, time allowed for equilibration, and the concentration measured in the blood plasma. With a substance such as the dyestuff T 1824 (Evans blue), which escapes but slowly from the blood vascular system, a close estimate of blood plasma volume is possible. With soluble bromides or thiocyanates, which diffuse through all extracellular fluids but do not significantly enter cells, extracellular fluid volume can be measured. For this latter type of measurement the use of radioactive  $Br^-$  permits the use of very small doses and avoids the pharmacological effects of this ion. For blood volume determinations, the use of red cells tagged with radioactive phosphorus obviates the errors inherent in the dye method. For measurement of total body water, deuterium oxide is the indicator of first choice, since it mixes freely with body water and traverses all cell boundaries. Its chief disadvantage is the special instrumentation required for its measurement (see "Stable Isotopes," below). Heavy water is toxic, but not in the low concentrations (0.2 atoms per cent deuterium) used in such studies. A minor error arises from exchange of deuterium and from its incorporation into organic molecules. This error has been estimated at less than 1.5 per cent.<sup>10</sup>

## EXPERIMENTS ON RADIOACTIVE ISOTOPES

**Determination of Blood Volume:**<sup>11</sup> **Principle.** The determination of blood volume in rabbits is accomplished by incubating blood cells from the animal with 80 to 100 microcuries of  $P^{32}$  labeled phosphate for 45 to 60 minutes at 37° C. Approximately 10 per cent of this activity is absorbed by the cells, which are then washed, reconstituted to volume, and injected into the animal. After an interval for distribution of the labeled cells throughout the circulation, a blood sample is withdrawn for counting. The dilution of the activity of the cells (the volume of the whole blood) is obtained by dividing the activity of the injected cells by that of the blood withdrawn.

The relative simplicity of the experiment allows for total working space on one 24-inch by 30-inch table. This is covered with a large blotter so that any spilled active material may be readily discarded. Special apparatus consists of a basic scaler and Geiger-Müller counter with a shielded manual sample changer. The counting apparatus is kept on a table separate from the working area. The radiation hazard is

<sup>10</sup> Edelman, Olney, James, Brooks, and Moore: *Science*, **115**, 447 (1952).

<sup>11</sup> Kelly, Simonsen, and Elman: *J. Clin. Invest.*, **27**, 795 (1948), modified for use with rabbits by Dr. Fabian Lionetti.

minimal to the animal or to the experimenters, as shown by Reid and Orr,<sup>12</sup> who give data for 100 humans with average uptake of the cells amounting to 7 per cent of the 50 to 100 microcuries incubated, with the largest single uptake 19.5 per cent. In calculating the hazard when the activity was injected into a human, they assumed a 20 per cent uptake in a 50-kg. individual. This would calculate to 0.07 rep for approximately one week, which would diminish to 0.035 rep in two weeks (14.3 days half-life). This calculated value is deliberately high, for it assumes no excretion, but is yet a small fraction of the normally permissible 0.3 rem. With but small precaution, therefore, no radiation hazard is encountered. Indeed, it is probable that the students are exposed to greater dangers in their other experiments by handling corrosive acids and hot solutions. As a means of illustrating fully the manner of working with isotopes, students may characterize the radiophosphorus they use by calibrating its millicurie strength against a set of simulated reference standards. They may also count a sample daily for two minutes, for seven or more successive days, in order to calculate the half-life of the  $P^{32}$  used and thus identify it. This also affords a check on the purity of the isotope shipment, and acquaints the student with the main remaining features of low-energy isotope experimentation.

**Procedure.** All glassware should be siliconed and dried. To all Cutler or similar tubes, a pinch of heparin (gauge by tip of spatula) should be added.

(a) **PREPARATION OF TAGGED CELLS.** To two 15-ml. centrifuge tubes approximately 1.5 to 2 ml. of acid-citrate-dextrose solution (ACD)<sup>13</sup> is added. Using a syringe wet with ACD, 20 to 30 ml. of blood is taken from a rabbit by cardiac puncture. Between 5 and 8 ml. of the blood is placed in one and the rest in the other centrifuge tube. These are covered with parafilm and inverted 20 to 30 times to prevent clotting. Both tubes are placed in the incubator at 37° C. until ready for use, and inverted intermittently. To the tube containing 5 to 8 ml. blood, add 80 to 100 microcuries  $P^{32}$  in volume less than 1 ml. (to maintain isotonicity). The tubes are inverted 5 to 10 times and returned to the incubator for 45 to 60 minutes. Invert the tubes 10 times approximately every 5 minutes. Care is required to avoid shaking the tubes. At the end of the incubation time, the cells are spun down in a refrigerated centrifuge at 2000 r.p.m. for 15 minutes. The fluid is removed with a capillary pipet and replaced with cold ACD to the original volume. Recentrifuging and reconstituting to volume is repeated 3 times, mixing being done by careful inversion 20 to 25 times. If slight hemolysis is observed during the washing, it is advisable to eliminate the final one or two washings. After removal of the third washing, the volume is replaced to original with cold ACD. The tube is inverted gently 20 to 25 times or more, and placed in the icebox until ready for use.

(b) **PREPARATION OF THE TAGGED CELLS FOR COUNTING INITIAL ACTIVITY.** Since the tagged cells are too active to count conveniently, they are diluted serially with inert blood. Into each of 4 small test tubes containing heparin place 3 ml. of blood. Care is required to prevent clotting. The pipet should be previously rinsed with ACD. To the first tube is carefully added exactly 1 ml. of the tagged red cells (making sure that the cells are well mixed before the addition). The tagged cells in the first tube have thus been diluted 4 times.

<sup>12</sup> Reid and Orr: *J. Clin. Invest.*, **29**, 313 (1950).

<sup>13</sup> ACD (*Acid-Citrate-Dextrose Solution*).

|                              |                     |
|------------------------------|---------------------|
| Trisodium citrate . . . . .  | 2.20 per cent (w/v) |
| Citric acid . . . . .        | 0.80 per cent       |
| Anhydrous dextrose . . . . . | 2.25 per cent       |

It is advisable to make up the solution in 500-ml. lots, and to keep it stoppered and refrigerated.

One ml. of the 1:4 suspension in the first tube is now removed and added to the second tube containing 3 ml. of untagged blood; this gives a 1:16 dilution. Transfers are continued until the fourth tube is prepared containing a 1:256 dilution of the initial 1 ml. of tagged cells. Mix carefully by drawing blood into and expelling it from the pipet 15 to 20 times. A pair of 1-ml. portions of the final dilution is placed in the planchet for counting. To each is added a drop of 1 per cent detergent solution (Duponol) to facilitate spreading in the planchet.

(c) INJECTION OF RADIOACTIVE CELLS. The rabbit is weighed and placed in a box with a cover so notched as to allow the head and ears to protrude. Both ears are shaved along the marginal ear veins. The tagged cells are removed from the icebox and inverted to mix them well. One ml. is drawn into a tuberculin syringe and all air bubbles are removed. Holding the right ear tightly, introduce the needle into the right marginal vein. Once in the vein, the needle is extended to the hilt. If the needle slides easily with little friction, the left thumb is placed over the needle and held securely, in order not to withdraw the needle if the animal moves its head. Inject the cells slowly. They are infused readily if the needle is in the vein. The needle is then withdrawn and the site clamped with the bulldog clamp. After 20 minutes of equilibration in the rabbit, a sample is obtained for counting by making a nick in the left marginal ear vein. Preliminary treatment with xylol or toluene on the surface of the ear may be used to promote a more rapid flow. Several ml. of blood are collected in a heparinized tube and 1 ml. is pipetted into a planchet. Five drops of Duponol (ca. 1 per cent) is added. The planchet of diluted tagged cells (1:256) and the one prepared from the animal are incubated at 37° C. to dryness (overnight). A third sample of untagged whole blood is similarly prepared for taking background counts. If it is necessary to save time, the wet samples may be counted, but the counts are less reproducible and less accurate.

(d) PACKED CELL VOLUME. This part of the procedure is necessary only if plasma volume is to be determined. The plasma volume is found from the whole-blood volume by a hematocrit determination, finding the plasma fraction of the whole-blood volume. The tube with the remainder of the blood is spun at 2500 to 3000 r.p.m. for 60 minutes. The top level of the plasma at the meniscus is read. The level of the packed red cells is noted, ignoring the buffy coat. The second decimal is estimated in the reading.

CALCULATION. The instrument background  $B$  is measured in counts per minute, using the sample of inert blood. The background count  $B$  is subtracted from the counts of both the experimental and injected samples. The experimental samples withdrawn from the animal are counted for a time interval corresponding to several thousand counts, and the activity in counts per minute is recorded ( $E$ ), after subtracting  $B$ . The activity of the injected sample  $I$  is found from the count (corrected for background) of the diluted tagged blood  $D$  multiplied by the dilution factor 256, thus

$$I = D \times 256$$

The whole-blood volume (WBV) in milliliters is therefore

$$\text{WBV} = \frac{I}{E}$$

## RADIOACTIVE ISOTOPES IN MEDICINE

Ionizing radiation has been applied with increasing skill and success to destroy tumors or other undesired tissues. Radioactive isotopes in

general are applicable as sources of ionizing radiation for this purpose. Certain radioactive isotopes are concentrated by physiological mechanisms in certain cells or tissues—I<sup>131</sup> in the thyroid, P<sup>32</sup> in blood cells—just as the normal stable isotopes of these elements are so concentrated. In this manner, ionizing radiation can be localized to certain tissues for their destruction when they have become neoplastic. After administration of P<sup>32</sup> by mouth or intravenously (in the form of a phosphate), it is taken up first by the red cells, with concentrations in white cells increasing after the second day. In leukemic patients who have received P<sup>32</sup>, after one week the isotope concentration in leukocytes is four to five times that in red cells.<sup>14</sup>

Smaller doses of radioactive isotopes may be used in diagnostic studies. The amount of I<sup>131</sup> in the thyroid gland of a human patient can be estimated by a measurement made externally over the thyroid region by a 4-tube Geiger-Müller counter.<sup>15</sup> If an oral tracer dose containing 100 to 150 microcuries of I<sup>131</sup> is given, 30 or 40 per cent of it should be demonstrable in the thyroid gland on the next day in patients with normal thyroids. Hyperthyroidism is characterized by higher uptake of iodine—around 70 per cent, while in hypothyroidism the uptake is low—around 12 per cent as measured under similar conditions. Administration of I<sup>131</sup> in larger amounts is utilized for the destruction by radiation of cancerous thyroid tissue, or in reducing the activity of the gland in hyperthyroid patients. This form of treatment brings about results comparable to surgical removal of the thyroid, in whole or in part according to the dosage of the radioactive material.

## STABLE ISOTOPES

Most of the common elements as ordinarily encountered in nature consist of mixtures of stable isotopes. Thus ordinary oxygen consists of the three stable isotopes O<sup>16</sup>, O<sup>17</sup>, and O<sup>18</sup>, in the proportion respectively of 99.76, 0.04, and 0.20 per cent. More than 200 stable isotopes of the various elements have been recognized as existing, but only a very few have been obtained in concentrated form. To obtain the separate isotopes from a mixture, or fractions relatively enriched with respect to one isotope, advantage is taken of properties such as diffusion or reaction velocity which may vary with mass differences. Thus a water molecule containing O<sup>18</sup> will be heavier than one containing O<sup>16</sup>, and the two types may be separated by controlled fractional distillation. By such methods or their equivalent, the stable isotopes H<sup>2</sup> (deuterium), C<sup>13</sup>, N<sup>15</sup>, O<sup>18</sup>, and S<sup>34</sup> have been made available for biological investigation. The first of these to become available in amount sufficient for investigative purposes was deuterium, first obtained by Washburn and Urey in 1932 by the fractional electrolysis of water. It was in fact the availability of deuterium which suggested to the imaginative genius of Schoenheimer and Rittenberg the possibility of its use in biological investigations, a concept which may be said to have initiated the present phase of application of isotopes to biological problems.

<sup>14</sup> Duffy and Howland: *N. Y. State J. Med.*, **52**, 551 (1952).

<sup>15</sup> Freedberg, Chamovitz, and Kurland: *Metabolism*, **1**, 26 (1952).

The chief application of the stable isotopes in biological investigation is for the purpose of labeling or tagging a molecule or part of a molecule. The stable isotopes have the advantage over the radioactive type in that the time of preparation of the compound incorporating the isotope, or the duration of the experiment, are of no importance; there is no question concerning the possible effect of radiation on the experiment; and in some instances the isotope may be recovered at the end of the experiment and used again. Disadvantages relative to radioactive isotopes include the increased difficulty of measurement; the necessity for a higher concentration, since measurements of radioactivity are far more sensitive than measurements of mass; and the relatively few stable isotopes available.

With the exception of deuterium, the stable isotopes are measured with an instrument called the mass spectrometer. The principle upon which this instrument operates is illustrated diagrammatically in Fig. 259. The sample in the form of a gas, e.g.  $\text{N}_2$ ,  $\text{CO}_2$ , is admitted to a highly evacuated chamber across which a stream of electrons is flowing. An electron colliding with a gas molecule causes it to become ionized, e.g.  $\text{CO}_2 \rightarrow \text{CO}_2^+$ . The gas ions so formed are accelerated by suitable means to produce a stream of ions which passes along the tube shown and through a powerful magnetic field, so arranged as to deflect the ion from its initial path. On leaving the magnetic field, the ions pass to a collector plate and produce an ion current which is what is actually measured as an index of the number of ions striking the plate. Ions of different mass, e.g.  $\text{C}^{12}\text{O}_2^+$  and  $\text{C}^{13}\text{O}_2^+$ , may be differentiated by either varying the strength of the magnetic field, or more commonly this strength is held constant and the accelerating voltage is varied. Results are obtained in the form of a graph relating ion current to accelerating voltage. Isotopic ions differ on such a graph in their position along the voltage scale (which can be converted into mass, since a constant relation exists between these two quantities); the ratio of one isotope to another is given by the ratio of ion currents at the respective points on the mass (voltage) scale. It is this ratio of isotopes which is ordinarily desired—i.e., the relative abundance for example of  $\text{C}^{12}$  over  $\text{C}^{13}$  in the sample as compared to their relative amounts in ordinary nonisotopic compounds.

The measurement of deuterium is a special case. It may of course be measured with the mass spectrometer, but equally satisfactory results can be obtained by converting the deuterium to the form of water (as by burning the sample in oxygen) and determining the specific gravity of the water so produced. There is a predictable relationship between the specific gravity of the water and its content of *heavy water*,  $\text{D}_2\text{O}$ . A common method for determining specific gravity is the *falling drop method*, in which the time required for a drop of water to fall through a definite distance in a nonaqueous solvent is measured. This method is capable of high accuracy.

The isotope content of compounds labeled with the stable isotopes usually is expressed in terms of *atoms per cent* of isotope. For example, if a substance contains 12 hydrogen atoms, and one of these is replaced by deuterium, the isotopic content will be  $1/12$ , or 8.3 atoms per cent.

This is subject to some correction, since an ordinary “nonisotopic” compound contains a certain proportion of isotopes in accordance with their normal abundance. The excess of a given isotope over that normally present is referred to as *atoms per cent excess*, a more satisfactory term when dealing with variations in the isotope content of compounds.

FIG. 259. OPERATION OF THE MASS SPECTROMETER TUBE: IDEALIZED VIEW.

The ion beam is projected into the tube and deflected by the magnetic field. The separation of the ions of different masses is indicated by the variance in the radius of curvature of the gray- and black-arrow beams in the area of the magnetic field.

Courtesy, Westinghouse *Engineer*.

A special problem arises in connection with the use of deuterium in metabolic tracer studies. Deuterium has twice the atomic weight of ordinary hydrogen, and hence diffuses more slowly and will slow down reaction rates. Differences in atomic weight exist (by definition) among all isotopes of a given element, but in no other instance is the difference nearly as great proportionately.

**Analysis by Isotope Dilution.** Stable or radioactive isotopes may be used in chemical analysis in instances where other methods fail or

account of lack of specificity, as for example in the assay of culture filtrates of *Penicillium chrysogenum* for penicillin G to the exclusion of other penicillins. Four steps are involved in such an isotope dilution assay: (a) a tracer sample of the compound to be determined (e.g., penicillin G) is prepared with a known isotopic content, and with the isotopic atom in a position which will not exchange; (b) a known quantity of this isotopically tagged compound is isolated in a state of purity, but not necessarily quantitatively; (c) the isotopic content of the isolated sample is determined. By comparison of this figure with the isotopic content of the tracer sample prepared in step (a), and knowing the proportions in which the mixture in step (b) was made, the quantity of the substance in the unknown sample (e.g., penicillin G in the culture filtrate) can be immediately calculated. If the isolated sample has the same isotopic content as the tracer sample, the quantity in the unknown was zero. If the isolated sample has half the isotopic content as the tracer, the quantity in the unknown was equal to that in the tracer added; if one-third, equal to twice that added; one-fourth, equal to three times that added, and so on. In general, if the isotopic content of the isolated sample is  $x$  per cent of the original, the quantity in the unknown is  $\frac{100 - x}{x}$  of the quantity added.

## Carbohydrate, Fat, and Protein Metabolism

### GENERAL

The components of a normal mixed diet which supply all the requirements of the animal body for growth and maintenance include proteins, fats, carbohydrates, the various vitamins, water, and certain inorganic elements. In the present chapter are considered some of the nutritional requirements for proteins, fats, and carbohydrates, and the changes which these substances undergo subsequent to their digestion and absorption into the animal body. The energy metabolism of these substances has been considered in Chapter 25. Brief discussions concerning certain metabolic phases are also found in the chapters dealing with the urinary constituents and in other connections. The questions of mineral metabolism, water, and the vitamins are discussed in subsequent chapters.

Throughout the discussions which follow, frequent mention will be made of the use of isotopes, which have proved such valuable tools in the study of intermediary metabolism and nutrition. The isotopes themselves and their use in biology are discussed in Chapter 32. Adequate entrance to the voluminous literature of intermediary metabolism and nutrition is afforded by the footnote references and the reviews and special articles listed in the bibliography at the end of this chapter.

### CARBOHYDRATE METABOLISM

Carbohydrates supply the major portion of the daily energy requirements of the normal individual; on an ordinary diet more than half of the total daily calories usually come from this source. In addition to being oxidized as a source of energy, carbohydrates may be transformed to glycogen, supply the carbon chain for certain amino acids, or be converted into fat. Of these various processes, glycogen formation and breakdown appears to occupy a central position.

**Glycogen Formation and Breakdown (Glycogenesis and Glycogenolysis).** Glycogen is found in practically all of the tissues of the body, but in varying amounts; the glycogen content of the brain, for example, is so low as to require special care for its detection. The muscles and liver contain most of the glycogen of the body, largely because of their bulk relative to that of the other tissues. Glycogens from various tissues—e.g., muscle glycogen, liver glycogen—appear to be chemically similar if not identical but to have markedly different physiological significance. Thus the glycogen content of muscle is relatively constant in the absence

of exhaustive muscular contraction and is little affected by starvation or the nature of the diet, which may produce variation in the liver glycogen content from a mere trace to upward of 8 per cent of the weight of this organ.

Glycogen, therefore, may have both a functional and a storage significance. The capacity of the animal to store carbohydrate as glycogen is relatively limited, however, as contrasted with its capacity to store fat. The adult human body may contain about 300 g. of glycogen, of which only that fraction found in the liver (normally about one-half of the total) represents a significant source of carbohydrate for general metabolic purposes. Fasting for a few days is usually sufficient to deplete the animal of all available stored carbohydrate. Any carbohydrate metabolism in a fasting animal after the exhaustion of stored carbohydrate is due presumably to synthesis of carbohydrate from noncarbohydrate precursors (gluconeogenesis).

Major precursors of liver glycogen within the animal body include the glucose, fructose, and galactose (but not pentose) produced by carbohydrate digestion in the intestinal tract; the glucose and lactate of the blood; the glycerol portion of the fats of either the diet or the body; and certain amino acid constituents of the proteins of either the diet or the tissues which are capable of being converted into glucose and hence into glycogen. Precursors of muscle glycogen include the glucose of the blood and, to an extent which is still debatable, the lactic acid produced from glycogen itself during muscle contraction. These various interrelationships with regard to liver and muscle glycogen may be summarized in the following diagram, adapted from Cori:

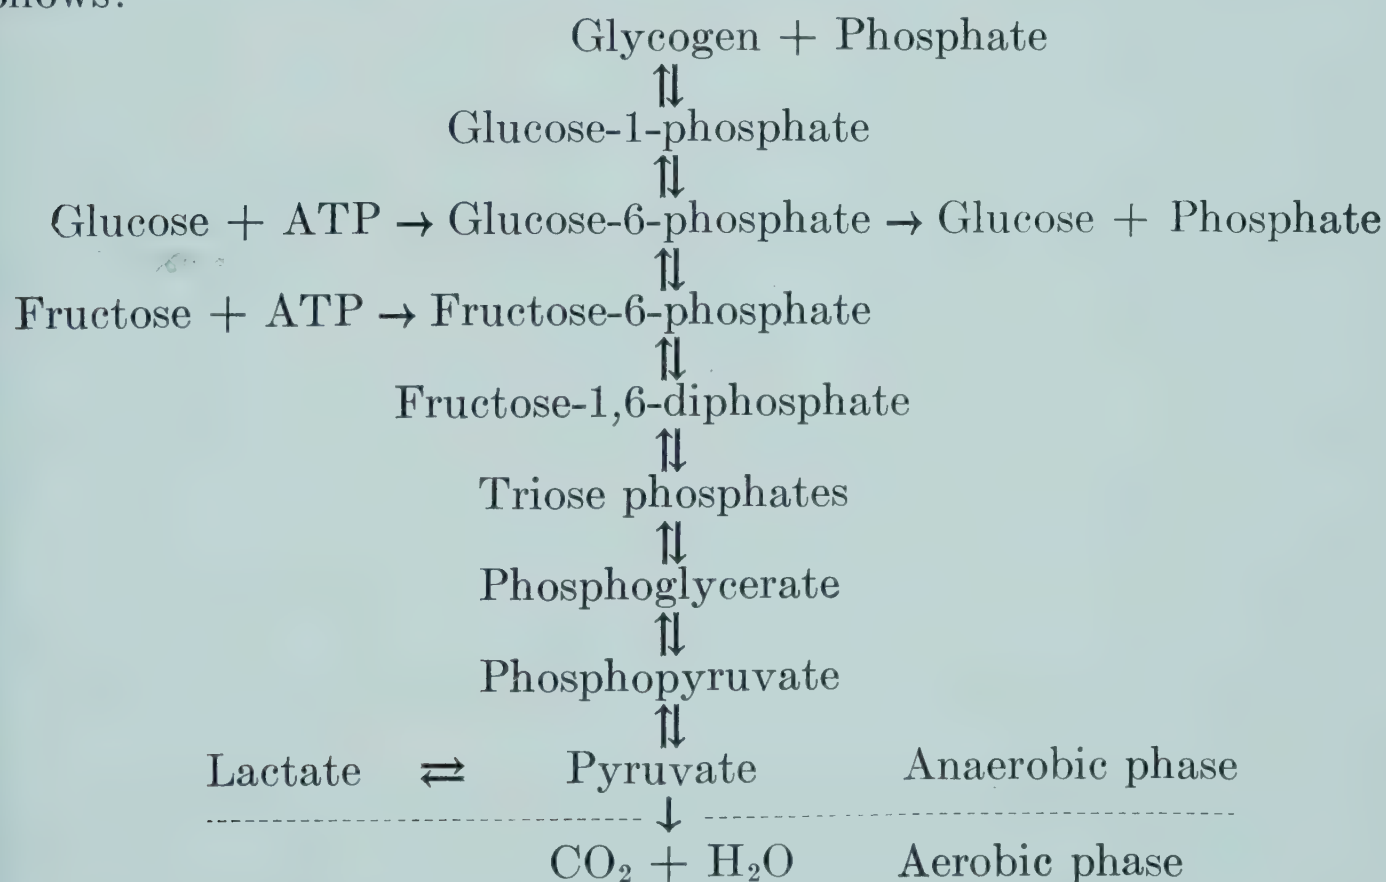

Knowledge that a particular substance is a precursor of liver glycogen, for example, usually has been obtained by demonstrating that an increased liver glycogen content follows the feeding of the test substance. Perfusion of the isolated organ and incubation with surviving liver slices also have been used. It has generally been assumed that if glycogen formation occurred, the test substance was directly incorporated into the newly formed glycogen. That the situation is not quite as simple as this has been unequivocally demonstrated by the use of glycogen precursors labeled with radioactive carbon. For example, if lactate labeled with radioactive carbon is fed to animals whose liver glycogen has been depleted by fasting, and the newly formed glycogen which results from the lactate feeding is subsequently isolated, only a fraction of this glycogen proves to contain the isotope label. Furthermore, the isotope is found distributed among the various carbon atoms of the glucose residues in the labeled glycogen in such a way as to indicate that the fed lactate had entered into other reactions before some of the carbon atoms became

incorporated into glycogen. Similar results have been obtained with glucogenic amino acids labeled with isotopic carbon. If glycogen formation is stimulated by glucose or lactate feeding in the presence of radioactive carbon dioxide (as bicarbonate), the radioactive carbon is also found in the glycogen subsequently isolated. Thus glycogen formation and breakdown is a complicated and continuous process within the body; according to Stetten,<sup>1</sup> the half-life of rat-liver glycogen is but one day. The accumulation of glycogen in the presence of an apparent precursor may be due only in part to direct utilization of the precursor itself, or may even represent a "sparing" action on glycogen metabolism without any direct connection with such metabolism.

Knowledge concerning the intermediate steps in glycogen formation and breakdown has been obtained largely with tissue preparations or isolated enzyme systems. Much of this work has been done with either muscle or liver; it is believed that conclusions drawn from such studies are generally applicable, in principle if not in specific detail. The various reactions known to be concerned in glycogen formation and breakdown may be divided into two phases, anaerobic and aerobic, summarized as follows:

Many of these reactions already have been discussed in detail in Chapter 10 in connection with the chemistry of lactic acid formation in muscle, and the chemical structures of the various intermediate compounds also will be found there.

It will be noted that the immediate chemical precursor of glycogen is the compound glucose-1-phosphate (the *Cori ester*). The enzyme catalyzing the reversible reaction between glycogen, inorganic phosphate, and glucose-1-phosphate is known as *phosphorylase*. The equilibrium in this reaction is in favor of glycogen; the direction of reaction appears to be determined largely by the concentration of inorganic phosphate. In the presence of excess inorganic phosphate, glycogen breakdown occurs; for

<sup>1</sup> Stetten and Boxer: *J. Biol. Chem.*, 155, 231, 237 (1944).

glycogen synthesis, it is necessary to keep the inorganic phosphate content low. This apparently is done in the cell by oxidative processes which incorporate the phosphate into phosphate esters, some of which are intermediates in the series of reactions shown. There is thus in effect a *phosphate cycle* (Cori), whereby inorganic phosphate liberated by glycogen formation is used to phosphorylate other compounds which, in turn, can give rise to glycogen and inorganic phosphate again.

For free glucose (or fructose) to be converted into glycogen by the reactions shown, phosphorylation is necessary. This phosphorylation—leading to the formation of either glucose-6-phosphate or fructose-6-phosphate, as the case may be—requires the presence of the “high energy phosphate” of adenosinetriphosphate (ATP), and of enzymes of the hexokinase type. In liver these enzymes are known as glucokinase and fructokinase; similar enzymes are found in muscle. In brain tissue there appears to be only one enzyme which, like yeast hexokinase, acts upon both glucose and fructose. The hexokinase enzymes, or at any rate their activities, are apparently under the control of certain hormones, as discussed on p. 1000, and knowledge concerning this control may prove to be of fundamental importance in understanding certain phases of carbohydrate metabolism.

After phosphorylation, glucose becomes available for either glycogen formation, reconversion to glucose, or breakdown to lactic acid anaerobically or complete oxidation aerobically. Reconversion to glucose is due to the enzyme phosphatase, which catalyzes hydrolysis of glucose-6-phosphate to glucose and inorganic phosphate. This is believed to be the origin of the glucose of the blood from the glycogen of the liver (and possibly also of the kidneys). In muscle tissue, which contains no phosphatase, glucose-6-phosphate is either converted to glycogen or degraded to form lactic acid anaerobically or completely oxidized aerobically. The formation of lactic acid from glycogen requires no oxygen; the oxidation of triosephosphate to phosphoglycerate is coupled with the simultaneous reduction of pyruvate to lactate, through the mediation of coenzyme I which is alternately reduced and oxidized, as described in Chapters 10 and 35.

**Aerobic Oxidation of Carbohydrate.** The precise mechanism whereby carbohydrate is completely oxidized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  is still a subject of discussion. It is felt by many that a reasonable answer to the mechanism of aerobic carbohydrate oxidation is afforded by the cyclic process first described in its essential principles by Krebs and called by him the *citric acid cycle*, later modified by Krebs and others and now more generally known as the *tricarboxylic acid cycle*.

According to this concept, carbohydrate is considered to be degraded to the stage of pyruvic acid,  $\text{CH}_3\text{COCOOH}$ , by the series of reactions just described for the anerobic breakdown; but whereas under anaerobic conditions pyruvic acid is converted to lactic acid as the chief end product of the process, under aerobic conditions the pyruvic acid undergoes a different series of reactions. These reactions of the tricarboxylic acid cycle are summarized in the accompanying diagram, which for purposes of clarity has been considerably simplified, as will be pointed out.

As shown in this diagram, the first major reaction in the aerobic oxidation of pyruvic acid is the production of citric acid from pyruvic acid and oxalacetic acid. Earlier doubts concerning the role of citric acid itself in the citric acid cycle have now been resolved, and there is general agreement as to its importance as indicated. Oxalacetic acid is normally present in small amount in actively respiring tissue, and is constantly being regenerated, as will be shown.

The exact mechanism of the formation of citric acid from pyruvic and oxalacetic acids has been the subject of intensive study. Earlier views, based on a variety of evidence, postulated the presence of a reactive 2-carbon fragment (active acetate), formed from pyruvic acid, which condensed with oxalacetic acid to form citric acid. Active acetate has now been identified by Lynen as the S-acetyl ester of coenzyme A, acetyl CoA, symbolized as follows:  $R-S-CO-CH_3$ , where R is the remainder of the coenzyme A molecule (see pp. 1190-1).

The mechanism of formation of acetyl CoA from pyruvic acid in animal tissues is not entirely clear in all its phases, but there is no doubt that it occurs; in fact, it is believed that all substances entering the citric acid cycle at the 2-carbon fragment level must be precursors of acetyl CoA. One method of formation of acetyl CoA from pyruvic acid which has been established for heart tissue by Korkes *et al.*<sup>2</sup> is the reaction between pyruvic acid, coenzyme A, and diphosphopyridine nucleotide (DPN, coenzyme I), in the presence of diphosphothiamine (cocarboxylase), to give acetyl CoA,  $CO_2$ , and reduced DPN:

In the presence of the condensing enzyme, which is the first enzyme of the citric acid cycle to be isolated from animal tissues in crystalline form (Ochoa), acetyl CoA readily condenses with oxalacetic acid to form citric acid and CoA:

Thus the over-all reaction results in the formation of citric acid from pyruvic acid (by way of acetyl CoA) and oxalacetic acid. The role of DPN is that of hydrogen acceptor; in the living cell the hydrogen is ultimately transferred to oxygen. The role of cocarboxylase is not entirely clear. A similar oxidation of pyruvic acid can be demonstrated in certain bacterial extracts; here the cocarboxylase is said to be associated with 6,8-thioctic acid (see Chapter 35) in its action.

Citric acid is readily metabolized in muscle and other animal tissues through the stages of *cis*-aconitic acid and isocitric acid as shown, in the presence of the enzyme aconitase, which mediates an equilibrium among the three compounds. Isocitric acid once formed undergoes oxidation by dehydrogenation in the presence of isocitric dehydrogenase to yield oxalosuccinic acid, which is then decarboxylated to give  $\alpha$ -ketoglutaric acid. It is not clear whether an oxalosuccinic decarboxylase is concerned here, or the entire reaction from isocitric acid to  $\alpha$ -ketoglutaric acid is

---

<sup>2</sup> Korkes, del Campillo, and Ochoa: *J. Biol. Chem.*, **195**, 541 (1952).

mediated by isocitric dehydrogenase alone. It is known however that triphosphopyridine nucleotide (TPN, coenzyme II) is coupled in these reactions, so that the oxidation of isocitric acid involves the reduction of TPN. The over-all reaction at this particular step is therefore as follows:

As in the previous reaction involving DPN, the hydrogen of the reduced TPN is ultimately transferred to oxygen to form water.

The substance  $\alpha$ -ketoglutaric acid is readily converted by decarboxylation and dehydrogenation (with DPN as hydrogen acceptor) to give the  $\text{C}_4$  dicarboxylic acid succinic acid. The intermediate stages in this reaction are not entirely clear, but they appear to involve the formation of succinyl CoA as an intermediate. Succinic acid is then acted upon by the enzyme succinic dehydrogenase, present in most animal tissues, to give fumaric acid by oxidative dehydrogenation. Fumaric acid readily undergoes hydration in the presence of the enzyme fumarase to form malic acid, which on oxidation in the presence of the enzyme malic dehydrogenase yields oxalacetic acid. At this point the entrance of another molecule of pyruvic acid permits the entire cycle to be repeated.

Thus the net result of the cycle is the complete disappearance of one molecule of pyruvic acid, giving rise to three molecules of  $\text{CO}_2$  in the process and requiring the ultimate presence of five oxygen atoms ( $2.5\text{O}_2$ ) to accept the 10 hydrogen atoms removed by the various dehydrogenation reactions. As indicated above, the mechanism of hydrogen transport to oxygen is by way of the di- and triphosphopyridine nucleotides (coenzymes I and II), the flavoproteins, the cytochromes, and cytochrome oxidase, as described in Chapter 12, "Enzymes."

The over-all reaction is therefore:

with a respiratory quotient (R.Q.) of  $3/2.5 = 1.2$ . By the combination of reactions described, involving the formation of pyruvate from carbohydrate and the participation of pyruvate in the tricarboxylic acid cycle, it is possible therefore to account for the complete oxidation of carbohydrate to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . To obtain an R.Q. of 1.0, which is the R.Q. of carbohydrate oxidation, the transfer of two more hydrogen atoms to an oxygen atom must enter into the picture. These two hydrogen atoms are presumably those which arise in the oxidation of triosephosphate during the anaerobic phase of carbohydrate breakdown (see p. 274), and which produce lactic acid from pyruvic acid under these conditions. In aerobic metabolism they are transferred to oxygen by way of diphosphopyridine nucleotide (DPN).

The major evidence in favor of such a cyclic process as that described may be summarized as follows: the various postulated intermediates usually increase the respiratory rate of suitable tissue preparations (e.g., minced muscle) when added in catalytic amounts; many of the individual

and Slotin<sup>3</sup> using bicarbonate containing radioactive carbon; the  $\alpha$ -ketoglutaric acid synthesized by pigeon-liver preparations in the presence of pyruvate and the isotopic bicarbonate was found to contain a significant amount of the isotopic carbon. The carbon of radioactive sodium bicarbonate administered to rats is also found in the glycogen subsequently isolated from the liver.<sup>4</sup> When fatty acids are oxidized to acetoacetate by liver preparations in the presence of radioactive carbon dioxide, the isotope is found incorporated, to a small but significant extent, in the carboxyl group of the acetoacetate formed.<sup>5</sup> Other examples could be cited; they all demonstrate that the release of carbon dioxide by animal tissues is not an exclusively one-way process.

Although the Wood-Werkman reaction has been much studied in connection with CO<sub>2</sub> fixation by animal tissues, there is no good evidence that it occurs elsewhere than in bacteria. Of greater interest in this connection is the reaction discovered by Ochoa in liver extracts, in which malic acid is reversibly oxidized and decarboxylated to give pyruvic acid and CO<sub>2</sub>. This reaction requires TPN as hydrogen acceptor, and is catalyzed by the *malic enzyme*:

If this system is coupled with another TPN-requiring system, such as the combination of glucose-6-phosphate and glucose-6-phosphate dehydrogenase, the TPN may be removed from the system to such an extent that the reaction proceeds to the left and there is a net synthesis of malic acid from pyruvic acid and carbon dioxide.

It is of interest to note here that Ochoa had previously shown that the oxidative decarboxylation of isocitric acid to form  $\alpha$ -ketoglutaric acid was experimentally reversible under the proper conditions; however, the equilibrium conditions for the malic enzyme are stated to be 15 times more favorable for CO<sub>2</sub> fixation by the malic enzyme reaction than for the isocitrate-ketoglutarate reaction. It is to be noted that, once malic acid is formed from pyruvic acid and carbon dioxide, the presence of malic dehydrogenase in a tissue will lead to the production of oxalacetic acid. Thus the malic enzyme provides a mechanism for the entry of pyruvic acid into the citric acid cycle other than by way of acetyl CoA.

Despite the undoubted demonstration of its existence, the significance of CO<sub>2</sub> fixation by animal tissues remains obscure. The extent of fixation is usually quite small, since equilibrium conditions ordinarily favor decarboxylation. The comparative ability of various animal tissues to fix CO<sub>2</sub> has been studied by Crane and Ball.<sup>6</sup> According to Ochoa, the malic enzyme reaction provides the only means thus far known whereby a net synthesis of dicarboxylic acids can be obtained from pyruvic acid and carbon dioxide. It has been suggested that CO<sub>2</sub> fixation provides for the constant presence of the catalytic amounts of dicarboxylic acids neces-

sary for the continuous operation of the citric acid cycle. It is interesting to recall here that, as discussed in Chapter 2, the assimilation of  $\text{CO}_2$  by green plants during photosynthesis leads to the formation of phosphoglyceric and phosphopyruvic acids, and that malic acid is a subsequent product of the reaction. Thus the fundamental processes of  $\text{CO}_2$  assimilation in plant and animal tissues may well be similar.

Despite the extensive knowledge which has been obtained concerning intermediary carbohydrate metabolism, there is much that is still obscure. The aerobic oxidation of lactic acid, for example, usually is considered to occur by way of conversion to pyruvic acid which is then oxidized by the processes just described. There is some evidence that other as yet unknown and possibly important pathways exist. In certain tissues, glucose can be shown to be oxidizable to form gluconic or phosphogluconic acid, and the latter has been shown to be converted into ribose phosphate, one of the building blocks of nucleic acids. The conversion of carbohydrate to pyruvate and the reactions of the tricarboxylic acid cycle have been studied largely in one tissue, i.e., muscle, and the conclusions derived are not necessarily applicable *in toto* to other tissues. Yet Krebs has pointed out that the various animal tissues thus far investigated possess enzymes similar in general to those required for the tricarboxylic acid cycle, so that while individual differences between tissues doubtless occur, the basic reactions could be fundamentally similar in all tissues.

**Formation of Carbohydrate from Amino Acids.** The reactions of the tricarboxylic acid cycle afford a reasonable explanation for the ability of certain amino acids to give rise to glucose or extra glycogen in the animal body. Thus the amino acids glutamic acid, aspartic acid, and alanine, by metabolic deamination, give rise to  $\alpha$ -ketoglutaric acid, oxalacetic acid, and pyruvic acid, respectively. These three latter compounds are recognized components of the tricarboxylic acid cycle.

After deamination, therefore, these three amino acid constituents of the protein molecule become indistinguishable from carbohydrate metabolites. Since the reactions of the tricarboxylic acid cycle are reversible, a mechanism is available for either the synthesis of carbohydrate or metabolism via carbohydrate pathways for these amino acids, and for any others which are convertible into these amino acids by metabolic processes. That pathways exist other than those described is quite probable, but they remain to be discovered.

**Conversion of Carbohydrate to Fat.** The fattening of farm animals and the development of obesity in man on high carbohydrate diets suggest that carbohydrate can be converted to fat in the animal body. In feeding experiments in which a control animal is killed and analyzed for fat while a litter mate is fed a high carbohydrate diet, it can be shown that the latter may, after a time, contain more fat than could be derived from all of the fat and protein fed. In the same way, milch cows without

loss of fat from their bodies may secrete in their milk much more fat than can be accounted for by fat and protein ingested. Studies of the respiratory quotient yield similar evidence with regard to the conversion of carbohydrate into fat (see Chapter 24). The availability of isotope-labeled glucose has provided a more direct demonstration of the conversion of carbohydrate to fat. For example, if mice and rats kept on an essentially fat-free diet are given a dose of labeled glucose, between 10 and 15 per cent of the labeled carbon atoms are found in the fatty acids of the animal body after 24 hours.<sup>7</sup> These and other results lead to the conclusion that conversion of carbohydrate to fat does not represent merely the storage of energy, but is also an important pathway in the metabolism of carbohydrate itself.

The glycerol for fat synthesis may arise very easily from carbohydrate, possibly directly from phosphoglyceraldehyde, a normal intermediate in carbohydrate metabolism in tissues:

The mode of synthesis of the fatty acid portion of the fat molecule is not yet clear. It is generally agreed that the first step in the synthesis involves the formation of reactive 2-carbon fragments, which are then condensed with each other. On the basis of available evidence, the reactive 2-carbon fragments arise by the breakdown of carbohydrate to the stage of pyruvic acid, as described above, followed by oxidative decarboxylation of the pyruvic acid. There is a strong possibility that acetyl CoA is the reactive intermediate in the condensation, although the nature of this condensation has not as yet been precisely defined. Much of the work on fatty acid synthesis from carbohydrate has been done with bacterial systems, and it is not certain to what extent the conclusions reached are applicable to animal tissues. Although fatty acid synthesis has been demonstrated in animal tissue preparations, these preparations are usually too complex to permit a precise explanation of the reaction mechanism.

The formation of neutral fat from carbohydrate by way of pyruvic acid would involve the production of reactive 2-carbon fragments, condensation, reduction of the  $\beta$ -keto compounds formed to saturated acids, and lastly esterification of the saturated acids. Acetoacetic acid itself is known not to be an intermediate in this synthesis, although the possibility remains that an active form of acetoacetic acid, e.g. acetoacetyl CoA, may be concerned. Acetic acid has been shown to be a precursor of the higher fatty acids, presumably after conversion to either acetyl-phosphate or acetyl CoA; fatty acid synthesis from labeled acetate has

<sup>7</sup> Masoro, Chaikoff, and Dauben: *J. Biol. Chem.*, **179**, 1117 (1949).

been demonstrated in liver homogenates.<sup>8</sup> Moreover, the mammary gland has been shown to be especially active in lipogenesis. Large amounts of acetate arise in ruminants, owing to the fermentation of carbohydrate by microorganisms in the rumen. This acetate is absorbed from the rumen by the blood and carried to the mammary gland, where it is used not only as a source of energy but also for fat synthesis; in fact, Popják<sup>9</sup> reported that 50 per cent of the retained dose of acetate injected into a goat could be accounted for in the milk fat. The relationship of acetic acid to carbohydrate and fat metabolism is further discussed on p. 1009.

**The Blood Sugar.** The sugar of the blood is glucose, present normally at a concentration of about 80 mg. per 100 ml. of blood, or 0.08 per cent. This level is maintained constant within relatively narrow limits under all ordinary circumstances; significant variations from the normal range usually indicate some aberration of carbohydrate metabolism. The constancy of the blood sugar level apparently is due to a balance between the rate at which glucose enters the blood and the rate at which it leaves the blood. Blood glucose appears to originate chiefly in the liver; the rapid fall in blood glucose level after hepatectomy indicates that other tissues cannot contribute materially to the blood sugar content, although there is some evidence that the kidneys may play a minor role in this respect. The glycogen of the liver usually is considered to be the major source of the blood glucose, but the maintenance of a normal blood sugar level in the fasting animal long after liver glycogen stores are exhausted indicates that carbohydrate synthesis in the liver may also play an important part in this connection.

Factors which lead to a removal of glucose from the blood include oxidation by the tissues, conversion to glycogen in liver and muscle, and to a minor extent in other tissues, storage as fat, and under certain conditions excretion in the urine. Increased oxidation in the tissues and increased conversion to liver and muscle glycogen each tend to lower the blood sugar level; when these two factors operate together, as after the administration of insulin, the resulting hypoglycemia may be profound. In the absence of insulin, as in diabetes mellitus, the inability to store glycogen in the liver coupled with decreased oxidative utilization in the peripheral tissues generally is believed to be responsible for the elevated blood sugar values seen in this condition. An alternate explanation for the hyperglycemia of diabetes mellitus is accelerated gluconeogenesis ("overproduction") rather than impaired oxidative utilization ("underconsumption"). Evidence in favor of the overproduction theory is limited.

Increased glycogenolysis in liver (but not in muscle), as after the administration of adrenaline or during ether anesthesia, likewise causes an elevation of the blood sugar. The glycogen of muscle is not a direct factor in the maintenance of the blood sugar level, but operates only indirectly insofar as the muscles remove glucose for glycogen formation or contribute lactic acid to the blood which is then carried to the liver,

where blood lactate may be a significant source of liver glycogen and hence of blood glucose.

Storage of carbohydrate as fat (discussed on p. 996) is apparently a property of most of the tissues of the body. Loss of glucose from the blood because of excretion in the urine will occur whenever the rate of reabsorption of glucose by the renal tubular cells falls behind the rate of entrance of glucose into the glomerular ultrafiltrate—i.e., when the level of plasma glucose exceeds the renal threshold concentration. Ordinarily, the renal threshold concentration corresponds to a plasma glucose level of 150 mg. per cent or so, and this is only transitorily exceeded after ingestion of a large amount of carbohydrate, during emotional stress, etc. In the rare condition known as renal diabetes the renal reabsorption of glucose is so diminished that significant amounts escape into the urine, and after poisoning with the drug phlorizin the renal reabsorption of glucose is almost completely abolished (*phlorizin diabetes*, see p. 1022). The excretion of blood glucose in the urine in diabetes mellitus is due more to the elevated concentration in the blood than to any significant alteration in the renal threshold. In none of the various conditions described which lead to excretion of glucose in the urine is the loss from the blood ordinarily sufficient to affect appreciably the level of the blood sugar concentration.

**Hormonal Control of Carbohydrate Metabolism.** The metabolism of carbohydrate in the animal body is under the control of hormones from several of the endocrine glands, of which the pancreas, the anterior pituitary gland, and the adrenal cortex appear to be of major importance. Some aspects of this hormonal control have been indicated in the preceding pages; the endocrine glands themselves are discussed in Chapter 26.

Knowledge concerning the relation between the pancreas and carbohydrate metabolism began with the classical demonstration by Von Mering and Minkowski in 1889 that removal of the pancreas in the dog was followed by development of the symptoms of diabetes mellitus. In 1921 Banting, Best, and Macleod obtained the active principle of the pancreas in this connection, the hormone insulin. Administration of insulin to a normal animal leads to a profound hypoglycemia which may result in convulsions or unconsciousness (insulin shock). In the diabetic, a maintained administration of insulin will completely alleviate the condition. Opinions differ as to the mechanism of insulin action; some feel that insulin accelerates carbohydrate oxidation, while others regard its function as primarily concerned with the synthesis of carbohydrate from noncarbohydrate precursors (gluconeogenesis) or possibly with the conversion of carbohydrate to fat. The significance of insulin in the hexokinase reaction is discussed on the following page.

A further notable advance in knowledge concerning the hormonal control of carbohydrate metabolism was the demonstration by Houssay that removal of the pituitary gland ameliorated the symptoms of diabetes in the pancreatectomized dog. Removal of the adrenal cortex is likewise effective in ameliorating the symptoms of pancreatic diabetes (Long and Lukens). These and other results suggest that control of carbohydrate

metabolism by the hormones of the pancreas, the anterior pituitary gland, and the adrenal cortex is essentially a balance between opposing forces, with the effect of insulin opposed by either or both the pituitary and adrenal-cortex principles. Striking confirmation of this concept is afforded by the work of the Coris and their associates, who have found that the ability of tissue extracts to phosphorylate glucose by the hexokinase (glucokinase) reaction (see p. 990) is inhibited by a fraction of anterior-pituitary extract, and also by adrenal-cortical extract; this inhibition is overcome by insulin. Tissue extracts from diabetic animals showed an inhibited hexokinase activity which was overcome *in vitro* or *in vivo* by insulin. This was the first demonstration of the hormonal control of a specific enzymatic reaction of carbohydrate metabolism; these experiments have been confirmed by others.

In another series of experiments, Sutherland and Cori<sup>10</sup> present evidence which indicates that the phosphorylase enzyme of the liver is under the control of epinephrine and the *hyperglycemic factor* (HGF, see p. 769) of the pancreas; small amounts of epinephrine or of HGF markedly increased phosphorylase activity in liver slices where activity was low, and preserved activity in liver homogenates; similar effects were observed *in vivo*. It is suggested that phosphorylase activity in liver represents a balance between inactivation and resynthesis of active enzyme, and that this is in some as yet unknown way under hormonal control. It will be recalled that both epinephrine and HGF promote the breakdown of liver glycogen in the animal body.

Knowledge concerning relationships between the various other hormones of the body and carbohydrate metabolism is relatively meager and difficult to evaluate. The thyroid hormone influences the rate of metabolism in the tissues, but no specific relation to carbohydrate metabolism has been demonstrated, although a role in gluconeogenesis has been postulated. A role in gluconeogenesis has likewise been delegated to certain of the steroid hormones of the adrenal cortex (see Chapter 26). The subject is rendered difficult by the lack of purity of the hormone preparations in some instances, and by the possibility that a postulated action or lack of action may in reality involve the mediation of some other gland or hormone in addition to the one thought to be concerned.

## FAT METABOLISM

The fats of the diet and of the animal body represent largely a concentrated form of energy, for metabolic or storage purposes, but there is adequate evidence that fats may subserve important noncaloric metabolic functions as well. In this connection, Burr and Barnes conclude that "there are ample reasons for recommending that the fat intake be not reduced much below the normal established by habit." Thus the fat content of the diet may influence such diverse processes as the digestibility and absorbability of other foodstuffs in the gastrointestinal tract, and the rate of calcification of the bones; fatty acids represent important constituents of the lipid structural components of tissues; the fats of the

diet serve as a vehicle for the fat-soluble vitamins; and the presence in the diet of certain highly unsaturated fatty acids which cannot be synthesized by the animal body has been shown to be necessary for normal growth and tissue metabolism. Moreover, the presence of fat in protein-free diets exerts a favorable effect on nitrogen retention, as well as on the course of pregnancy and lactation. The physical capacity of rats has been shown to be greater on high-fat diets than on fat-free regimens. Dietary fat has likewise been shown to exert beneficial effects on rats subjected to such stress factors as thyrotoxicosis,<sup>11</sup> x-radiation,<sup>12</sup> and cold.<sup>13</sup>

The proportion of total calories furnished by dietary fat may vary widely from one group of individuals to another, and depends chiefly on such factors as availability, cost, and established nutritional customs. The recommendation of the National Research Council is that fat be present in the diet to the extent of furnishing 20 to 25 per cent of the total calories (30 to 35 per cent at higher levels of calorie expenditure) and that at least 1 per cent of the total calories be in the form of the essential unsaturated fatty acids (see p. 1004).

**Comparative Nutritive Value of Fats.** The variety of fats found in nature has stimulated investigation into their relative nutritional merits, for economic as well as for nutritive reasons. These studies have failed to reveal any significant nutritional differences between the common animal and vegetable food fats and oils other than those attributable to slight variation in digestibility or in content of fat-soluble vitamins. Deuel, *et al.*<sup>14</sup> have furnished experimental evidence to refute the concept that butter fat possesses certain saturated fatty acids, not present in other fats, which are essential for growth. While rats prefer a diet containing butter to one in which the fat is corn, cottonseed, olive, peanut, or soybean oil or margarine, this preference is apparently due to flavor alone; margarine fat and butter fat promote similar growth responses when fed to weanling rats under controlled conditions.<sup>15</sup> Deuel has reported that adequate growth and reproduction have been maintained in rats through 36 generations on a diet in which skimmed milk powder and margarine fat replaced the whole milk powder of Sherman's well-known whole milk powder-ground whole wheat basal diet. The equivalence of margarine and butter diets in promoting the growth of children has been demonstrated in tests carried out over a two-year period under well-controlled conditions.<sup>16</sup> These and other results lead to the conclusion that butter fat possesses no special nutritive powers as compared to vegetable fats, and that properly fortified margarine is an adequate substitute for butter and has substantially equivalent nutritional value.<sup>17</sup> Fortification of the first American margarine was carried out in the laboratory of the senior

author, who also demonstrated in rats that margarine so fortified was the nutritive equivalent of butter.<sup>18</sup>

Studies on the digestibility of natural fats and oils have shown that the common cooking oils such as cottonseed, corn, peanut, and olive oils, as well as butter, lard, and various margarines, are equally (95 per cent) digestible. Beef and mutton tallow are somewhat less digestible. Rapeseed oil, which contains a large proportion of erucic acid, has a digestibility coefficient of only 82 in the rat,<sup>19</sup> although it is almost completely digested in man.<sup>20</sup> Moreover, castor oil does not produce the catharsis in guinea pigs, rabbits, rats, or sheep that it does in human beings. Under such conditions, it is utilized to the extent of 92 to 99 per cent.<sup>21</sup> Among the fatty acids themselves, myristic and lauric acids are practically completely digestible by the rat when fed in olive oil, stearic acid has a low digestibility, and palmitic acid occupies an intermediate position.<sup>22</sup> The triglycerides of these acids behave in the same manner.

**Relation Between Diet Fat and Body Fat.** Prior to the work of Schoenheimer and Rittenberg on fat metabolism as studied with the aid of fats labeled with isotopic hydrogen (deuterium), it had been believed generally that the fats of the diet were directly metabolized and that only the excess above energy requirements was stored in the fat depots of the body. These authors<sup>23</sup> showed that even when fat is fed at a low level, some is first deposited in the tissues instead of being subjected to direct combustion. The experimental details are of interest. Normal mice were kept on a diet low in fat, and containing 1 per cent of linseed oil which had been partially hydrogenated with deuterium. Later post mortem examination of the body fat for the presence of the deuterio fat indicated that, even though the total amount of depot fat remained constant, 47 per cent of the dietary fat had been incorporated in the depot fat. Thus the animals were burning an approximately equal mixture of depot fat and food fat, in spite of the fact that the fat content of the diet was below that needed for energy purposes if completely burned.

Depot fat is therefore not inert storage material but is constantly involved in metabolic processes. The admixture of dietary and tissue fat shown by such experiments as that just described is, however, subject to some modifying control, since the animal tends to produce a body fat of fairly uniform composition and succeeds moderately well as long as the fat of the diet is not altered to too great an extent. If, however, large amounts of fats containing foreign types of fatty acids are taken in, some of these may be deposited in the tissues unchanged and may modify the character of the body fat. Thus the melting point of the body fat of the dog has been raised from the usual 20° C. to 40° C. by feeding mutton

tallow and has been decreased to 0° C. by feeding linseed oil. Anderson and Mendel fed rats diets of skimmed-milk powder and added fat, and found that the iodine number of the body fat could be varied from 122 to 35 by feeding soybean and coconut oils with iodine numbers of 132 and 7.7, respectively. This matter is of commercial importance since feeding hogs rations too high in liquid fats gives rise to a soft body fat yielding a soft lard. In such cases, feeding for some time of a diet high in carbohydrate has a hardening effect, since the fat formed from carbohydrate has a higher melting point and tends gradually to replace a portion of the lower-melting-point fats.

However, animals vary considerably with regard to the susceptibility of tissue fats to alteration in composition due to the fats present in the diet. Shorland<sup>24</sup> designates the body fats from species such as cows, sheep, and other ruminants which resist change due to diet as *homolipides*, while the fats from species which respond more or less readily to food fats of unusual composition by a change in body fat composition are called *heterolipides*. In considering this problem from an evolutionary viewpoint, it has been suggested that the storage depot fats of the lower marine forms, which have the most complex fatty acid make-up of all species, merely mirror the composition of the food fats.<sup>25</sup> This is because such animals are unable to dilute the food fat with synthetic fats, since they do not possess the ability to change carbohydrate and protein into fat. As the capacity for transforming these nonlipide components into fatty acids develops in the forms ranking higher in the evolutionary pattern, the modification of the storage fat by diet becomes less pronounced. In the ruminants, most of the storage fat is newly synthesized from protein and carbohydrate; dietary fat is largely modified in the complicated gastrointestinal tract, and it exerts no appreciable effect upon the composition of the fat in the storage depots. According to Wertheimer and Shapiro,<sup>26</sup> synthesis of fat from carbohydrate actually takes place in the adipose tissue.

Some modification of ingested fat may occur during absorption and resynthesis in the intestinal wall. That the various saturated fatty acids found in the mixed triglycerides of animal body fats are in synthetic equilibrium is shown by the fact that, after the feeding of a particular fatty acid labeled with deuterium i.e., deuterio-palmitic acid, a significant amount of the deuterium is subsequently found incorporated in the other saturated fatty acids of the body fats. Deuterium is also found in the oleic and palmitoleic acid fractions, thus proving that these mono-unsaturated acids may be synthesized from dietary components.<sup>27</sup> This synthesis may be by direct dehydrogenation, but it appears more probable that the fed fatty acid enters into degradation reactions to produce smaller fragments from which the oleic acid is then synthesized. No deuterium is found in the linoleic acid fraction, thus confirming the original observations of Burr and Burr (see p. 1004)

<sup>24</sup> Shorland: *Nature*, **165**, 766 (1950).

that the animal is unable to synthesize these highly unsaturated fatty acids.

**Essential Fatty Acids.** The inability of the animal body to synthesize certain highly unsaturated fatty acids essential for its normal nutrition was first demonstrated by Burr and Burr,<sup>28</sup> in 1929. These investigators found that rats placed on a diet devoid of fat but otherwise apparently complete failed to grow and developed characteristic lesions of the skin and tail (see p. 1073 and Fig. 268 for complete description of this condition). Addition to the diet of the normal saturated fatty acids or of oleic acid did not render the diet complete; in fact, the administration of hydrogenated coconut oil has been shown to shorten the depletion period of rats on a diet free from essential fatty acids, as well as to intensify the accompanying symptoms.<sup>29</sup> When triolein was the fat employed, this effect was not noted.<sup>30</sup> When small amounts of highly unsaturated fatty acids such as linoleic or linolenic acid were added to the diet the deficiency did not develop. Further study has confirmed these findings; the deficiency is apparently not concerned with the formation of fat from carbohydrate, or fat storage; arachidonic acid is more effective than the other unsaturated fatty acids in promoting growth; and in the deficient animal the arachidonic acid content of the liver is maintained at the expense of continuous depletion of the other tissues.<sup>31</sup> This would imply that the presence of highly unsaturated fatty acids in liver, at one time thought to be a characteristic of fat metabolism in this organ, is in reality due to selection and retention of these compounds from the blood. Arachidonic acid appears to be the essential fatty acid which is the physiological member of the group. Using spectrophotometric procedures for the determination of the number of double bonds in the fatty acid fraction of blood and tissue fats, Reiser<sup>32</sup> and Witten and Holman<sup>33</sup> have demonstrated the synthesis of tetraenoic acid (arachidonic) from linoleic acid.

**Oxidation of Fats.** The glycerol portion of the fat molecule is undoubtedly oxidized in the body by pathways of carbohydrate metabolism, probably after preliminary phosphorylation to form phosphoglycerol, which then by oxidation could give rise to either phosphoglyceric aldehyde or phosphoglyceric acid, both of which are recognized intermediates in carbohydrate breakdown (see p. 989). The fatty acids are oxidized in quite a different way.

**$\beta$ -OXIDATION.** It is generally agreed that the major method whereby fatty acids are oxidized in the animal body is by the process known as  $\beta$ -oxidation. According to this concept, the fatty acid chain is oxidized at the carbon atom  $\beta$  to the carboxyl group, with the splitting off of a

2-carbon fragment and the production of a fatty acid having two less carbon atoms than the original. This process continues along the chain until the entire fatty acid molecule has been broken down to 2-carbon fragments by the removal of two carbon atoms at a time.

The first biological evidence for  $\beta$ -oxidation was afforded by the experiments of Knoop. This investigator found that on feeding animals fatty acids of varying chain length but in each case with the  $\omega$ -carbon (the one farthest removed from the carboxyl carbon) attached to a phenyl group, there could be isolated from the urine either benzoic acid or phenylacetic acid, in the form of the conjugated derivatives hippuric acid and phenaceturic acid, respectively. Benzoic acid was obtained when the fatty acid chain contained three or five carbon atoms; phenylacetic acid when it contained two (i.e., phenylacetic acid itself) or four carbon atoms. These results led Knoop to conclude that the carbon atoms could not be removed one by one during oxidative breakdown of the fatty acid, but must come off in pairs, i.e., by oxidative removal at the  $\beta$ -carbon.

The mechanism of  $\beta$ -oxidation, and the nature and fate of the 2-carbon fragment thereby produced, has been the subject of prolonged and intensive study. A major difficulty in the past, since overcome, has been the inability to obtain cell-free preparations from animal tissues which were capable of oxidizing fatty acids and were susceptible to experimental study. Munoz and Leloir<sup>34</sup> and Lehninger<sup>35</sup> were the first to describe such preparations from liver tissue. Lehninger's preparations under the proper conditions readily brought about the oxidation of all of the normal saturated fatty acids containing from 4 to 16 carbon atoms, with acetoacetic acid as the main product. In the oxidation of octanoic acid, for example, two moles of acetoacetic acid could be obtained for each mole of octanoic acid oxidized:

The interesting observation was made that if oxalacetate was added to the system, the yield of acetoacetate decreased and some citrate,  $\alpha$ -ketoglutarate, and succinate were formed, suggesting that the citric acid cycle of Krebs (see p. 990) was entering into the picture. Since added acetoacetate was not oxidized, even in the presence of oxalacetate, and pyruvate was found to be oxidized in a manner similar to the oxidation of fatty acids, it was postulated that both fatty acid oxidation and pyruvate oxidation produced a reactive 2-carbon fragment as a common intermediate. This 2-carbon compound could then condense either with itself to form acetoacetate as end product, or with oxalacetate to form citrate, the citrate then entering the oxidative metabolism of the Krebs cycle. With the identification of the reactive 2-carbon fragment as the acetyl group of acetyl-coenzyme A (p. 1010), the process is now pictured by Lehninger as follows:

<sup>34</sup> Munoz and Leloir: *J. Biol. Chem.*, **147**, 355 (1943).

<sup>35</sup> Lehninger: *J. Biol. Chem.*, **161**, 437 (1945).

Further aspects of the metabolic significance of acetoacetic acid and acetyl groups are considered on pp. 1007 and 1010. In connection with the breakdown of long-chain fatty acids to the stage of acetyl groups, it has been suggested that the first step in the reaction is the formation of a fatty acid-coenzyme A combination, through the mediation of adenosine-triphosphate (ATP). In the case of heart-muscle preparations which oxidize fatty acids, Mahler<sup>36</sup> has formulated this reaction (for butyrate) as follows:

where AMP is adenosinemonophosphate, or adenylic acid. Presumably a similar reaction occurs with other fatty acids as well. Evidence to this effect has been obtained by the use of hydroxylamine to “trap” fatty acid esters of coenzyme A through the formation and identification of the corresponding hydroxamic acids:

Using this procedure, caprylyl hydroxamic acid has been isolated from liver extracts actively oxidizing caprylic acid, the oxidation presumably going through the intermediate formation of a caprylyl-coenzyme A ester.

A second method for the formation of fatty acid-coenzyme A combinations, which thus far appears limited in its applicability to butyric and acetoacetic acids, is through exchange with succinyl CoA. According to Mahler,<sup>36</sup> oxidation of  $\alpha$ -ketoglutaric acid to succinic acid in the presence of coenzyme A gives rise to the intermediate formation of succinyl CoA, which can then convert butyric acid into butyryl CoA:

It is to be noted that this reaction involves DPN (in the ketoglutarate-succinate stage) but not ATP, and it may account for the differences which have been noted occasionally between the oxidative metabolism of butyric acid and that of other fatty acids.

It appears likely that the fatty acid-coenzyme A combination, once formed, is a substrate for a dehydrogenase action involving DPN and resulting in the formation of a  $\beta$ -keto group in the fatty acid chain:

<sup>36</sup> Mahler: *Phosphorus Metabolism*, Vol. II, Baltimore, Johns Hopkins University Press, 1952.

According to current views, the  $\beta$ -keto acyl ester thus formed can react with another molecule of coenzyme A at the keto group, to split off acetyl CoA and leave an acyl-coenzyme A combination containing two less carbon atoms:

Thus by this thioclastic reaction the acetoacetyl CoA formed in butyrate oxidation will give rise to acetyl CoA, whereas for the higher fatty acids the combination of dehydrogenase activity and reaction with coenzyme A results in the shortening of the chain by 2 carbon atoms at a time, with the concomitant release of acetyl groups in the form of acetyl CoA, until the entire molecule is broken down.

As stated above, the acetyl groups which are the intermediate products of fatty acid oxidation give rise to acetoacetic acid or are further oxidized by the metabolic processes of the Krebs cycle. There is some evidence that acetyl groups derived from the carboxyl end of a fatty acid chain may have a somewhat different metabolic significance from those derived from the methyl end of the chain; further work will be needed to clarify this point. There is much in the picture of fatty acid oxidation presented here that is obscure and that will presumably be subject to modification as knowledge increases in this field. At the same time, it is believed that a reasonably satisfactory explanation is now available for most of the known facts regarding fatty acid oxidation in animal tissues, and that this explanation represents a significant advance in understanding over previous concepts. It is likely that other pathways of fat oxidation exist. For example, it is known that fatty acids may undergo  $\omega$ -oxidation—i.e., oxidation beginning at the carbon atom farthest removed from the carboxyl group—since certain long-chain dicarboxylic acids have been isolated from the urine of animals after the feeding of fatty acids. The significance, if any, of this type of oxidation in the normal metabolism of fatty acids is obscure.

**Metabolism of Acetoacetic Acid.** Acetoacetic acid, its equilibrium reduction product  $\beta$ -hydroxybutyric acid,  $\text{CH}_3\cdot\text{CHOH}\cdot\text{CH}_2\cdot\text{COOH}$ , and its decarboxylation product acetone,  $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_3$ , are the ketone bodies (“acetone bodies”) which normally are found only in very small amounts in the blood and urine. Under certain conditions, as in diabetes mellitus, during starvation, or prolonged subsistence on a low-carbohydrate diet, the amount of these ketone bodies in the blood rises and considerable quantities may be excreted in the urine (see experiment on p. 1073). Such a condition is known as ketosis. It was believed for some time that acetoacetic acid and its associated ketone bodies were abnormal metabolic end products, and in particular that acetoacetic acid represented the inability of the tissues to carry fatty acid oxidation by the  $\beta$ -oxidation process beyond the stage of the 4-carbon compound.

It is now known that acetoacetic acid is a normal end product of fatty acid oxidation in liver. The acetoacetic acid formed in liver is not further

utilized by this organ, except possibly to a slight extent in fasting. Other tissues, however, readily metabolize acetoacetic acid to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , and there appears to be no impairment in this respect in diabetes (Soskin). The intensity of ketone-body production (ketogenesis) by liver appears to be largely a question of substrate availability. If adequate carbohydrate is available, the liver apparently prefers carbohydrate oxidation as a source of energy, and ketone-body production is small. Carbohydrate is therefore an "antiketogenic" substance. In the absence of carbohydrate oxidation, as in diabetes or when glycogen stores are exhausted, oxidative energy is derived almost entirely from fatty acid breakdown and ketone bodies result. They may be produced by the liver in such quantities that the peripheral tissues are unable to oxidize them as fast as they are formed, in which case they will accumulate in the blood (ketonemia) and be excreted in the urine (ketonuria).

It was felt at one time that ketogenesis was harmful and that it could be controlled by the proper ratio in the diet of ketogenic material (fats, and the ketogenic portion of proteins) to antiketogenic material (carbohydrate, and the glucogenic portion of protein). These views are no longer held. The major effect of ketosis on the animal body appears to be in relation to acid-base balance; excretion of large amounts of acetoacetic acid and  $\beta$ -hydroxybutyric acid in the urine as their alkali salts depletes the body of available base and may lead to the development of an acidosis.

That ketone bodies may arise from sources other than fatty acid oxidation is well recognized. Their origin from pyruvate under certain circumstances has been shown, and it is well established that certain amino acids such as leucine and phenylalanine are metabolized via the intermediate formation of acetoacetic acid. Presumably any metabolic source of acetic acid could also serve as a source of acetoacetic acid (see p. 1009). Thus ketone body production is not a characteristic of fatty acid oxidation alone, but is rather to be considered only one of the various metabolic processes which yield energy to the organism.

Ketonuria during fasting occurs spontaneously to an appreciable extent only in man and the higher apes. However, when the salts of ketogenic acids are administered to fasting rats, a marked ketonuria obtains, which is physiologic. This is defined as an *exogenous* ketonuria. Likewise, after the development of fatty livers in rats, a spontaneous ketonuria of considerable magnitude results on fasting; this type of ketonuria is known as *endogenous* ketonuria. Women exhibit a much higher degree of fasting ketonuria than do men;<sup>37</sup> the same sex difference has been shown to occur in both the exogenous<sup>38</sup> and the endogenous types<sup>39</sup> of ketonuria in the rat.

Further stages in the breakdown of acetoacetic acid to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  occur largely in tissues other than the liver and are considered to involve the participation of coenzyme A and the reaction mechanism of the Krebs tricarboxylic acid cycle. The role of the Krebs cycle in acetoacetate metabolism was first postulated by Breusch<sup>40</sup> and by Wieland<sup>41</sup> and has

<sup>37</sup> Deuel and Gulick: *J. Biol. Chem.*, **96**, 25 (1932).

<sup>38</sup> Butts and Deuel: *J. Biol. Chem.*, **100**, 415 (1933).

<sup>39</sup> Deuel, Hallman, and Murray: *J. Biol. Chem.*, **119**, 257 (1937).

<sup>40</sup> Breusch: *Science*, **97**, 490 (1943).

<sup>41</sup> Wieland and Rosenthal: *Ann.*, **554**, 241 (1943).

been confirmed by other investigators. For example, Buchanan *et al.*<sup>42</sup> found that, after incubating kidney tissue with carbon-labeled acetoacetate in the presence of an excess of nonisotopic ketoglutarate, succinate, and fumarate, on subsequent isolation these three intermediates in the Krebs cycle contained isotopic carbon derived from the acetoacetate. These results, and those of many other investigators, leave no doubt concerning the participation of the Krebs cycle in acetoacetate metabolism.

In the discussion of the  $\beta$ -oxidation of fatty acids on p. 1005, it was pointed out that the production of acetoacetate itself as an intermediate in the breakdown of fatty acids by extrahepatic tissue is considered to be unlikely; rather, there is formed the acetoacetyl ester of coenzyme A, acetoacetyl CoA. This  $\beta$ -keto acyl ester can undergo the thioclastic reaction with more coenzyme A described on p. 1007, to give rise to acetyl CoA, which then follows well-recognized metabolic pathways discussed below. If this view is correct, then acetoacetic acid formed by the liver and brought by the blood to the extrahepatic tissues must be converted into acetoacetyl CoA before being further metabolized. One mechanism for the activation of acetoacetic acid is found in the reactions described by Mahler<sup>36</sup> and discussed earlier in this chapter; according to this report, acetoacetate is similar to butyrate in its ability to react with succinyl CoA to give (presumably) acetoacetyl CoA and succinate. If this or an equivalent reaction is found to prevail generally in the extrahepatic tissues, the metabolism of acetoacetate by these tissues becomes readily understood.

The possible relationship between fat and carbohydrate metabolism exemplified by the entrance of the reactions of the tricarboxylic acid cycle into acetoacetate metabolism may afford some basis for the aphorism that "fats burn in the fire of the carbohydrates," which has fallen into some disrepute in recent years, possibly because it is clearly not applicable to fat metabolism in the liver. Certainly if it can be shown that carbohydrate metabolism facilitates acetoacetate combustion (which has not as yet been done but which appears likely) the existence of a "ketolytic" as well as an antiketogenic action of carbohydrate must once again be considered, at least in reference to organs other than liver. For further discussions of ketone bodies, see Chapters 29 and 31.

**Metabolism of Acetic Acid.** Acetic acid is the simplest possible fatty acid with an even number of carbon atoms. It is readily metabolizable when fed to an animal, or when incubated with liver, kidney, or heart tissue (but not brain or muscle). It has been somewhat difficult to evaluate the metabolic significance of acetic acid in the past, because of its metabolic lability and the lack of precise methods for its quantitative determination. By the use of isotope labeling, acetic acid has been implicated in the synthesis of a variety of substances such as acetoacetic acid, fatty acids, cholesterol, protoporphyrin, glycogen, and the dicarboxylic amino acids, as well as in the acetylation of choline to form acetylcholine and of such substances as sulfanilamide and *p*-aminobenzoic acid, which are excreted in part as acetyl derivatives in the urine. On the basis of the "dilution" of isotopic dietary acetate by the nonisotopic acetate of the tissues,

<sup>42</sup> Buchanan, Sakami, Gurin, and Wilson: *J. Biol. Chem.*, **159**, 695 (1945).

Bloch and Rittenberg<sup>43</sup> estimate that a 100-g. rat produces about 1 g. of acetic acid per day by all metabolic processes, of which both carbohydrate breakdown and the  $\beta$ -oxidation of fatty acids are major components. Since the animal normally excretes little if any acetic acid in the urine, all of the acetic acid produced must be further metabolized.

The mechanisms of acetate metabolism have been intensively studied in many laboratories. As is evident from the previous discussions in this chapter, the oxidative breakdown of both carbohydrate and fatty acids appeared to require the formation of an intermediate 2-carbon compound which was clearly not acetate itself but which was closely similar to acetate, and hence called by many *active acetate*. Studies on the generation of acetyl groups by animal tissues, e.g., the formation of acetylsulfanilamide from sulfanilamide by liver tissue, likewise pointed to the existence of an active form of acetate. A major contribution to this field was made by Lipmann in the discovery of coenzyme A (for acetate) as the coenzyme required in the enzymatic transformations of acetate by bacterial and animal tissues. Many illustrations of the role of coenzyme A in carbohydrate and fat oxidation have already been presented in this chapter; the structure and vitamin relationships of coenzyme A will be found in Chapter 35.

The search for active acetate appears to have reached a successful conclusion in the discovery by Lynen<sup>44</sup> of the formation of the S-acetyl ester of coenzyme A as an intermediate in the metabolism of acetate by yeast. Coenzyme A contains a mercaptoethanolamine residue in the molecule; the relation between the structures of coenzyme A and acetyl coenzyme A is as follows:

Acetyl coenzyme A fulfills all of the requirements for active acetate in the test systems thus far studied. For example, while ordinary acetate requires the presence of ATP to form citrate in tissue extracts containing oxalacetate, acetyl CoA yields citrate without ATP being present. Similarly, the requirement for a source of energy in the formation of acetylcholine and acetylsulfanilamide by tissue preparations disappears if acetyl CoA rather than acetate is used as a source of acetyl groups. Other examples of the significance of acetyl CoA in reactions requiring the presence of active acetate have been given in the discussions of carbohydrate and fat oxidation.

It is clear therefore that acetate as such is essentially inert metabolically until it is activated by conversion to acetyl CoA. That such activation occurs in animal tissues is generally believed; the mechanism however is still not clear. Lipmann<sup>45</sup> has shown in both yeast and liver extracts that the formation of acetyl CoA from acetate in the presence of ATP may occur as follows:

<sup>43</sup> Bloch and Rittenberg: *J. Biol. Chem.*, **159**, 45 (1945).

<sup>44</sup> Lynen and Reichert: *Angew. Chem.*, **63**, 47 (1951).

<sup>45</sup> Lipmann, Jones, Black and Flynn: *J. Am. Chem. Soc.*, **74**, 2384 (1952).

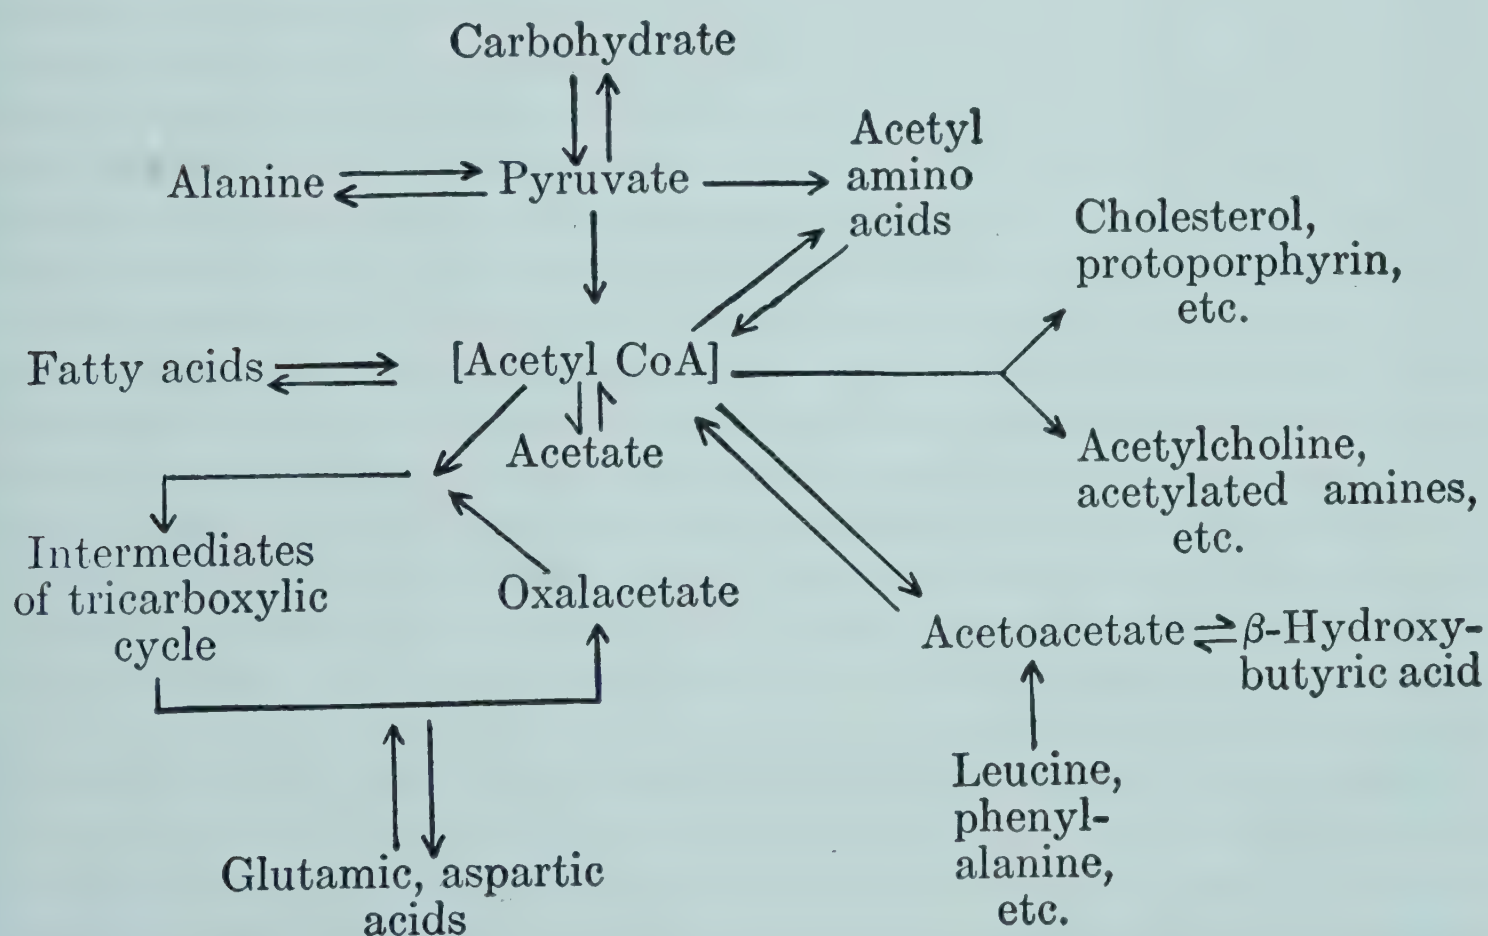

Another reaction found in bacteria which is of possible interest here involves the transacetylation of acetyl groups from acetylphosphate to coenzyme A:

Acetylphosphoric acid has the structure:  $\text{CH}_3\text{—CO—OPO}_3\text{H}_2$ . Its role in bacteria as a precursor of acetyl CoA (and hence of acetate) is as indicated in the above equation; the precise significance of acetylphosphate in animal tissues is not clearly defined. The presence of a transacetylase has not been demonstrated in animal tissue extracts; if bacterial transacetylase is added to such extracts, acetylphosphate is readily utilized as a source of active acetate through the intermediate formation of acetyl CoA.

Available evidence concerning the metabolic pathways of acetic acid is summarized in the following diagram:

It will be noted that, according to this formulation, acetic acid in the form of acetyl CoA occupies a key position in the metabolism of not only fatty acids but also carbohydrate and certain amino acids; in fact, the diagram may be taken as a general summary of the metabolic interrelationships of carbohydrate, fat, and protein.

The participation of acetate in the formation of such compounds as acetylcholine and acetylsulfanilamide has been definitely established; both reactions require acetyl CoA although taking place in different tissues (brain and liver, respectively).

The formation of acetyl derivatives of foreign aromatic amines (sulfanilamide, *p*-aminobenzoic acid) and amino acids (phenylaminobutyric acid) has been studied with the aid of the various available isotopes, and by other means; both acetic acid and pyruvic acid have been shown to be precursors of acetyl groups in this connection, with possible qualitative and quantitative differences between them. The significance of the origin of acetyl amino acids from pyruvate is further discussed on p. 1018, in connection with amino acid metabolism.

**Interconvertibility of Fat and Carbohydrate.** That the fat of the body may arise from carbohydrate has long been known (see p. 996). The reverse process, the production of carbohydrate from fat and particularly from the fatty acid portion, has been the subject of considerable controversy. Experimental methods based upon the production of extra glucose or glycogen by which it is readily possible to demonstrate the glucogenic power of certain amino acids, for example, yield essentially negative results when fatty acids are studied. For these and other reasons, many have maintained that fats do not give rise to carbohydrate in the animal body, although this conversion can be demonstrated in certain other organisms. The opposing view, held by some, is that gluconeogenesis from fatty acids is readily possible and indeed is the major explanation for the hyperglycemia of diabetes mellitus. Much of the evidence cited in favor of this latter view is faulty. It has nevertheless been unequivocally demonstrated by the use of isotopes that the carbon of certain fatty acids can be incorporated into the glycogen of the animal body,<sup>46</sup> thus proving that fatty acids and carbohydrate are reversibly related, as would indeed be expected from the equilibrium relations shown on p. 1011. The amount of conversion found, however, is extremely small relative to that expected if the conversion of fatty acid to carbohydrate were of any value to the organism. It has been suggested that such conversion must be uneconomical to the body in the light of current concepts of carbohydrate metabolism, since carbohydrate formation from fatty acids must inevitably be at the expense of the metabolic energy of carbohydrate breakdown. Whether or not the altered metabolic state of the diabetic facilitates or even requires the conversion of fatty acid to carbohydrate still remains to be unequivocally demonstrated.

**Lipotropic Factors.** On diets which are high in fats containing much saturated fatty acid and which are low in protein or in choline, there is observed a large increase in the fat content of the liver. A high cholesterol diet likewise leads to the production of a fatty liver, the lipides in this case consisting of cholesterol as well as neutral fat. In either case, an increase in choline in the diet brings about a reduction in liver fat. This is of interest in connection with the possible role of lecithin in fat metabolism, but the explanation for the so-called lipotropic action of choline is not yet established. Methionine likewise exerts a marked lipotropic action, owing to its ability to promote the synthesis of choline by the transfer of methyl groups to suitable precursors (see p. 1024).

---

<sup>46</sup> Buchanan, Hastings, and Nesbitt: *J. Biol. Chem.*, **150**, 413 (1943); Lorber, Lifson, and Wood: *J. Biol. Chem.*, **161**, 411 (1945).

Other substances which exert a lipotropic action include *lipocaic*, a substance of as yet unknown nature claimed to be present in the pancreas; inositol, a member of the vitamin B complex (Chapter 35) and a constituent of certain phospholipides (Chapter 11); tryptophan, and possibly glutamic acid. Whether these various substances act in an independent fashion or through the mediation of choline action is not clear. Fatty livers are also found under certain conditions in animals deficient in the essential fatty acids, in pantothenic acid or in riboflavin, or in animals which have been provided with an excess of thiamine or biotin (Chapter 35). The relation between these various dietary constituents and the deposition of liver fat is not well defined; it is felt by some that they may represent nonspecific factors acting through some general change in the nutritional state.

**Parenteral Fat Administration.** Although glucose and amino acids have been employed successfully in intravenous therapy for a number of years, practical procedures for the administration of fat are still in the process of development. The two obstacles which prevented the earlier application of the procedure to man were the difficulty of obtaining a preparation stable enough to resist sterilization and which would not cause fat embolism. However, as early as 1935, in this country, Holt and associates,<sup>47</sup> employing a butter emulsion stabilized with purified commercial egg lecithin and containing 7 to 7.5 per cent of lipides, administered the preparation successfully to infants. The emulsion was prepared by homogenization at 4000 pounds pressure, followed by sterilization; most of the particles were less than 60  $\mu$  in diameter. Since this earlier work, a number of satisfactory fat emulsions have been prepared, using butterfat, corn oil, coconut oil, or other fats, by employing soya phosphatide,<sup>48</sup> or glycerol monostearate<sup>49</sup> as a stabilizer, or by subjecting the fat to supersonic radiations.<sup>50</sup> Shafiroff et al.<sup>51</sup> reported that, when fat was administered subcutaneously, a better utilization obtained when the spreading agent *hyaluronidase* was incorporated in the emulsion.

Proof that emulsified fats are utilized following their intravenous administration has been obtained by the use of tagged compounds.<sup>52</sup> For example, Lerner and co-workers have found that, when a C<sup>14</sup>-labeled palmitic acid was injected intravenously into rats as a tripalmitin emulsion, as much as 59 per cent of the administered isotopic carbon was expired as CO<sub>2</sub> within 24 hours; moreover, considerable amounts of the injected fatty acid were stored in the several adipose tissues. The bulk of the C<sup>14</sup>-labeled fatty acid stored in the liver and intestine was present in the phospholipide fraction. Further confirmation that fat can be used when

injected intravenously has been adduced by Mann *et al.*,<sup>53</sup> who proved that it spares protein in growing puppies, and provides energy; as much as 30 per cent of the total energy requirement could be used efficiently in the form of intravenous fat.

Glycerides of short-chain acids were reported to be toxic, while those of lauric, myristic, palmitic, and stearic acids were found to be nontoxic when injected intravenously as emulsions in man. Oleic and linoleic acid esters can be tolerated by human subjects, at least in small concentrations.<sup>54</sup> Geyer and associates<sup>55</sup> reported a moderate increase in the total lipides in the spleen, lungs, and liver when stable emulsions of fats were administered by vein to rats. Gorens *et al.*<sup>56</sup> successfully administered as much as 3 g. of fat daily per kilogram of body weight to adults, and 6 g. of fat per kilogram of body weight to a 7-week-old infant for periods up to 27 days. Under these conditions weight loss was prevented, and positive nitrogen and potassium balances were maintained. Furthermore, fat injections produced no gross or microscopic changes in the tissues. However, one should not overlook the report that intravenous fat produces a febrile response, which is termed *thermogenic* rather than *pyrogenic*, since it is not of bacterial origin.<sup>57</sup> Lambert and associates<sup>57</sup> suggest that this effect may possibly result from an overburdening of the fat storage facilities due to the rapid influx of this foodstuff into the tissues. Considerable work is in progress to find methods of preparation of fat emulsions which will not produce the febrile reaction.

## PROTEIN METABOLISM

The proteins of the diet are considered to be completely broken down to their constituent amino acids in the digestive tract by the action of the various proteolytic enzymes present, and to be absorbed into the animal body in the form of these individual amino acids. The requirement for protein is therefore fundamentally (if perhaps not exclusively) a requirement for amino acids, and it should be possible to express the protein requirement of an animal in terms of the amount and kind of amino acids rather than of protein itself. The ability of amino acids to replace protein in the animal diet was first demonstrated many years ago by the use of hydrolyzed protein, supplemented with those amino acids known to be lost during the hydrolysis, in place of protein itself to supply the nitrogen requirements of the animal. This demonstration reaches its peak in the experimental procedure available today, for both human and animal experiments, whereby mixtures of highly purified amino acids, in many cases synthetic products, are used to replace protein completely in experimental diets. The availability of this type of experimental procedure, which was achieved only after the isolation and characterization of the amino acid threonine by McCoy, Meyer, and Rose in 1935, has led to

major advances in the science of nutrition. It is also largely responsible for directing attention to the clinical practicality of supplying nitrogen requirements during disease and convalescence by either feeding concentrated intact proteins or intravenous administration of hydrolyzates and amino acid mixtures, an application of nutritional science which promises to be of outstanding medical value. It is an interesting commentary on scientific progress that approximately four decades elapsed between the demonstration that protein hydrolyzates were of nutritional value and the extensive application of this fact in medical practice.

**Dispensable and Indispensable Amino Acids.** The amino acids supplied by the protein of the diet are needed for the synthesis of new body proteins during growth and for the continuous regeneration of the tissue proteins of the adult, as well as for many special purposes such as the formation of hormones, enzymes, purines, bile salts, creatine, and many other similar compounds. It has long been recognized that certain of the amino acids needed by the animal body for these various purposes need not necessarily be present in the proteins of the diet, since they can be synthesized within the tissues from suitable precursors. On the other hand, there are certain amino acids required by the body which cannot be synthesized under ordinary circumstances and which therefore *must* be present in the diet in adequate amount or nutritional failure, leading ultimately to death, will result.

Those amino acids which can be synthesized by the body from the other constituents of the ordinary diet at a rate adequate for nutritional demands are called *dispensable* or *nonessential* amino acids; those which cannot be so synthesized but must be present in the diet are called *indispensable* or *essential* amino acids. It must be clearly understood that these terms refer solely to the presence of these amino acids *in the diet*; as far as we know, *all* of the amino acid constituents of the protein molecule are essential in one way or another for the metabolic processes of the animal body. In fact, as du Vigneaud has pointed out, the so-called nonessential amino acids are more properly regarded as being so essential to the animal economy that it has been forced to retain the ability to synthesize them even at the expense of other constituents of the diet.

Knowledge concerning the dietary dispensability or indispensability of various amino acids has been obtained in the past largely by feeding experiments with young animals (e.g., rats) using a diet containing protein known to be low or lacking in certain specific amino acids, or containing a protein hydrolyzate from which certain amino acids (e.g., tyrosine, tryptophan) could be removed. Failure of the animal to grow on such a diet, followed by good growth when the diet was supplemented by the missing amino acids, afforded evidence as to the indispensability of the amino acids in question.

This procedure has certain obvious limitations and occasionally gave obscure results. A more adequate experimental basis is afforded by the use of mixtures of pure amino acids as the sole source of dietary nitrogen (Rose). To establish the nutritional significance of any one amino acid, it is only necessary to prepare the mixture without that particular amino acid and to use this deficient mixture as the source of nitrogen for the

animal. Much progress has been made in this field since this experimental technique became available.

As a result of the extensive experiments of Osborne and Mendel, of Hopkins, and of Rose, using the various procedures just described, the following tentative classification of the common amino acids with regard to their dietary dispensability or indispensability for the young growing mammal was suggested by Block:

| <i>Indispensable</i> | <i>Partly Indispensable</i> |                | <i>Dispensable</i> |
|----------------------|-----------------------------|----------------|--------------------|
|                      | <i>Group A</i>              | <i>Group B</i> |                    |
| Histidine            | Cystine                     | Arginine       | Glutamic acid      |
| Lysine               | Tyrosine                    | Glycine        | Aspartic acid      |
| Tryptophan           |                             |                | Alanine            |
| Phenylalanine        |                             |                | Serine             |
| Methionine           |                             |                | Proline            |
| Threonine            |                             |                | Hydroxyproline     |
| Leucine              |                             |                |                    |
| Isoleucine           |                             |                |                    |
| Valine               |                             |                |                    |

As one might expect, the division between the various groups of amino acids is not entirely a sharp one. Thus, although methionine in sufficient amount will supply the needs of the animal for cystine, cystine is an important constituent of the diet in that it is able to spare that portion of methionine which otherwise would be converted into cystine. A similar situation holds true with respect to the conversion of phenylalanine into tyrosine.

The amino acids in Group B, arginine and glycine, apparently can be synthesized by young mammals but often at a rate insufficient to permit maximum growth. On the other hand, both of these amino acids are necessary for normal growth of chicks. This is an instance where an amino acid may be dispensable for one species of animal and indispensable for another.

Knowledge concerning the amino acid requirements of man is somewhat limited.<sup>58</sup> Of the amino acids listed above as indispensable for the young animal, histidine is apparently dispensable from the diet of the adult human,<sup>59</sup> at least as judged by the criterion of maintenance of nitrogen equilibrium (see p. 1020). It is quite probable that as more specific criteria than growth or nitrogen balance are used, a somewhat different picture will be obtained than that described here. The conservative policy in human nutrition would indicate the presence in the diet of adequate amounts of all the amino acids listed in the first three columns above, even though experiments covering a short period in the life span may indicate that all of them are not needed for the period tested.

Three suggestions concerning the recommended daily intake of indispensable amino acids for human nutrition have been made. One is calcu-

<sup>58</sup> For review see Melnick: *J. Am. Dietet. Assoc.*, **19**, 685 (1943).

<sup>59</sup> Rose, Haines, and Warner: *J. Biol. Chem.*, **206**, 421 (1954).

lated from Rose's data on twice the minimum daily intake of each amino acid required to induce nitrogen equilibrium in young healthy adult men, another by Block and Bolling, calculated from the estimated per capita consumption of the principal protein foods in the United States in 1944, and the third from experiments on young soldiers on the low-calorie (900 calories per day) army survival ration.<sup>60</sup> These suggestions are summarized below.

RECOMMENDED DAILY CONSUMPTION OF INDISPENSABLE AMINO ACIDS  
(AVERAGE FOR ENTIRE POPULATION)

**Origin of Amino Acids.** Although plants are able to synthesize all the known amino acids when supplied with a source of nitrogen, inorganic as well as organic, the higher animals at least are able to synthesize only a little more than one-half of the common amino acids from the ordinary constituents of the diet or tissues. The limiting factor in the case of those amino acids which cannot ordinarily be synthesized appears in many instances to be the carbon chain or ring structure and not the nitrogen, since it is frequently found experimentally that the synthetic keto- or hydroxy-acid analog of the amino acid will take the place of the latter in the diet:

<sup>60</sup> Spector: *Nutrition Revs.*, 10, 289 (1952).  
<sup>61</sup> It is not believed that these values, which are only twice the minimum daily requirements of young healthy adult males, should be used as the recommended amino acid intakes of the entire American population.

Sometimes, but not always, both keto acid and hydroxy acid are effective in this respect; the hydroxy acid presumably gives rise to the keto acid by oxidation. Replacement of a dietary amino acid by its corresponding keto acid indicates that metabolism of the amino acid proceeds reversibly through the keto acid stage.

Synthesis of an amino acid from a keto acid usually is considered to involve a reversible equilibrium with ammonia; this may proceed through the intermediate formation of the imino acid:

The biological formation of the amino acid from the keto acid may also involve acetylation (du Vigneaud and Irish):<sup>62</sup>

Another mechanism for the formation of amino acid from keto acid is by the transamination reactions described on p. 1024. It is not possible at the present time to evaluate the relative significance of these various processes in the synthesis of amino acids within tissues.

The amino acids found in animal tissues are all of the L configuration (see Chapter 4). In the case of certain amino acids it has been found that the "unnatural" or D configuration is convertible into the natural form by the body. This presumably involves loss of the asymmetry around the  $\alpha$  carbon by conversion of the amino acid to the keto acid, followed by asymmetric synthesis of the amino acid in its natural configuration. Enzymes capable of converting D amino acids to keto acids are found in many animal tissues. In supplying the amino acid needs of an animal or human with the synthetic DL amino acid, however, it is usually assumed that the D component will be unavailable and twice as much of the DL mixture is supplied as compared to the requirement for the L form. For some amino acids the D form is largely excreted in the urine unchanged, but there are instances (e.g., serine) where the D amino acid has been shown to produce toxic manifestations.

<sup>62</sup> du Vigneaud and Irish: *J. Biol. Chem.*, **122**, 349 (1937). See also Bloch and Borek: *J. Biol. Chem.*, **164**, 483 (1946).

**Daily Protein Requirement.** The amount of protein required by the individual per day is a nutritional factor of obvious practical significance. A variety of conditions will clearly influence estimations of the protein requirement. Among these may be mentioned growth, pregnancy, or other special demands of the individual; digestibility and absorbability and amino acid composition of the protein; possibly economic availability, individual idiosyncrasy, etc. Estimates of the protein requirement of man usually have been based on studies of the nutritional status of groups of individuals on varying kinds and amounts of protein, and on the extension of the results of animal feeding experiments to man. The Food and Nutrition Board of the National Research Council has recommended that the protein intake of an adult be 1.0 g. per kg. per day, of good quality protein, for adequate nutrition. This corresponds to about 65 g. per day for an average adult human, and will result in a daily urinary nitrogen excretion of about 10 g. The recommended protein allowance for the female is increased during pregnancy and lactation; and for children it varies with age.<sup>63</sup>

The efficiency with which a given protein supplies the nitrogen requirements of an animal may be defined in terms of its so-called "biological value." Although the methods used in the past for the determination of biological value may be subject to revision in the light of changing concepts of protein metabolism (see p. 1048), the concept itself retains its usefulness. Broadly speaking, a protein of high biological value is one which has a high digestibility and absorbability and supplies the organism with adequate amounts of those amino acids which it needs. The amino acids will include not only those which cannot be synthesized by the animal, but also sufficient of the dispensable amino acids to minimize the requirements for their synthesis. The presence of low or inadequate amounts of even one of the indispensable amino acids may be the limiting factor in the biological value of a protein. For example, if one such amino acid were present in a protein in such low amount that at ordinary levels of ingestion of the protein only half the animal's requirement for this amino acid were met, a nutritional deficiency would result unless the protein intake were raised considerably above the usual level, thus leading to a lowered efficiency with respect to utilization of the other amino acids present. In general, animal proteins are found to have a higher biological value than plant proteins because of the more satisfactory distribution in kind and amount of the various amino acids present. Endosperm proteins of the cereal grains (corn, wheat, rice) are lower in certain of the indispensable amino acids, particularly lysine, than are the commonly consumed proteins of animal origin. This has led to the erroneous generalization that *all* plant proteins are incomplete or poorly balanced with respect to their essential amino acid composition; as a matter of fact, many vegetable proteins, such as those of oats, beans, yeasts, wheat and corn embryos, leafy vegetables, and grasses, are almost as suitable sources of the amino acids as many of the more expensive animal products. It is sometimes recommended that at least half the protein of the diet be of animal origin. This

---

<sup>63</sup> See table, p. 1108.

is not necessarily an adequate criterion *per se*, and several proteins of low biological value individually may so complement one another with regard to amino acid composition as to provide a mixture of high biological value provided that they are ingested simultaneously.

Since the absence of any one of the indispensable amino acids will result in incomplete retention (utilization) of the remainder, it has been proposed<sup>64</sup> that the biological value of certain proteins may be related not only to their content of indispensable amino acids but to the relative rates of their release in and absorption from the intestinal tract. For example, the biological value of soy protein is increased when the raw soybean meal is autoclaved, while that of casein is diminished by baking; in neither case is any difference in indispensable amino acid content observed by analysis. Nevertheless it has been demonstrated that the processing of soy protein increases the rates of release of methionine, leucine, and lysine during enzymatic digestion but at relatively different rates. The effect of differential rates of absorption *in vivo* would be to furnish incomplete mixtures of absorbed amino acids at the early stage of absorption followed by the too late release and absorption of the supplementary amino acids needed for most efficient utilization. It is well known that ingested amino acids do not accumulate in the blood stream. Hence the proteins of highest biological value are those that not only contain the essential amino acids in adequate amounts but make them available for absorption at relative rates consistent with most efficient utilization for protein synthesis and retention.

**Nitrogen Balance and Nitrogen Equilibrium.** The relation between the amount of nitrogen entering the body from the diet in the form of amino acids, and the amount of nitrogen excreted from the body in the form of metabolic end products (chiefly as urea, but to some extent as uric acid, creatinine, etc.) is known as the nitrogen balance. The nitrogen balance is positive if intake exceeds output, negative if output exceeds intake, and if intake and output are essentially equal, nitrogen equilibrium results. The young growing animal must be in positive nitrogen balance, since a certain portion of the ingested nitrogen is retained as newly formed body proteins and nonprotein nitrogenous compounds. During fasting, or illness associated with wastage of tissues, a negative nitrogen balance exists. The normal healthy adult is ordinarily in a state of nitrogen equilibrium. That is, if the dietary intake of nitrogen is, say, 15 g. per day, the total nitrogen excreted by all channels (urine, feces, skin) will be approximately 15 g. Of this excreted nitrogen, the urine ordinarily contributes about 90 per cent.

Nitrogen equilibrium may be established at almost any desired level of nitrogen intake, from as low as 2 g. per day to 25 or 30 g. or even more. This apparently is because within these limits the intensity of nitrogen metabolism is determined by the rate of entrance of nitrogen into the body. It was thought at one time that equality of nitrogen intake and excretion represented essentially a disposal of dietary nitrogen in excess of the needs of the animal; that is, a small portion of the entering nitrogen

---

<sup>64</sup> Melnick, Oser, and Weiss: *Science*, **103**, 326 (1946).

was considered to be utilized by the body for the replacement of nitrogen loss due to wear and tear on the body tissues, but the bulk of dietary nitrogen was essentially surplus material and was promptly utilized for energy-yielding purposes without contributing to the nitrogen metabolism of the tissues. This was the basis for the classical distinction of Folin between endogenous and exogenous nitrogen metabolism; according to this concept, the bulk of excreted nitrogen was of exogenous origin and did not arise by the metabolism of tissue protein.

It is now known that this concept is not true, and that in general the nitrogenous constituents of the diet promptly enter into the varied nitrogen and protein metabolism of the body tissues, becoming indistinguishable from similar substances already present, and the equality between nitrogen intake and output is due primarily to the fact that the rate at which a certain amino acid is metabolized is determined largely by the rate at which that amino acid becomes available to the tissues. In other words, the entrance of a given amount of amino acid into the metabolic processes of the tissue brings about the metabolism of an equal amount of the amino acid molecules which are already present. Thus the distinction between endogenous and exogenous breakdown disappears, and must be replaced by the concept of a continuous and dynamic nitrogen metabolism the rate of which is determined, as are all chemical reactions, by the concentration of reactants present at a particular time. The only biological exception to this thus far discovered is in connection with purine metabolism; apparently dietary purines cannot penetrate the cell nucleus and thus enter into the endogenous metabolism of nuclear purines.<sup>65</sup>

This overthrow of the classical distinction between endogenous and exogenous metabolism is due largely to the pioneer work of Schoenheimer and his associates, based upon the application of isotopes to biological problems. The details of some of this work are instructive. Various amino acids (e.g., leucine, glycine) were synthesized in the presence of isotopic nitrogen ( $N^{15}$ ) so that the amino acid contained a significant amount of the isotope. These amino acids were then incorporated in small amount in the diet of rats. The urine was collected over a three-day period, after which the animals were sacrificed and the body nitrogen fractionated into protein and nonprotein portions. These, as well as the excreta, were then analyzed for the presence of the isotopic nitrogen. According to the classical concept of endogenous and exogenous metabolism, the urinary urea should have contained most of the dietary nitrogen and therefore most of the isotopic nitrogen should have appeared promptly in the urine. This did not happen. Less than one-half of the isotopic nitrogen of the glycine was excreted, and less than one-third of that of the leucine. The bulk of the unexcreted isotopic nitrogen was found in the tissue proteins. Later experiments have shown that the labeled amino acid is to a certain extent incorporated directly into the tissue proteins, and likewise contributes its nitrogen to various other amino acids of the body, since both the fed amino acid and other amino acids isolated from the tissue proteins were proved to contain the isotope.

---

<sup>65</sup> Plentl and Schoenheimer: *J. Biol. Chem.*, **153**, 203 (1944).

In general, therefore, one may state that the amino acids of the diet enter rapidly into biological equilibrium with the amino acids of the body, becoming incorporated into newly formed protein or entering into reactions which supply nitrogen for the synthesis of other amino acids or other nitrogenous constituents of the tissues. These reactions occur more or less rapidly among the various tissues and somewhat independently of the nutritional state of the animal; labeled amino acids are found incorporated into the animal body proteins both when there is an abundance of that particular amino acid in the diet, and when on a nitrogen-free diet the tissue proteins are being extensively broken down for energy purposes.

**Conversion of Protein to Carbohydrate and Fat.** It has been well established that after metabolic removal of nitrogen, the carbon chain of certain of the amino acids may be utilized by the animal for the formation of carbohydrate. The classical basis for demonstrating this formation entails the use of the drug phlorizin. If an animal is treated with phlorizin, the renal threshold for glucose is lowered to such a degree that administered glucose, or that formed within the animal body by metabolic processes, is excreted almost quantitatively in the urine ("phlorizin diabetes"). A fasting phlorizinized animal will continue to excrete glucose in the urine long after all carbohydrate stores have been exhausted. It is usually (but not invariably) found that such an animal excretes about 3.6 g. of glucose for every gram of urinary nitrogen. The ratio of urinary glucose (dextrose) to urinary nitrogen is known as the D/N ratio, which in this instance is 3.6.

A D/N ratio of 3.6 usually is interpreted to mean that out of every 100 g. of body protein metabolized by the fasting animal, which would correspond to the excretion of 16 g. of urinary nitrogen, about 58 g. of glucose are formed, since  $58/16 = 3.6$ . The remaining 26 g. of protein, i.e.,  $100 - (58 + 16)$ , presumably represents that portion which is metabolized via fatty acid or ketone body formation. It should be noted here that there are some who disagree with this interpretation of the significance of the D/N ratio.

If to a fasting phlorizinized animal either protein or certain amino acids are administered, extra glucose is found in the urine, along with extra metabolic nitrogen. By quantitative measurement it is believed possible to evaluate the ability of either protein or amino acids to yield glucose in the animal body. Using this method, it has been found, for example, that various proteins yield from about 50 to as high as 80 per cent of their weight as glucose, and that certain amino acids are glucose-formers while others are not. Those amino acids which have been shown to be glucogenic by this procedure include glycine, alanine, cysteine, methionine, nor-leucine, proline, serine, valine, arginine, aspartic acid, and glutamic acid. Those amino acids which do not yield extra glucose in the phlorizinized animal include isoleucine, leucine, lysine, phenylalanine, tyrosine, and tryptophan.

The ability of protein to yield glucose would thus appear to be related to the relative proportion of glucogenic amino acids in the molecule and wide variation among proteins may be expected. It is interesting to note that there is a rough parallelism between the glucogenic amino acids and

those capable of being synthesized within the animal body. In the light of current knowledge concerning intermediary carbohydrate and protein metabolism, it is not surprising that such amino acids as alanine, glutamic acid, and aspartic acid are glucogenic, since after metabolic removal of their nitrogen there remain the substances pyruvic acid, ketoglutaric acid, and oxalacetic acid respectively, and these latter compounds are recognized intermediates in carbohydrate breakdown and synthesis.

Other methods of studying the conversion of amino acids to carbohydrate include the use of perfusion through isolated organs; the ability of the compound to lead to increased liver glycogen content when administered to the fasting rat; and the ability of the amino acid to reduce an experimentally induced ketosis. Results by the various methods described are not always concordant for a particular amino acid. Tryptophan, for example, will reduce an experimental ketosis but will not lead to an increased liver glycogen content or an increased excretion of glucose in the phlorizinized dog; and other examples might be cited. It is possible that these various procedures measure metabolically independent functions rather than the same general property of carbohydrate formation; but more must be learned about the individual reactions concerned before the subject will be better understood.

The conversion of amino acids to fats or fat metabolites is less well understood than that of carbohydrate formation. Certain of the amino acids (e.g., tyrosine, phenylalanine, leucine) appear to be oxidized directly by way of the formation of acetoacetic acid, and this may in turn give rise to the synthesis of fatty acids. Since proteins can be converted into glucose, and glucose into fat, some fat may arise from protein in this fashion. The significance of this in normal nutrition is uncertain.

**Protein Storage.** There is as yet no evidence for the existence within the animal body of a storage form of protein analogous to the storage of carbohydrate as glycogen, or of fat. Yet there does appear to be a reserve protein supply which can be drawn upon to furnish the fundamental nitrogen requirements of the animal when the protein intake is inadequate. This reserve protein appears to be drawn from the tissues themselves; such organs as the liver and kidney, and the blood plasma, appear to be capable of undergoing a considerable depletion of protein content to supply the needs of other parts of the body for nitrogen during fasting. Other organs—e.g., brain—are more resistant to protein depletion.

**Specific Dynamic Action of Protein.** When protein is fed, more heat is produced in the body than can be accounted for by the combustion of the protein ingested. One view is that this action is due to the stimulating action on the tissue cells of certain products of amino acid catabolism, perhaps hydroxy acids, leading to increased oxidation of carbohydrate by such cells. Glycine, alanine, and phenylalanine appear responsible for much of the specific dynamic action of proteins. Carbohydrates and fats also exert a specific dynamic action, but to a lesser extent than proteins and amino acids. For a further discussion of this subject, the reader is referred to Borsook<sup>66</sup> and Kriss.<sup>67</sup>

<sup>66</sup> Borsook: *Biol. Revs.*, **11**, 147 (1936).

<sup>67</sup> Kriss: *J. Nutrition*, **21**, 257 (1941).

**General Physiological Transformation of Amino Acids.** The amino acids in the body undergo many varied and complicated reactions. Some of these are being revealed in detail as a result of the extensive use of isotope techniques.

**TRANSAMINATION.** This refers to the transfer of amino groups from one compound to another. An amino acid under the influence of a specific enzyme loses its amino group to a keto acid and the original compound becomes a keto acid.

The keto acids found in these reversible reactions are concerned in oxidation-reduction systems (carbohydrate metabolism) and thus may furnish amino acids or carbohydrate intermediates as required, i.e., transamination is one link between protein and carbohydrate intermediary metabolism.

**TRANSMETHYLATION.** When methyl groups are linked to the nitrogen or sulfur of certain organic compounds they are capable of being shifted intact among these substances (du Vigneaud).

These so-called labile methyl groups<sup>68</sup> may then react with other labile methyl group substances (guanidoacetic acid, nicotinic acid, purines, etc.) to methylate these compounds.

<sup>68</sup> See p. 1029.

However, the methyl groups now become fixed and are no longer able to transmethyrate. Further aspects of transamination and transmethylation are given on p. 1034 and p. 1029. Reactions thought to be concerned are given here:

## METABOLISM OF INDIVIDUAL AMINO ACIDS

**Glycine.** This amino acid enters into a variety of metabolic functions. In addition to its presence in many of the body proteins (collagen, for example, is rich in glycine), it is concerned in the synthesis of such non-protein compounds as (1) the glycocholic acid of the liver, (2) the creatine of muscle and other tissues, (3) the glutathione of the cells, (4) the protoporphyrin (heme) portion of hemoglobin, (5) the hippuric acid and similar compounds found in the urine after ingestion of benzoic acid and other unoxidizable substances, and (6) the methyl group of choline, methionine, etc. Other aspects of glycine metabolism undoubtedly remain to be recognized.

Glycine is readily synthesizable by both the rat and the adult human; it is thus "dispensable" from the diet of these species. It has been shown, however, that about 1 per cent of glycine is necessary in the diet of the chick to ensure adequate nutrition (Almquist). This is one of several known examples of species specificity with regard to dietary amino acid requirements. The rate of synthesis of glycine in man has been estimated by Quick, on the basis of the rate of excretion of hippuric acid after benzoate administration, to be somewhat over 0.5 g. per hour. It has been shown by Rittenberg and Schoenheimer that synthesized glycine may be derived from sources within the body as well as from the diet. It has been demonstrated that the amino acid serine is a significant precursor of glycine, and there is some indication that glutamic acid may also give rise to glycine, possibly through the intermediary formation of serine.

Knowledge concerning the metabolic degradation of glycine is ex-

tensive; only a small portion will be reviewed here. In the diabetic dog, the carbon chain of glycine can be shown to be readily convertible into glucose. Animal tissues contain a flavoprotein enzyme which catalyzes the oxidation of glycine to glyoxylic acid and ammonia.

This reaction may be of importance in connection with the possible formation of labile methyl groups by way of formaldehyde, as postulated on p. 1025.

Of major interest is the part played by glycine, along with arginine and a labile methyl group, in the biological synthesis of creatine. The separate steps in the formation of creatine have been shown to be as follows:

Bloch and Schoenheimer<sup>69</sup> demonstrated by feeding experiments using both glycine and arginine containing isotopic nitrogen that the two nitro-

gen atoms in the amidine portion ( $\text{—}\overset{\text{NH}_2}{\text{C}}=\text{NH}$ ) of creatine were derived from the amidine portion of arginine, and the third nitrogen atom came from glycine. Borsook and Dubnoff<sup>70</sup> showed that kidney tissue appears to form guanidoacetic acid from arginine and glycine, and that liver tissue probably synthesizes creatine from guanidoacetic acid in the presence of methionine. Guanidoacetic acid itself, the intermediate in creatine synthesis, is found normally in only small amounts in animal tissues, but readily gives rise to extra creatine formation when fed. Glycine appears also to be directly concerned in the synthesis of glutathione, the tripeptide which is thought to be of importance in intracellular oxidation and reduction. It has been shown that when isotopic glycine is fed to an animal, the labeled glycine appears so rapidly in the glutathione of the animal body as to indicate the direct participation of glycine in the synthesis of this compound. Involvement of glycine in the synthesis of hemin by the adult human is also indicated by the use of isotopic glycine.

<sup>69</sup> Bloch and Schoenheimer: *J. Biol. Chem.*, **138**, 167 (1941).

<sup>70</sup> Borsook and Dubnoff: *J. Biol. Chem.*, **132**, 559 (1940); **138**, 389 (1941).

After prolonged administration of labeled glycine to an individual, the hemin isolated from the red blood cells contains sufficient isotopic carbon to indicate a major role of glycine in the synthesis of the pyrrole ring of the hemoglobin molecule. In fact the formation of heme from glycine has been found by *in vitro* studies in which glycine labeled with N<sup>15</sup> and C<sup>14</sup> was incubated with red blood cells of sickle-cell anemic patients or with the nucleated red cells of birds. Acetic acid also has been implicated in this synthesis (see p. 1009).

Although it was formerly believed that the animal was unable to synthesize methyl groups and thus was forced to obtain preformed methyl groups for creatine, etc. from methionine or choline, it has now been demonstrated that many compounds are capable of supplying this metabolic essential. Thus choline, betaine, and methionine are able to contribute labile methyl groups<sup>71</sup> to each other and to guanidoacetic acid by the process of transmethylation, while glycine, serine, methylol, formic acid, formaldehyde, and others are sources of methyl groups by conversion to an unknown one-carbon intermediate.

Relatively little work has been done on the role of glycine in the synthesis of the glycocholic acid of the liver. The relationship of glycine to hippuric acid formation is discussed in detail in Chapter 20. The ability of certain tissues to synthesize hippuric acid *in vitro* has been used as a means of establishing possible precursors of glycine.

**Alanine.** This 3-carbon amino acid is readily synthesized by the animal body and hence is dispensable from the diet. Metabolism and synthesis are usually considered to involve the reversible equilibrium of oxidative deamination (see p. 1018) and transamination (see p. 1034). The reaction of oxidative deamination is as follows:

There is little evidence that this reaction actually occurs in the tissues; the L-amino acid oxidase of Blanchard, *et al.*,<sup>72</sup> attacks alanine but slowly, and there is no biological evidence for the synthesis of alanine from pyruvic acid and free ammonia. A more plausible metabolic pathway is by the reactions of transamination described on p. 1034, whereby synthesis would entail the transfer of the amino group of either glutamic or aspartic acid to pyruvic acid, to yield alanine and either ketoglutaric acid or oxalacetic acid, and metabolic breakdown would be the reverse of these reactions. The pyruvic acid thus formed from alanine by transamination may then follow the normal course of oxidation of carbohydrate intermediates (p. 990). Conversion to pyruvic acid presumably is the explanation for the glucogenic action of alanine. By the use of alanine

<sup>71</sup> See p. 1029.

<sup>72</sup> Blanchard, Green, Nocito, and Ratner: *J. Biol. Chem.*, **161**, 583 (1945).

labeled with isotopic hydrogen (deuterium), it has been shown that alanine may be a source of acetyl groups in the acetylation of certain foreign amino acids excreted in the urine as acetyl derivatives (see p. 1012 and Chapter 20).

**Serine.** This hydroxy-amino acid is readily synthesizable by the animal body and is thus dispensable from the diet. It nevertheless participates in a somewhat unusual variety of metabolic reactions in the tissues. In addition to its presence in proteins, it has been found in phospholipide material, where it apparently serves in a manner analogous to choline and ethanolamine in the structure of phospholipide molecules (see Chapter 11). In fact, studies using serine labeled with isotopic nitrogen indicate that ethanolamine arises by the decarboxylation of serine; ethanolamine can then give rise to choline by methylation. Serine is also a precursor of glycine (see p. 1025).

Serine is also concerned in the formation of cystine (see p. 1031). Serine is glucogenic in the diabetic dog. The "unnatural" optical isomer of serine, D-serine, is toxic to rats. The nitrogen of serine has been shown by isotopic experiments to be incorporated into the N<sub>7</sub> of uric acid while the β-carbon appeared at C<sub>2</sub> and C<sub>8</sub> having been initially converted to formate.

The anaerobic deamination of serine appears to take the following course:

**Threonine.** This amino acid cannot be synthesized by the animal body, and its presence in the diet in adequate amount is required both for growth in the young rat and for the maintenance of nitrogen equilibrium in the adult human. Threonine was the last "essential" amino acid to be discovered, in the sense that its isolation from casein and characterization by McCoy, Meyer, and Rose in 1935 first permitted the use of a mixture of pure amino acids as the sole source of nitrogen in an experimental diet.

Relatively little is known concerning the metabolism of threonine. It is glucogenic and antiketogenic. It is not attacked by the L-amino acid oxidase of rat kidney, but there may be another enzyme concerned since it has been reported to be deaminated by kidney tissue under anaerobic conditions to produce α-ketobutyric acid, CH<sub>3</sub>·CH<sub>2</sub>·CO·COOH. Only the optically active form found naturally is utilizable for growth. Threonine and lysine are the only amino acids known which do not transaminate.

**Methionine.** This sulfur-containing amino acid cannot be synthesized by the animal body from the ordinary constituents of the diet, and must be present in adequate amount for the promotion of growth in the young

animal and for the maintenance of nitrogen equilibrium in the adult human. Methionine alone will satisfy all of the sulfur requirements of the animal, since it is readily converted into cystine in the tissues, as described on p. 1031.

Methionine is glucogenic in the diabetic dog. Metabolism may proceed in part by deamination through the corresponding keto acid,  $\text{CH}_3\cdot\text{S}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}\cdot\text{COOH}$ , since this latter compound is formed to considerable extent on incubating methionine with liver tissue, and the young rat will grow on a diet containing the keto acid in place of methionine. Further stages in the oxidative breakdown of methionine are obscure. On complete oxidation, the sulfur is found in the urine as sulfate, either inorganic or ester, as with cystine (p. 1032).

**TRANSMETHYLATION.** An important metabolic function of methionine is in connection with the process known as transmethylation. It has been shown by du Vigneaud and associates that the animal body is able to use the methyl group of methionine to methylate certain nitrogen- and sulfur-containing compounds of the body. Methionine, choline, and betaine (trimethylglycine) have been shown to be suitable dietary sources of such methyl groups; of these, methionine appears to be quantitatively the most important. In the biological synthesis of creatine, for example (see p. 1026) the methyl group of creatine is derived by transfer from methionine. The process of methyl transfer from one compound to another is called *transmethylation*. A methyl group which may be so transferred is called a *labile methyl group*; thus far, only methyl groups attached to either nitrogen or sulfur appear to be labile and to participate in transmethylation. Contrary to the former opinion, labile methyl groups need *not* be supplied in the diet but can be synthesized from glycine, serine, formic acid, and their precursors (see p. 1025).

The role of methionine in transmethylation has been adequately proved by the use of methionine synthesized to contain isotopic hydrogen (deuterium) in the methyl group. When such labeled methionine is included in the diet of an animal, the methylated compounds choline and creatine subsequently isolated from the animal tissues prove to contain sufficient isotope to justify the conclusion that methyl groups have been transferred from the methionine to the other compounds in question. The ability of methionine to furnish methyl groups for the synthesis of choline from suitable precursors explains the lipotropic effect of this amino acid (see p. 1012). The transfer of methyl groups from methionine to choline is reversible, most probably through the intermediate formation of the amino acid homocysteine (see below); methylation of guanidoacetic acid to form creatine is irreversible, and the constant excretion of body creatine as urinary creatinine represents a loss of methyl groups from the body. The daily requirement for methyl groups, however, appears to be considerably in excess of such urinary loss, so that other pathways of methyl group degradation must be present; relatively little is known about this at the present time. Most of the evidence for transmethylation has been obtained with the rat, but the process has also been shown to occur in the adult human.

After removal of the methyl group from methionine, the amino acid

homocysteine results. Homocysteine,  $\text{HS}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$ , and its disulfide form homocystine (analogous to the relation between cysteine and cystine) are synthetic amino acids which have not as yet been isolated from natural sources. Their biological availability is such, however, as to lead to the belief that they represent normal intermediates in methionine metabolism. If an animal is placed on a diet containing no methionine but adequate amounts of homocysteine or homocystine, together with a source of labile methyl groups such as choline, betaine, or serine, the animal will synthesize the methionine it needs for normal growth. If the methyl groups of the dietary choline are labeled with deuterium, the methionine subsequently isolated from the tissue proteins proves to contain the isotope in its methyl group. The animal body is therefore capable of transferring methyl groups from choline via betaine to homocysteine, to form methionine; as has already been pointed out, this transfer is reversible. Since the reversible exchange of methyl groups between methionine and choline can be demonstrated not only on the homocysteine diet but also when the diet contains adequate amounts of methionine and choline, it is believed to represent a normal metabolic process of the tissues. The implication of homocysteine in the formation of cystine from methionine is discussed on p. 1031. The general metabolic relation between methionine, homocysteine, and related compounds may be represented as follows:

In addition to its known metabolic functions, methionine appears to play a specific part in protecting the liver from damage by such poisons as carbon tetrachloride, phosphorus, arsenic, and chloroform. The mode of action here is unknown.

**Cystine and Cysteine.** These two sulfur-containing amino acids are usually considered to be metabolically equivalent since one may be so readily converted into the other by oxidation or reduction. There is some evidence, however, that there may be biological differences between cysteine and cystine, particularly in specific organs such as the liver and kidney. In the rare metabolic abnormality known as *cystinuria*, individuals regularly excrete significant amounts of cystine in the urine. This

excretion continues during fasting, and is not increased by the oral administration of cystine itself; the feeding of cysteine or of methionine does, however, augment cystine excretion. Thus the cystinuric distinguishes between orally administered cystine and cysteine, and the normal individual may do so in specific tissues as well.

It was thought for a long time that cystine was an indispensable amino acid, but Jackson and Block showed in 1932 that methionine could replace cystine for growth purposes in the rat on a low-cystine diet, and the ability of the animal body to form cystine from methionine is now well established. In 1939 Tarver and Schmidt demonstrated, by the use of methionine containing radioactive sulfur, that the sulfur of cystine was derived from the sulfur of methionine.

The mechanism of formation of cystine from methionine has been the subject of considerable study, and appears to have been finally established by the work of du Vigneaud and his associates as follows: methionine is demethylated to form the amino acid homocysteine; this condenses with serine to form an unsymmetrical thio-ether, called cystathionine; the cystathionine undergoes enzymatic cleavage so that the sulfur remains with the serine moiety, to produce cysteine. The fate of the remaining portion of the cystathionine molecule is as yet not known. These various steps may be illustrated as follows:

Evidence for the conversion of methionine to homocysteine has already been presented (p. 1029). When homocysteine and serine are incubated with liver tissue, cysteine is formed. It has also been shown by Stetten that when serine labeled with isotopic nitrogen is fed to animals, the cystine isolated from the tissues contains such a high proportion of the isotope as to indicate (but not prove) the direct conversion of serine to cysteine. Cystathionine, the postulated intermediate, has been found in the livers of fasting rats which were fed *both* L-methionine and L-serine.<sup>73</sup> If either amino acid were fed alone, no cystathionine was observed. If methionine is synthesized to contain both isotopic sulfur and isotopic carbon, and this doubly labeled compound is fed to rats, the cystine isolated from the hair proves to contain as much as 80 per cent of the isotopic sulfur, but no isotopic carbon.<sup>74</sup> This is further evidence that it is

<sup>73</sup> Hess: *Arch. Biochem. Biophys.*, **40**, 127 (1952).

<sup>74</sup> du Vigneaud, Kilmer, Rachele, and Cohn: *J. Biol. Chem.*, **155**, 645 (1944).

the sulfur and not the carbon chain of methionine which is involved in the formation of cystine.

Cystine and cysteine contribute to the formation of many important sulfur-containing compounds in the animal body. Cysteine is a component of glutathione ( $\gamma$ -glutamyl-cysteyl-glycine); and appears to be the precursor of the taurine of the taurocholic acid of the bile, probably through intermediate oxidation to form cysteic acid:

Cysteine is likewise found in the urine in combination with certain unoxidizable substances (detoxication), to form what are called mercapturic acids (see Chapter 20). Cysteine is glucogenic in the animal body, possibly through the intermediate formation of serine. On complete oxidation of cysteine and cystine, the sulfur is found in the urine either as inorganic sulfate or to some extent as organic esters of sulfuric acid with such compounds as indoxyl, phenol, etc. This is also discussed in Chapter 20.

ONE-CARBON INTERMEDIATES. In the discussion of the metabolism of glycine, serine, methionine, cystine, and histidine, mention is made of labile methyl groups and one-carbon intermediates. Whether these are

the same compounds or not, it is known that they are metabolically related and for purposes of simplification have been formulated as HCOOH in the diagram on p. 1032 which illustrates some of the metabolic pathways of these one-carbon intermediates.

**Leucine and Isoleucine.** Relatively little is known concerning the metabolism of these two amino acids. They are not synthesizable from dietary constituents and are required in the diet for the growth of young animals and the maintenance of nitrogen equilibrium in the adult. Leucine and isoleucine are ketogenic rather than glucogenic amino acids. The conversion of leucine to acetoacetic acid possibly proceeds as follows:

**Valine.** This amino acid is required in the diet in adequate amount, as evidenced both by growth studies with young animals and by the maintenance of nitrogen equilibrium in the adult human. A possible metabolic pathway involves deamination to form  $\alpha$ -ketoisovaleric acid, since this compound will replace valine in an experimental diet.

Valine is convertible, in part at least, to glucose in the diabetic dog.

**Proline and Hydroxyproline.** These two amino acids can be synthesized by the animal body from dietary or tissue precursors, and proline is glucogenic in the diabetic dog. A probable precursor of proline is ornithine; since ornithine and proline are interconvertible in the organism, proline metabolism may proceed through ornithine formation. Glutamic acid has likewise been shown to arise from proline; further metabolism via this pathway would then be that of glutamic acid, and this may be the origin of the glucogenic action of proline. Hydroxyproline can be synthesized from dietary proline; there is some evidence that this reaction is not reversible, and that the further metabolism of hydroxyproline may

not be similar to that of proline. These various relationships may be summarized as follows:

**Glutamic Acid.** This dicarboxylic amino acid is present in fairly large amount in many animal and vegetable proteins. It is readily synthesizable by the animal body, and is thus dispensable from the diet; it is probable, however, that the ease of synthesis within the tissues is more properly a reflection of the important part played by glutamic acid in the general processes of nitrogen metabolism within the cell rather than an indication of a "nonessential" function.

Evidence that glutamic acid may be an important intermediate in general nitrogen metabolism is afforded by the work of Schoenheimer and associates using various amino acids labeled with isotopic nitrogen ( $\text{N}^{15}$ ). When such labeled amino acids are fed to an animal, the isotopic nitrogen is found not only in the fed amino acid incorporated into the tissue proteins of the animal, but also to a significant extent in various other amino acids as well, and of these, glutamic acid usually exhibits the highest concentration of isotope. It is probable that transamination (see below) is partly responsible for this; the presence of glutamic acid in glutathione may also be connected with the apparently rapid transfer of dietary amino nitrogen via glutamic acid.

**TRANSAMINATION.** An important metabolic aspect of glutamic acid is its participation in the reactions of *transamination*. In the transamination reaction the amino group of glutamic acid is transferable to either pyruvic or oxalacetic acid to produce  $\alpha$ -ketoglutaric acid and the amino acids alanine or aspartic acid, as the case may be. These reactions are reversible so that glutamic acid may be synthesized from  $\alpha$ -ketoglutaric acid and either alanine or aspartic acid. The diagram on p. 1035 illustrates the transamination reactions.

Enzymes catalyzing the upper reaction (glutamic-aspartic transaminase) and the lower reaction (glutamic-alanine transaminase) have been isolated from animal tissues, and are believed to contain a pyridoxine (vitamin  $\text{B}_6$ ) derivative as prosthetic group. A third postulated reaction, between aspartic acid and pyruvic acid to produce oxalacetic acid and alanine, is due, according to Green, to the presence of both of the transaminases mentioned. It is noteworthy that no free ammonia is formed during transamination, the reaction apparently involving condensation of

amino acid and keto acid through the amino and keto groups to form an intermediate which is then split in such a way that the amino nitrogen is transferred from the original amino acid to the keto acid chain.

In addition to transamination, glutamic acid likewise undergoes reversible oxidative deamination.

The reversal of this reaction is one of the few known examples of the biological synthesis of an amino acid from the keto acid and ammonia, and may represent one of the pathways for the demonstrated (although limited) conversion of dietary ammonia nitrogen into amino acid nitrogen.

As would be expected from the equilibrium between glutamic acid and its keto acid,  $\alpha$ -ketoglutaric acid, which is an intermediate in carbohydrate metabolism (p. 990), glutamic acid is glucogenic in the diabetic dog. Certain other amino acids such as proline, ornithine, and histidine are known to give rise to glutamic acid in metabolism, and this may also explain their glucogenic action. The other keto acids involved in transamination (oxalacetic acid and pyruvic acid) are likewise carbohydrate breakdown products, and this fact may represent an important link between amino acid metabolism and carbohydrate metabolism.

Glutamic acid is combined as one of the three portions of the molecule of the vitamin pteroylglutamic (folic) acid, the other two being *p*-aminobenzoic acid and pteric acid; the various conjugated forms of this vitamin are due to the multiplicity of glutamic acid units present in peptide linkage—e.g., the conjugate in liver contains seven such units while that obtained from fermentation contains three. (See Chapter 35.)

Glutamic acid appears to be present in proteins largely in the form of its amide, glutamine,  $\text{HOOC}\cdot\text{CH}(\text{NH}_2)\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CONH}_2$ . Free glutamine has been found in small amount in the blood, and according to Van Slyke and associates, glutamine or a glutaminelike compound is of importance as a precursor of urinary ammonia. Glutamine has also been implicated

in the processes of urea formation by the liver, but its role here, if any, is obscure. The reported presence in cancer tissue of the "unnatural" optical isomer of glutamic acid, D-glutamic acid, has not been confirmed, but D-glutamic acid is found in the capsule of the anthrax bacillus and in other products of bacterial origin.

Glutamic acid is decarboxylated in the  $\alpha$  position to give  $\gamma$ -aminobutyric acid. Glutamic decarboxylases are widespread in plants and bacteria, but have been found only in the higher portions of the central nervous system of animals. The importance of glutamic acid, glutamine, and  $\gamma$ -aminobutyric acid in the metabolism of the brain is not yet clear but the present evidence indicates that these compounds must play a basic part in the physiology of nervous tissue.

**Aspartic Acid.** The metabolic aspects of this amino acid are less well understood than those of glutamic acid, but it appears to be similar to the latter in certain respects. It is readily synthesizable within the body, and shares with glutamic acid in the transfer of dietary amino nitrogen as described on p. 1034, but to a lesser extent. Synthesis probably proceeds via the transamination reaction involving the keto acid, oxalacetic acid, and glutamic acid as described previously. Metabolic breakdown by the reversal of this reaction to form oxalacetic acid, which is a carbohydrate intermediate, serves to explain the glucogenic power of aspartic acid as well as to indicate the pathway of further degradation. The amide of aspartic acid, asparagine,  $\text{HOOC} \cdot \text{CH}(\text{NH}_2) \cdot \text{CH}_2 \cdot \text{CONH}_2$ , is found in tissue proteins, but its significance is obscure.

**Histidine.** Histidine is required in the diet of the young growing animal but is apparently dispensable from the diet of the adult human, as established by the maintenance of nitrogen equilibrium in man on diets free of histidine. Here, as with arginine, it may be that rate of synthesis is the limiting factor, with the possibility that bacterial action in the intestinal tract may also be concerned. Histidine is apparently metabolized via the pathway shown at top of p. 1037.<sup>75</sup>

In addition to its presence in tissue proteins, histidine is found in the animal body in the muscle constituents carnosine ( $\beta$ -alanyl histidine) and anserine ( $\beta$ -alanyl methyl histidine), and it is probably a precursor of the red blood cell constituent ergothioneine, which is a betaine of thiolhistidine. Histidine is regularly found in the urine during pregnancy (and also

<sup>75</sup> Edlbacher and Kraus: *Z. physiol. Chem.*, **191**, 225 (1930).

in some other conditions); the significance of this is unknown. Histidine is glucogenic, possibly because it gives rise to glutamic acid during metabolism.

Decarboxylation of histidine produces histamine:

Histamine is an organic base with a very powerful pharmacological action on certain body structures. In addition to its well-known effect on blood pressure (capillary dilatation), it is a potent stimulant of gastric secretion (see p. 360), and has been implicated in the complex symptomatology of anaphylactic shock and in eclampsia. Drugs which have an action specifically antagonistic to that of histamine are known as antihistamines; many if not all of these compounds are structural analogs of histamine and presumably owe their effect to an antimetabolite action (see Chapter 36).

**Lysine.** This amino acid is required in the diet of the young growing animal and for the maintenance of nitrogen equilibrium in the adult human. It is not glucogenic in the diabetic dog. It is unique among all the amino acids thus far investigated in that it does not appear to be capable of obtaining its nitrogen from other dietary sources, as can be done by certain other amino acids (see discussion on p. 1022). Lysine, however, can contribute its nitrogen to other amino acids after metabolic breakdown.

The metabolism, therefore, may involve an oxidative deamination which for some reason is irreversible. This is borne out by the fact that neither the keto acid nor the hydroxy acid derivative of lysine can substitute for this amino acid in experimental diets. Studies have indicated that lysine may first form  $\alpha$ -amino adipic acid which is then converted into glutaric acid and hence to glutamic acid.

**Arginine.** The question of whether or not this amino acid can be synthesized by the animal body has been the subject of considerable debate in the past. It now appears to be settled, largely through the work of Rose, using diets containing mixtures of pure amino acids, that arginine can be synthesized by the tissues of the young growing rat, for example, but not at a rate fast enough to supply the needs of the animal for optimal growth. It is thus indispensable in this sense in the diet of the young growing rat. The adult rat (and the adult human) apparently can supply arginine by synthesis from other sources at a rate adequate for nutritional needs. On the other hand, the requirements of the chick for arginine are such that this amino acid must be considered indispensable in the diet—an example of species differences with respect to amino acid requirements.

Various studies using amino acids labeled with isotopic nitrogen and hydrogen have indicated that arginine is synthesized in the body by the

$$\begin{array}{c} \text{NH}_2 \\ | \\ \text{—C=NH} \end{array}$$

addition of an amidine group ( $\text{—C=NH}$ ) to ornithine,  $\text{HOOC} \cdot \text{CH}(\text{NH}_2) \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{NH}_2$ . The origin of the amidine group is not known (a possible mechanism is by the ornithine cycle discussed below), but ornithine is readily synthesizable biologically—for example, from proline (p. 1033). Evidence that the synthesis of arginine is reversible is not available, but it is known that the amidine portion may be transferred to glycine to form guanidoacetic acid in the synthesis of creatine (p. 1026). Arginine also may be degraded to form ornithine and urea in the presence of the enzyme arginase, as described below. There is evidence that arginine may give rise via ornithine to proline, hydroxyproline, and glutamic acid, and these may represent further stages in metabolism. Both arginine and ornithine are glucogenic, possibly because of their convertibility to the amino acids just mentioned. There is some evidence that the  $\alpha$ -amino

nitrogen of arginine does not undergo oxidative deamination to form the corresponding keto acid, or if so, that this process is irreversible.

Interest in the metabolic function of arginine has been directed primarily toward its possible relation to the synthesis of creatine and the formation of urea. The role of arginine in creatine formation is described in detail on p. 1026. Interestingly enough, an arginine analog of phosphocreatine (namely, phosphoarginine) appears to serve in place of phosphocreatine in the muscles of certain lower animal species.

The possible role of arginine in urea formation by mammalian liver has been evident for a long time because of the presence of the enzyme arginase in liver; arginase catalyzes the hydrolytic splitting of arginine into ornithine and urea. According to Krebs and Henseleit, arginine enters into a cyclic mechanism, along with the amino acids ornithine and citrulline, for the conversion of ammonia into urea in the liver. On the basis of later developments, the process is now pictured as follows:

According to this view, ammonia and carbon dioxide are added to the amino acid ornithine to produce the amino acid citrulline. On the further addition of ammonia to citrulline, arginine is formed which then undergoes action by the enzyme arginase to produce urea and to regenerate ornithine, which can then proceed through the cycle again. The original evidence for this theory was based largely on the demonstration that both ornithine and citrulline catalyzed the synthesis of urea from free ammonia by liver slices. Additional evidence tending to support the theory has come from several sources. If the liver slices are incubated in the presence of bicarbonate containing isotopic carbon, the carbon isotope is found in the urea synthesized. Schoenheimer's work on the distribution of isotopic dietary nitrogen between the amidine moiety and the ornithine moiety of arginine isolated from tissue proteins, and the isotope content of the urinary urea, led him to conclude that the results supported the ornithine cycle theory. According to Gornall and Hunter, the accumulation of citrulline in liver tissue during urea formation under special conditions may be demonstrated, and citrulline may also be found in small amount in the blood. Beadle and Tatum also have presented evidence

that the ornithine-cycle mechanism functions in the red bread mold *Neurospora*.

**Tryptophan.** This amino acid is required in the diet for growth of the young animal and the maintenance of nitrogen equilibrium in the adult human. It has several metabolic pathways which appear to vary somewhat in different species of animals. One of the most interesting findings in recent years is that tryptophan is converted in the body to the vitamin, nicotinic acid (niacin). Other end products appear to be alanine, anthranilic acid, kynurenic acid, etc. (cf. diagram). The quantitative aspects of these known metabolic pathways have not as yet been elucidated, but it appears that the conversion to nicotinic acid plays a minor role, for it requires from 50 to 300 g. of tryptophan to make 1 g. of the vitamin.

Some animal species (but not others) will excrete kynurenic acid in the

<sup>76</sup> Kynureninase contains pyridoxine (vitamin B<sub>6</sub>) as a prosthetic group. In the absence of this vitamin there is an increased production of xanthurenic acid especially if riboflavin is present.

urine after the ingestion of large doses of tryptophan (Jackson). There is some basis for the belief that kynurenic acid is an end product and not an intermediate in tryptophan metabolism. Kynurenine is claimed to be a hormone for *Drosophila*. Tryptophan is converted into 4,8-dihydroxyquinoline-2-carboxylic acid (xanthurenic acid) by the rat on a diet deficient in vitamin B<sub>6</sub>. The red bread mold *Neurospora* can synthesize tryptophan from indole and serine. The reverse of this reaction, i.e., the production of indole by bacterial action on tryptophan in the intestinal tract, is believed to be the origin of the indole, skatole (methyl indole) and indican of the feces and urine. Tryptophan deficiency produces a type of cataract in the rat, and certain evidence indicates a relation between anemia, tryptophan, and vitamin B<sub>6</sub> (pyridoxine).

Tryptophan catabolism may also proceed by oxidative deamination to the corresponding keto acid, indolepyruvic acid, since this compound (and indolelactic acid) will replace tryptophan in experimental diets. Tryptophan is apparently not ketogenic and will alleviate experimental ketonuria in the rat.

**Phenylalanine and Tyrosine.** These two aromatic amino acids usually are considered together because of their close metabolic relationship. Of the two, phenylalanine cannot be synthesized by the animal body (except from its corresponding keto- or hydroxy-acid, which are not ordinary constituents of the diet) and therefore must be present in the diet in adequate amounts. The needs of the animal for tyrosine, however, can be readily supplied by dietary phenylalanine, as established by growth studies with young rats and by the maintenance of nitrogen equilibrium in the adult human. Phenylalanine, therefore, is convertible into tyrosine by the organism; this conversion has been directly demonstrated by the feeding of phenylalanine labeled with isotopic hydrogen (deuterium) to rats, followed by the subsequent isolation of tyrosine from the animal's tissue proteins; such isolated tyrosine contained sufficient deuterium to establish its origin from the fed phenylalanine. All available experimental evidence indicates, however, that the conversion of phenylalanine into tyrosine is *irreversible*; tyrosine cannot be converted into phenylalanine in the animal body.

Knowledge concerning the intermediary metabolism of both phenylalanine and tyrosine is still far from complete. In addition to their roles as essential components of the body proteins, these two amino acids, and particularly tyrosine, appear to be concerned with the formation of a variety of physiologically important substances such as thyroxine, adrenaline, the pigment melanin, and others. Certain of the known or postulated metabolic interrelationships of tyrosine and phenylalanine are summarized in the diagram on p. 1042.

Both phenylalanine and tyrosine are ketogenic amino acids, i.e., they can be shown to give rise to acetoacetic acid under the proper conditions, and neither amino acid is glucogenic. It is postulated, therefore, that after the loss of nitrogen which is excreted as urea, both phenylalanine and tyrosine are normally oxidized to carbon dioxide and water through the intermediate formation of acetoacetic acid. Whether these two amino acids follow a common metabolic pathway (i.e., phenylalanine → tyrosine

$\rightarrow$  intermediates  $\rightarrow \text{CO}_2 + \text{H}_2\text{O}$ ) is a matter of dispute. Possible direct metabolites of phenylalanine other than tyrosine include phenylpyruvic and phenyllactic acids; phenylpyruvic acid is found in the urine of animals after feeding with phenylalanine.

Fölling reported that a certain proportion of individuals with mental disease regularly excrete phenylpyruvic acid in the urine. This condition

has been called *oligophrenia phenylpyruvica*. If phenylalanine is administered to individuals suffering from this metabolic abnormality, the excretion of phenylpyruvic acid is increased.<sup>77</sup> Thus there is good evidence that phenylpyruvic and phenyllactic acids are produced from phenylalanine; there is equally good evidence that the reactions leading to their production are reversible; for instance, both phenylpyruvic acid and phenyllactic acid can replace phenylalanine in the diet of the growing rat.

The metabolic fate of tyrosine is somewhat better understood than that of phenylalanine; the irreversible blockage between tyrosine and phenylalanine permits a more precise estimation of the significance of possible intermediates obtained under experimental and abnormal conditions. As with phenylalanine, possible metabolites of tyrosine include the corresponding keto- and hydroxy-acids, *p*-hydroxyphenylpyruvic and *p*-hydroxyphenyllactic acids, respectively. Both of these compounds have been isolated from human and animal urine under certain conditions. Medes has described a condition called *tyrosinosis* (only one such case has thus far been found) in which an adult human excreted significant amounts of *p*-hydroxyphenylpyruvic acid in the urine. The output of this compound was augmented with increased intake of protein or of pure tyrosine or phenylalanine; feeding the compound itself resulted in the unchanged excretion of most of it. Levine and associates discovered that the infant human may exhibit a spontaneous defect in tyrosine metabolism characterized by the excretion of significant amounts of *p*-hydroxyphenylpyruvic and *p*-hydroxyphenyllactic acids, in the presence of a low vitamin-C intake and an excessive intake of tyrosine or phenylalanine, either in the form of protein or as the pure amino acids. Vitamin-C administration abolished the defect except in the presence of excessive amounts of phenylalanine or tyrosine. Sealock and associates have shown that the scorbutic guinea pig excretes tyrosine metabolites (*p*-hydroxyphenylpyruvic acid, homogentisic acid) after administration of tyrosine or phenylalanine; vitamin-C administration prevented the excretion of these compounds. It has also been shown that scorbutic guinea-pig liver is unable to oxidize tyrosine *in vitro* except in the presence of vitamin C.

It would appear from these and other findings that the keto acid of tyrosine is a normal intermediate in tyrosine metabolism, and that vitamin C is concerned in the further utilization of the keto acid. The possibility remains open, however, that oxidative deamination of tyrosine is only one metabolic pathway and that the metabolism may follow some as yet unknown sequence of reactions.

Further knowledge concerning tyrosine metabolism has been afforded by the study of the metabolic abnormality known as *alkaptonuria*. In this relatively rare condition, individuals excrete the compound homo-

---

<sup>77</sup> This disease is characterized by the fact that the individual has lost the ability to convert phenylalanine into tyrosine. As a consequence phenylalanine must be oxidized via the pathway phenylalanine → phenylpyruvic acid → phenylacetic acid. Phenylacetic acid is a neurotoxic agent which is detoxified by combination with glutamine to yield phenylacetylglutamine. As pointed out on p. 1036, glutamic acid and glutamine appear to be of special significance in the metabolism of the higher centers of the central nervous system. All patients with *oligophrenia phenylpyruvica* are mentally defective. Is this due to a chronic deficiency of glutamine?

gentisic acid (for structure see diagram on p. 1042) in the urine.<sup>78</sup> In the presence of alkali and oxygen, homogentisic acid forms a dark brown or black pigment, and it is the darkening of the urine under these conditions which usually leads to the discovery of alkaptonuria. Homogentisic acid is believed to be a normal intermediate in tyrosine metabolism, probably through the intermediary formation of 2,5-dihydroxyphenylpyruvic acid (see diagram, p. 1042), and the metabolic defect in alkaptonuria is thought to be the lack of ability to carry the oxidation beyond the stage of homogentisic acid formation. Feeding of tyrosine or phenylalanine to an alkaptonuric increases the output of homogentisic acid, and fed homogentisic acid is excreted unchanged. The normal individual is able to oxidize homogentisic acid completely. Alkaptonuria may be produced experimentally in animals (and in man) by prolonged or excessive feeding of either tyrosine or phenylalanine, and in scurvy. Vitamin-C administration will correct the alkaptonuria of the scorbutic guinea pig, but has no apparent effect on human alkaptonuria.

Certain other aspects of tyrosine metabolism are of physiological importance. Both the diiodotyrosine and thyroxine of the thyroid gland are considered to arise from tyrosine. Both of these substances have been isolated from casein and other tyrosine-containing proteins treated *in vitro* with alkaline iodide solution, and the incubation of thyroid gland slices in the presence of radioactive iodide as a tracer results in the production of diiodotyrosine and thyroxine containing the radioactive material. Epinephrine is likewise thought to originate from tyrosine. It has been shown that animal tissue can decarboxylate tyrosine to yield tyramine; oxidation and methylation of this compound could produce epinephrine.<sup>79</sup> An alternate possible pathway would involve the intermediate formation of 3,4-dihydroxyphenylalanine, followed by decarboxylation to yield hydroxytyramine, and oxidation and methylation to produce epinephrine.

According to Bloch and to Raper, it would appear that the pigment melanin is related to tyrosine metabolism. Melanin is not a simple chemical substance, but rather a mixture of pigments of ill-defined composition. It is a normal skin pigment, and appears to be low or lacking in the condition known as *albinism*. It is produced in excessive amounts by melanotic tumor cells, and may even be excreted in the urine (*melanuria*) under these conditions. It is also produced in excessive amount in Addison's disease (bronzed diabetes). Bloch showed some years ago that the skin contains an enzyme (dopase) capable of converting the compound 3,4-dihydroxyphenylalanine (dopa) into melaninlike material, and that this enzyme was absent from the skin of albinos. According to Raper, the probable precursor of 3,4-dihydroxyphenylalanine is tyrosine.

## I. GENERAL PROCEDURES IN METABOLIC STUDIES

**1. Collection and Preservation of the Urine.** In metabolism tests such as those given in this chapter accurate collection of urine for the *exact* 24-hour period is of the *utmost importance*. Proceed as follows: Empty the bladder at a given hour, e.g., 8 A.M.,

<sup>78</sup> See p. 810.

<sup>79</sup> See p. 1042.

and *discard the urine*. Prepare a *thoroughly clean* bottle of proper size, introduce into it sufficient toluene to cover the bottom of the bottle, and use this bottle for the collection of all urine voided during the following 24 hours, including the urine obtained by emptying the bladder at the close of the 24-hour period, e.g., at 8 A.M. the next day. During the day, when not actually in use for the introduction of a urine fraction, the bottle should be kept in a refrigerator or cold room in order that the sample may not deteriorate before it is examined. Measure the volume of the sample and determine its specific gravity (see p. 785) and reaction before proceeding to the quantitative estimation of any specific urinary constituents.

For metabolism work on *dogs*, a cage is used which is provided with a screen bottom. Below this is a tray which slopes toward a central hole through which the urine passes into a bottle containing toluene. Each day's output is collected and filtered to remove hair, etc., and may then be diluted to a definite volume, usually 500 or 1000 ml. This procedure facilitates subsequent calculation.

To obtain the complete 24-hour secretion of urine of *dogs*, catheterization must be resorted to. Because of the difficulty of catheterizing male dogs, bitches (especially those who have had pups, and hence have stretched vaginas) are used for this type of experimentation. Care must be taken to have the catheter sterile, in order to avoid infection or cystitis. Rubber catheters are sterilized by boiling in water, while metal or glass catheters may be washed and kept in alcohol. The simplest procedure is to use a speculum (a nasal dilator is about the right size) to stretch the vagina and then to insert the catheter directly into the urethra, avoiding contact with the vaginal wall. The exact location of the urethral orifice can be determined with a little experience. Force should never be used. After the bladder has been emptied, it is washed out several times with warm water, the washings being collected with the urine and made up to volume as described above. Finally, if it does not interfere with the experiment, it is desirable to introduce about 50 ml. of warm saturated boric acid solution into the bladder from time to time.

The most satisfactory method for obtaining urine from a *rabbit* is to hold its head up between one's knees and to apply gentle pressure on the lower abdomen. By this process of "milking," practically all the urine may be obtained.

For the collection of urine in metabolism work on *rats*, a metabolism cage (see Appendix) is employed.

**2. Complete Analysis of Urine.** Ingest an ordinary mixed diet (or any special diet) and collect the urine accurately for a 24-hour period (see above). Measure the volume of the sample, determine the specific gravity, and preserve the urine (see above) until the following constituents have been determined (for methods of analysis, see Chapter 31): total solids, titratable acidity, hydrogen-ion concentration, total nitrogen, amino acid nitrogen, ammonia, urea, uric acid, creatinine, total sulfur, ethereal sulfates, inorganic sulfates, neutral sulfur (by difference), total phosphates and sodium chloride.

Calculate the nitrogen and sulfur partitions, i.e., the percentages of the total nitrogen and sulfur which occur in the different forms, and tabulate the data from the complete analysis. Compare your results with those listed in the tables on pp. 1055 and 1057.

**3. Collection and Preservation of Feces and the Mixing and Weighing for Analysis.** The old methods in vogue in metabolism work embraced the analysis of *dried* feces. Various investigators later demonstrated that the drying of feces was accompanied by losses and changes of some of the organic constituents of the feces. Therefore the chemical examination of all stools wherever possible should be made on the *fresh* feces. If a study is being made which extends over several days and it is de-

sired to economize time and effort in the chemical examination, the daily fecal output or an aliquot portion of each stool may be collected in a friction-top can or pail of suitable size and preserved by thymol and refrigeration. This method has been found satisfactory when the feces are to be examined for inorganic constituents or total nitrogen. For the determination of fat, carbohydrate, etc., the *fresh* stool should be employed because of the possibility of error due to hydrolysis of fat to fatty acid, etc.

In the preservation of feces for the determination of total nitrogen, the following simple procedure may be used: Introduce each stool into a weighed friction-top can or pail and place the vessel in a cold room or refrigerator preferably near or below 0° C. At the end of the period, mix the feces thoroughly and analyze weighed portions. In case individual stools are analyzed, the stool should be collected in a *weighed* flat-bottomed porcelain dish.<sup>80</sup> After mixing the feces *very thoroughly*, the weight of dish, spatula, and feces is determined and the weight of the feces secured by difference.<sup>81</sup> A portion of the well-mixed feces is then introduced into a large weighing bottle containing a glass hoe. Desired amounts of feces are then removed for analysis and the exact weight of such amounts obtained by difference.

The daily output of feces in *dogs* is quite variable, so that in metabolism work it is advisable to collect feces in periods, rather than each day. The stools are collected from the screen floor of the cage and placed in weighed pans. They are dried by adding alcohol, stirring and evaporating on the water bath, and then weighed. A few drops of sulfuric acid should be added to prevent the loss of ammonia. After drying the feces may be ground in a mill or mortar, to facilitate uniform sampling.

**4. Separation of Feces.**<sup>82</sup> In order to differentiate the feces which correspond to the food ingested during any given interval, it is customary to cause the subject under observation to ingest some substance, at the beginning and end of the period in question, which shall sufficiently differ in color and consistency from the surrounding feces as to render such differentiation comparatively easy. Two markers very widely used in such tests are *wood charcoal* and *carmine*. In making an actual separation of feces in a metabolism experiment, proceed as follows: Just preceding or in the early part of the first meal (usually breakfast) of the metabolism test, ingest a gelatine capsule (No. 00) containing 0.2 to 0.3 g. carmine or charcoal. From this time collect all stools in *flat-bottomed* porcelain dishes and examine for the presence of the marker. All fecal matter containing portions of the marker may be considered as representing the diet in question. This fecal matter should be retained and preserved (see above). Just before or in the early part of the first meal (usually breakfast) following the end of the metabolism test, a second marker in a gelatin capsule should be ingested. The feces should be carefully inspected until the marker makes its appearance. Retain all fecal matter uncolored by the marker, and reject the remainder. Frequent difficulties are encountered in the practical separation of feces, but the character of such difficulties will be most satisfactorily impressed by the performance of actual separations. Chromic oxide ( $\text{Cr}_2\text{O}_3$ ) has also been used as marker in feces separation. See Chapter 21.

**5. The Use of Agar-agar to Increase Fecal Bulk.** The indigestible hemicellulose agar-agar (as well as other gummy substances such as psyllium seed, bassorin, etc.) has the property of absorbing water readily and therefore when ingested it increases the bulk of the feces considerably. This fact is made use of in the determination of metabolic product nitrogen (see Exp. 11, p. 1055), and clinically in some forms of constipation.

<sup>80</sup> The spatula for mixing the feces should be weighed with the dish.

<sup>81</sup> In case it is desired an *aliquot part* of each stool may be placed in a friction-top can or pail and preserved as a composite sample for the period.

<sup>82</sup> For other practical work on feces, see p. 452.

**Experiment.** Ingest a uniform diet for four days, or longer for greater accuracy. Divide the interval into two equal periods and separate the feces by charcoal or carmine (see Exp. 4 above). During the second period ingest 10 g. of agar-agar at each meal. Collect the feces for each period (see Exp. 4, above) and note the increase in the daily excretion under the influence of the agar ingestion. What was the increase per gram of agar?

## II. EXPERIMENTS ON NITROGEN METABOLISM

**1. Time Relations of Protein Metabolism.** It is a well-known physiological fact that an interval elapses between the ingestion of protein food and the appearance in the urine of certain products representing the complete catabolism of this food. The chief among these is urea. The term *nitrogen lag* has been used to designate the period elapsing between the ingestion of protein and the excretion in the urine of a quantity of nitrogen equivalent to that contained in the protein.

**Experiment.** Ingest a simple uniform diet whose exact composition has been determined by analysis or whose approximate composition has been estimated. (See Appendix for table showing composition of foods.) Continue this diet from 1 to 4 days. Collect the urine in 2-hour periods from 7 A.M. to 11 P.M. and in an 8-hour period between 11 P.M. and 7 A.M. Analyze each specimen for total nitrogen or urea. At the end of this preliminary period add to the uniform diet, at one meal, a weighed quantity (150–250 g.) of lean meat specially prepared and analyzed. Collect the urine in periods as before and determine total nitrogen or urea. Calculate the total nitrogen or urea excretion; tabulate the data and plot curves showing the course of the nitrogen excretion on the various days of the experiment. How long was the “nitrogen lag”?

A less accurate experiment than the above but one which yields interesting data may be carried out as follows:

Ingest a simple diet whose nitrogen content can be estimated with some degree of accuracy. Collect the urine in 2-hour periods from 7 A.M. to 11 P.M. and in an 8-hour period from 11 P.M. to 7 A.M. and analyze for total nitrogen or urea. The next day ingest the same diet plus 150–250 g. of lean meat whose nitrogen content has been determined by analysis or estimated. Collect the urine as upon the previous day and determine its total nitrogen or urea content. Plot curves showing the course of the nitrogen or urea excretion on each of the days. How soon after the ingestion of the large quantity of meat did you note an increase in the nitrogen or urea excretion? How many hours after the meal was the maximum quantity of nitrogen or urea excreted?

**2. Digestibility and Biological Value of Protein.** The term *protein utilization* or *biological value* is used to indicate the percentage of the ingested food nitrogen actually assimilated. *Absorbability* or *digestibility* indicates the percentage of the ingested food nitrogen which is absorbed.

The digestibility of food protein may be approximated by the following procedure. Ingest any diet of known nitrogen content for a period of three days (see Appendix, “Composition of Foods”). Longer periods are necessary for accurate work. Collect all feces from the diet, making the separations as directed on p. 1046, using carmine as the initial marker and charcoal as the final marker or vice versa. Preserve the feces as directed on p. 1045. Mix the total feces thoroughly and determine the nitrogen by the Kjeldahl method. The approximate nitrogen utilization may be calculated as follows:

$$\frac{(\text{Food N} - \text{Feces N}) \times 100}{\text{Food N}} = \text{Approximate percentage N utilization}$$

Inasmuch as the nitrogen content of the feces does not originate entirely from the food, but represents in part residual metabolic products, i.e., intestinal epithelium, bacteria, secretions, etc., a correction is usually made for metabolic nitrogen in more exact work (see p. 1055). The value thus obtained is more properly designated as the *percentage digestibility* or the *coefficient of digestibility*.

To determine the true percentage digestibility of food protein, proceed as follows: Ingest a nonnitrogenous diet as described on p. 1055 for a period of two days, using sufficient agar-agar to insure a daily fecal output which shall approximate in weight that obtained when the regular protein diet was ingested.<sup>83</sup> Separate and preserve the feces as directed on p. 1046. Mix thoroughly and analyze for nitrogen according to the Kjeldahl method. This gives the metabolic fecal nitrogen. Follow this period with a test period during which the protein in question is included in the diet. Calculate the percentage digestibility of the protein of the diet as follows:

$$\frac{[\text{Food N} - (\text{Fecal N} - \text{Metabolic N})] \times 100}{\text{Food N}} = \text{Percentage digestibility}$$

The estimation of protein utilization in the body must take into account not only absorption from the intestine, but also that fraction of the absorbed nitrogen which is retained.

Mitchell,<sup>84</sup> who has used this procedure extensively in the biological evaluation of proteins, felt that this could be done by determining the urinary nitrogen excretion on a nonnitrogenous diet (endogenous nitrogen) and subtracting this from the urinary nitrogen on the protein-containing diet, to obtain the urinary nitrogen actually due to the metabolism of the protein. It is not clear that this procedure is entirely valid, based as it is upon Folin's classical distinction between endogenous and exogenous metabolism, which now appears incorrect (see discussion on p. 1021). Nevertheless the procedure under the conditions prescribed by Mitchell is capable of giving reasonable and consistent results, whatever may be its theoretical basis. The nitrogen balance method has been employed by Rose to determine the indispensable amino acid requirements of young men.

Various investigators<sup>84a</sup> have pointed out that to determine the minimum amount of dietary protein necessary to maintain nitrogen equilibrium, data are required for at least two levels of nitrogen intake near the region of balance, in order that the value at exact equilibrium may be obtained by interpolation or extrapolation.

**Procedure.** Ingest a nonnitrogenous diet as described above, insuring sufficient energy to provide for the body's requirements so that oxidation of tissue for this purpose may be avoided. Feces and urine are collected as described in the early part of this chapter. By means of Kjeldahl analyses, values are determined for metabolic nitrogen of feces and endogenous nitrogen of the urine. Follow this period with a test period during which the protein under investigation is included in the experimental diet. The following

<sup>83</sup> It is frequently difficult to so regulate the agar-agar intake as to secure the proper fecal output. In such an event the proper value for metabolic nitrogen must be obtained by calculation. For example, if 89.1 g. feces were excreted per day on the protein diet, and 166.5 g. per day (with a nitrogen value of 0.5 g.) when agar was employed, the actual value for metabolic product nitrogen may be obtained by the following proportion, assuming that the content of metabolic nitrogen is proportional to the weight of feces excreted  $89.1:166.5::x:0.5$ .  $x = 0.268$  g. metabolic nitrogen per day.

<sup>84</sup> Mitchell: *J. Biol. Chem.*, **58**, 873 (1924); *Ind. Eng. Chem., Anal. Ed.*, **16**, 696 (1944); *Nutrition Revs.*, **10**, 33 (1952).

<sup>84a</sup> Melnick and Cowgill: *J. Nutrition*, **13**, 401 (1937); Allison: *Adv. in. Protein Chem.*, **5**, 155 (1949)—a review of methods for the biological evaluation of proteins; Arnold and Schad: *J. Nutrition*, **48**, 377 (1952).

equation represents the percentage of the absorbed food nitrogen which is retained by the body:

$$\frac{[\text{Food N} - (\text{Fecal N} - \text{Metabolic N}) - (\text{Urinary N} - \text{Endogenous N})]100}{\text{Food N} - (\text{Fecal N} - \text{Metabolic N})} = \text{Biological Value}$$

**3. Protein-sparing Action of Carbohydrate and Fat.** The nonnitrogenous nutrients, carbohydrate and fat, have the power to diminish the extent of the catabolism of protein in the normal human body. In other words, they are said to “spare” protein. This point is illustrated in data reported by Von Noorden and Dieters, which are tabulated below.

PROTEIN-SPARING ACTION OF CARBOHYDRATE

| <i>Nitrogen Ingested</i>    | <i>Nitrogen in Urine</i> | <i>Remarks</i>                                 |
|-----------------------------|--------------------------|------------------------------------------------|
| 12.6 g.                     | 10.4 g.                  |                                                |
| 12.6 g.<br>+ 200 g. sucrose | 9.0 g.                   | 13 per cent reduction in<br>protein catabolism |

It will be observed that the addition of 200 g. of sucrose to the diet was accompanied by a decrease of 13 per cent in the amount of protein catabolized. It has been established that carbohydrates are more efficient protein sparsers than are the fats. For example, Voit found carbohydrate to produce a 9 per cent decrease in protein catabolism whereas fats produced only a 7 per cent decrease.

**Experiment.** Ingest a uniform diet of known or estimated nitrogen content for a period of four days. Collect and preserve the urine accurately (see p. 1044) in 24-hour samples and analyze the excretion of the *third and fourth days* for total nitrogen. On the fifth day *add 200 g. of sucrose to the diet*. Analyze this urine also for total nitrogen. Calculate your results and tabulate the data as shown in the table above.

Did the sucrose influence the catabolism of protein in your body?

**4. Influence of a High Caloric Nonnitrogenous Diet.** When an individual fasts, a certain amount of protein tissue is consumed each day of the fast. The destruction of such tissue is rather low on the first day because the glycogen stores of the body are being utilized to furnish the necessary energy. If an individual, instead of fasting, ingests a diet of high calorific value and very low in nitrogen the output of nitrogen in the urine of the third or fourth day will be less than on the third or fourth day in fasting. This is due to the fact that the body derives sufficient energy from the high-calorie diet and there is less destruction of tissue protein than occurs in fasting. For a discussion of energy value of foods see “Determination of Fuel Value of Food” below, and the table “Composition of Foods,” in the Appendix.

**Experiment.** Ingest a high-calorie diet which is very low in nitrogen or actually nonnitrogenous. A satisfactory diet may include sugar, butter, starch, cream, agar-agar, and water. (For energy values see below and table, Appendix.) Ingest such a diet for three days. Collect the urine in 24-hour periods,

preserve, and analyze it for total nitrogen, acidity, and ammonia. Note the low nitrogen excretion on the third day as compared with the nitrogen output of the third day of fasting. If so desired, you may (at some later date) fast for three days and repeat the above analyses for comparison.

**Determination of Fuel Value of Food.** When organic substances are oxidized or burned in the human body, they liberate a certain amount of heat. This calorific

FIG. 260. BERTHELOT-ATWATER BOMB CALORIMETER.

energy or heat value varies according to the type of organic matter undergoing oxidation. Thus the proteins, fats, and carbohydrates of the diet when they are burned in the body yield different quantities of heat per unit of substance than do organic acids, alcohol, etc. The energy values of food protein, fat, and carbohydrate are as follows:

|              |                             |
|--------------|-----------------------------|
| Protein      | = 4.1 large Calories per g. |
| Fat          | = 9.3 large Calories per g. |
| Carbohydrate | = 4.1 large Calories per g. |

To allow for the incomplete digestion of these nutrients these caloric conversion factors are multiplied by the coefficients of digestibility and thus rounded off to 4, 9, and 4, respectively. The calorific value of foods may be estimated by applying these figures to the percentage composition as determined by chemical analysis. For this purpose, the proximate analysis includes moisture, ash, protein ( $N \times 6.25$ ), fat, crude fiber, and carbohydrate, the latter usually estimated by difference. Crude fiber represents the insoluble, indigestible residue remaining after alternate extractions with acid and alkali, and consists chiefly of cellulose, etc., from cell walls. Such calculations are predicated on the assumption of complete availability of the carbohydrates as estimated by difference, on the universal applicability of the factor 6.25 for converting total nitrogen to available protein, and on the assumption that the ether extract consists principally of glycerides.

In arriving at the total energy value of any given diet it is possible to burn weighed samples of the various foods in an oxygen atmosphere in an apparatus called a bomb calorimeter, illustrated in Fig. 260. By this means we may determine how much heat is liberated when the ingested food is oxidized in the body. A correction must be made for the incompletely oxidized substances of the urine and feces, e.g., organic nitrogen compounds. Thus while proteins yield about 5.7 Calories per gram when burned in a calorimeter, correction for incompletely oxidized urea and other N compounds reduces this value in the body to 4.1. Further correction must be made for indigestible carbohydrates usually grouped together under the designation "crude fiber." There is serious question, however, whether the latter, which resists hot acid and alkaline digestion, is an accurate measure of the polysaccharides which *in vivo* resist enzymatic digestion.

A simpler and less expensive form of apparatus for determining this calorific value of foods is the oxycalorimeter of Benedict and Fox, in which the volume of oxygen required to burn a known weight of substance is determined. A large mass of data concerning the heat value of foods has been collected and tabulated, and it is therefore possible to arrive at an approximate idea of the energy value of a diet by calculation (see table, Appendix).

**5. Influence of Purine-free and High Purine Diets.** The uric acid of the body has a twofold origin, i.e., it may arise from the metabolism of the purine (nucleoprotein, nucleotide) material of body tissue (glandular organs in particular) or it may arise from the ingestion of purine material. That uric acid which arises from the first source is called *endogenous* while that which arises from the second source is termed *exogenous*. Modern concepts hold that this distinction, made many years ago by Folin, is still valid. Secretory activity may also act to increase the endogenous uric acid output. The urine will therefore contain uric acid even though no precursor of the acid is ingested. We may also increase the uric acid output markedly by ingesting a high purine diet. However, no matter how much purine material is eaten, only a small part of it reappears in the urine as uric acid. That is, there must be some significant metabolic pathway for purine nitrogen other than excretion as uric acid. In gout there is an accumulation of uric acid in the blood. In this disease the excretion of uric acid may be low before an attack and increase considerably during an attack. The excretion of exogenous uric acid in gout is also much slower than normal.

**Experiment.** Ingest a purine-free diet containing about 16 g. of nitrogen and consisting of egg, cheese, milk, starch, fruit, sugar, and water for a period of two days (for purine content of foods, see table, p. 1053). Determine or estimate the nitrogen content (see Appendix) and during the next two days substitute sweetbreads, thymus, or liver for all the nitrogen of the diet, maintaining the calorific value of the diet the same as before. Return to the original purine-free diet for a third interval of two days. During the final

period of two days feed a diet of sweetbreads or liver containing 50 per cent more nitrogen than that of the first sweetbread period. Collect the urine for

each of the eight days of the experiment and determine uric acid and total nitrogen or urea. Note the rise in the uric acid output during the sweetbread periods. The uric acid output on the purine-free diet is endogenous in origin. Tabulate your results. The data shown above were secured by Taylor and Rose in a similar but much more carefully controlled test than that just outlined.

FIG. 262. ENDOGENOUS URIC ACID OUTPUT DURING FASTING.  
Courtesy, Mendel and Stehle: *J. Biol. Chem.*, **22**, 215 (1915).

**6. A Study of Endogenous Uric Acid Output.** The uric acid in the urine originates from the purine material of the tissues (*endogenous*) and from the purine material ingested (*exogenous*). Mares claims that foodstuffs act to increase the endogenous uric acid output by stimulating the digestive glands to activity. A similar finding is reported by Mendel and Stehle. The foodstuff having the most pronounced influence was protein. *Pilocarpine*, which stimulates the digestive glands, was found to increase the endogenous uric acid output whereas *atropine* which inhibits secretory activity

was found to decrease the output of endogenous uric acid. The influence of protein upon the endogenous uric acid excretion is shown by the chart in Fig. 261. The fasting output by the same individual is shown, for comparison, in Fig. 262.

**Experiment.** Ingest a purine-free diet consisting of milk, egg, fruit, cheese, butter, sugar, and bread for one day. Continue the diet for breakfast and luncheon the next day but eat nothing after 12 o'clock noon, until 12 o'clock noon the following day, i.e., the third day of the experiment. At that time ingest 125–150 g. of gluten or some other purine-free protein preparation. On the fourth day of the experiment eat nothing until 9 P.M.

Collect the urine each day in hour periods from 7 A.M. to 9 P.M. and analyze for uric acid (see methods on p. 905, ff.). Chart your data similarly to those shown in Figs. 261 and 262, and compare them with the findings there recorded.

**7. The Rate of Purine Excretion.** The purine material ingested by the average normal person and not transformed in the body is eliminated in about 24 hours. In

the case of persons afflicted with gout the purine elimination is delayed. The establishment of this delayed purine elimination is often of diagnostic assistance.

**Demonstrate the rate of purine excretion as follows:** Ingest a purine-free diet consisting of egg, milk, cheese, starch, sugar, fruit, and water for two days and follow this by a day in which sweetbreads, thymus, or liver is substituted for one of the meals of the day (see table, p. 1053 for purine content of foods). Finish the experiment by ingesting the original purine-free diet for two days. Collect each day's urine and analyze for uric acid. How soon after the sweetbread ingestion was the original plane of endogenous uric acid elimination reestablished? If one desires to locate this time more definitely the urine may be collected in short periods (1 to 2 hours) and the uric acid content of each specimen determined. Particularly instructive data may be collected by performing the above experiment on a gout patient and upon a normal person for comparison.

**8. A Study of Creatinine Elimination.** It has been established that a normal person ingesting a creatinine-free diet will excrete a uniform quantity of creatinine from day to day. The daily excretion of an adult man of average weight ranges from 1–1.5 g. For data as to creatinine excretion of a 60-kg. man see Taylor and Rose's figures in the table on p. 1052. The creatinine excretion depends primarily on the active mass of protoplasmic tissue, and therefore, it is generally true that fat men will show a lower creatinine output than lean men of like body weight. The fact that, in a given individual, the creatinine output is uniform from day to day is made use of in metabolism experiments, for checking the completeness of 24-hour collections of urine. For further discussion of creatinine see p. 797.

**Experiment.** Ingest an ordinary mixed diet (nonmeat) for a period of three days, varying the character of the diet daily. Collect the urine and analyze for creatinine. (See p. 899 for methods of analysis.)

Did the creatinine elimination change with the change in diet?

**9. Formation of Hippuric Acid in the Human Body.** Hippuric acid is present in human urine in small amount, about 0.7 g. being excreted per day. The urine of herbivorous animals contains much larger quantities. This acid is formed in the liver in man, by the conjugation of benzoic acid and glycine; this formation is used clinically as a test of liver function. For procedure of the test, see Chapter 31.

**10. The Partition of Urinary Nitrogen and Sulfur as Influenced by Diet.** It was first shown by Folin<sup>85</sup> that the percentage of the total nitrogen and total sulfur of the urine which appeared in the form of any particular nitrogenous constituent or in any particular form of sulfur was regulated directly by the extent of the total nitrogen and sulfur elimination. This point is well illustrated in the table shown on p. 1055 which contains data regarding the so-called *partition* or *distribution* of the urinary nitrogen and sulfur.

It will be observed from an examination of this table that a normal protein diet which gave 16.8 g. of urinary nitrogen yielded 87.5 per cent of this nitrogen as urea, 3 per cent as ammonia, 3.6 per cent as creatinine, and 1.1 per cent as uric acid; whereas a nonprotein diet (starch and cream containing about 1 g. of nitrogen) which gave only 3.6 g. of urinary nitrogen yielded only 61.7 per cent of this nitrogen as urea but gave a greatly *increased percentage output* in the case of each of the other nitrogenous constituents mentioned, e.g., 11.3 per cent as ammonia, 17.2 per cent as creatinine, and 2.5 per cent as uric acid. The *percentage output* of neutral sulfur was also *greatly increased*.

<sup>85</sup> Folin: *Am. J. Physiol.*, 13, 118 (1905).

It will further be observed that the *actual daily output* of certain of the constituents is uninfluenced by the amount of protein ingested. Among these are creatinine and neutral sulfur. On the other hand, the output of inorganic sulfur and urea is more or less directly proportional to the protein ingestion. The observation of such facts as these led Folin to formulate his theory of protein metabolism, which held sway for many years, but which has recently been considerably modified (see discussion on p. 1021).

THE NITROGEN AND SULFUR PARTITIONS AS INFLUENCED BY DIET<sup>85</sup>

**Experiment.** During a period of two or three days ingest an ordinary mixed diet containing 100–125 g. of protein (16–20 g. of nitrogen) per day. Collect the urine accurately in 24-hour periods (p. 1044), preserve it, and analyze the urine of the second and third days for total nitrogen, urea, creatinine, total sulfur, inorganic sulfates, ethereal sulfates, and neutral sulfur (by difference). For methods of analysis see Chapter 31. Follow this period by a three-day period in which a diet of starch and cream having a similar calorific value is ingested. Analyze the urine for the second and third days as indicated above. Calculate your results and tabulate as shown in the table above. How did the change in the diet alter the metabolism of nitrogen and sulfur?

In calculating the calorific value of a diet make use of the following values: protein or carbohydrate, 4 Calories per g.; fat, 9 Calories per g.

**11. “Metabolic Product” Nitrogen in Feces.** A certain quota of the fecal nitrogen is due to the presence of residues of digestive secretions, epithelial cells, bacteria, etc. The nitrogen in these forms has been called *metabolic product nitrogen*.

To determine this form of nitrogen one method<sup>86</sup> of procedure is as follows: Ingest a nonnitrogenous diet for a period of two days. The diet may include desired quantities of *starch, cream, sugar, butter, water, and sodium chloride*. About 15 g. *agar-agar* should be added to the diet to prevent constipation and to insure evacuation of approximately the normal quantity of feces. (For the influence of agar-agar, see Exp. 5, p. 1046.) To separate the feces properly, ingest a capsule of carmine at the beginning of the test and one of

<sup>86</sup> For a discussion of other methods of estimating metabolic product nitrogen see Forbes, Mangels, and Morgan: *J. Agr. Research*, 9, 405 (1917) and Schneider: *J. Biol. Chem.*, 109, 249 (1935).

charcoal at the end (see p. 1046). Preserve the feces as described on p. 1046. After mixing the feces thoroughly, determine the nitrogen in weighed quantities by the Kjeldahl method,<sup>87</sup> according to directions given on p. 874. Calculate the quantity of nitrogen eliminated per day. Inasmuch as no nitrogen was ingested, the nitrogen present in the feces is of metabolic origin, i.e., it is made up principally of nitrogen in the form of cells, digestive secretions, and bacteria.

**12. Influence of Defective Mastication on Food Residues in Feces.** Rapid eating accompanied by defective mastication leads to the appearance of relatively large macroscopic food residues in the feces. Under some conditions, however, *protein utilization* (see p. 1047) may be as satisfactory after bolting of food as when it is very thoroughly masticated. This problem may be studied by the following method:

**a.** Ingest a diet containing meat and be certain to masticate the diet very thoroughly. Collect a stool, examine macroscopically; mix carefully and examine microscopically (see pp. 448 and 449).

**b.** Ingest a diet similar to that employed in Exp. a, above. Bolt the food, i.e., ingest it practically without mastication. Examine the feces as above. Note the difference in the macroscopical and microscopical findings under (a) and (b).

If the nitrogen of food and feces is determined, we may calculate the protein utilization (see Exp. 2, p. 1047). By the additional determination of urinary nitrogen, we may prepare a nitrogen balance (see Exp. 13).

**13. Preparation of a Metabolic Balance.** This test entails the analysis of the food ingested and of the urine and feces excreted, i.e., a study of the *income* and *outgo*. Proceed as follows:

Select a diet which is simple, i.e., consists of few constituents, and which lends itself readily to accurate chemical analysis. A good type of diet for

BALANCE OF CALCIUM, MAGNESIUM, PHOSPHORUS, SULFUR, AND  
NITROGEN IN ACROMEGALY

ordinary metabolism experiments of this sort consists of crackers (graham or soda), milk, butter, water, and agar-agar (to prevent constipation). Meat, especially prepared in quantity sufficient for an entire experiment, may also be utilized. Ingest uniform quantities of these dietary constituents each day

<sup>87</sup> In the oxidation process use 10 g. of potassium sulfate instead of the copper sulfate. The remainder of the procedure is the same as for urine.

for a period of three days. Make an accurate collection of the urine passed during this interval (see p. 1044). Separate the feces representing the three-day period (see p. 1046), and analyze foods, urine, and feces. The balances ordinarily prepared are those for nitrogen, sulfur, phosphorus, and calcium. Analytical methods for the determination of these elements may be found in Chapter 31.

The table on p. 1056 includes balances obtained in a metabolism test in a case of acromegaly.

**14. The Influence of Water on Metabolism.** It has been demonstrated that increased water ingestion influences favorably many of the functions and activities of the human body.<sup>88</sup> The increase in protein catabolism which accompanies high water intake is shown in the following data collected from an experiment upon a normal man. In this experiment the water ingestion *at meals* was increased 3 liters per day during the water period.

The above data indicate an increased catabolism of protein material as shown by an increased output of total nitrogen upon the first and second days of the water period. Part of this increase may, however, have been due to a flushing of the tissues rather than to increased catabolism of protein structures.

<sup>88</sup> Hawk: "The relationship of water to certain life processes and more especially to nutrition." Read before *American Philosophical Society*, Philadelphia, Feb., 1914. (See *Biochem. Bull.*, 3, 420 (1914); also "Water as a Dietary Constituent," in *Endocrinology and Metabolism*, New York and London, D. Appleton and Co., 1924, Vol. 3, p. 277.) The so-called "water intoxication" demonstrated by Rowntree (*Arch. Int. Med.*, 32, 157 (1923)) and later by Underhill and Sallick (*J. Biol. Chem.*, 63, 61 (1925)) cannot be advanced as an argument against the value of a high water intake for the average individual. The observers mentioned experimented on animals and introduced as much as 50 ml. water per kg. body weight every half hour until a definite toxic result was obtained. A similar excessive ingestion of any standard food would probably produce results fully as serious.

a. **RELATION OF WATER INTAKE TO VOLUME AND SPECIFIC GRAVITY OF THE URINE.** Ingest an ordinary mixed diet for two days. Collect the urine in 24-hour periods. During the first day ingest very little fluid of any kind either at meals or between meals. On the second day ingest as much water as you can without physical inconvenience. A person of average size should have no difficulty in drinking 5–6 liters per day.

Measure the volume of each day's urine and take the specific gravity. Note the pronounced increase in volume and the low specific gravity of the urine under the influence of high water ingestion.

b. **INFLUENCE ON PROTEIN CATABOLISM.** That water stimulates protein catabolism may easily be demonstrated as follows: Ingest a uniform diet (milk, crackers, butter, peanut butter, and water) for a period of four days. During the first two days ingest your customary volume of water per day. During the last two days increase the water ingestion to 5–6 liters per day. Collect urine in 24-hour periods and analyze for total nitrogen by Kjeldahl method (see p. 874). Note the increased excretion of nitrogen under the influence of high water intake. If time permits, other nitrogenous urinary constituents may be determined (see table above).

c. **INFLUENCE OF WATER DEFICIENCY.** The importance of water in nutrition may be shown very satisfactorily in guinea pigs. Proceed as follows: Place two young pigs (150–200 g.) in separate cages, and give each free access to a diet of hay, oats, and lemon or orange juice which has been dried rapidly at a low temperature. Permit one pig water ad lib., and give the second pig no water. The pig receiving water will remain normal and will exhibit normal gain in body weight. The pig receiving no water will soon show pronounced losses in body weight and other signs of abnormality. The animal will die in a short time unless water is added to the diet. This experiment demonstrates very clearly that water is an indispensable dietary constituent. In fact, water is more important than food. The following experiment will show this.

d. **FOOD STARVATION VS. WATER STARVATION.** Place two young guinea pigs (150–200 g.) in separate cages. Give one a diet such as that described above, plus orange juice (5 ml.) but no water. Give the second pig no food, but permit free access to water. The pig receiving no water will quickly become abnormal, and it will be necessary to give it water to preserve its life. The second pig, which has access to water<sup>89</sup> but receives no food to eat, will live longer than the pig receiving an abundance of dry food. This little experiment impresses the important fact that man can live longer without food than without water. By restricting the amount of water in the diet of an albino rat, the animal may be kept at constant body weight for several weeks although the diet is otherwise adequate. In many respects the effect is similar to that of underfeeding. Some increased tolerance to water restriction may develop during such a test.

**15. The Metabolism of Fasting.**<sup>90</sup> The metabolism of a fasting man is entirely different from the metabolism of a well-nourished person. The collection and analysis of the urine during a short fast (three to seven days) will demonstrate many important facts. The following table, which contains data from fasting tests made in the senior

---

<sup>89</sup> In case the pig does not drink the water, the animal should be fed the fluid by a sound.

<sup>90</sup> For discussions of fasting see: Benedict: *A Study of Prolonged Fasting*, Carnegie Inst. Wash. Pub., 203, 1915; Morgulis: *Fasting and Undernutrition*, New York, E. P. Dutton and Co., 1923; and Jackson: *Inanition and Malnutrition*, Philadelphia, P. Blakiston's Son and Co., Inc., 1925.

author's laboratory,<sup>91</sup> illustrates some of the points in which fasting metabolism differs from normal metabolism:

METABOLISM IN FASTING

| Day of Period              | Body Weight, kg. | Total N, g. | Ammonia N, g. | Creatine N, g. | Acidity ml. 0.1 N NaOH | P <sub>2</sub> O <sub>5</sub> g. | Chloride as NaCl, g. |

Abstinence from food for a few days can in no way operate to the disadvantage of a normal person. In fact, individuals affected with certain types of gastrointestinal dis-

FIG. 263. SHOWING IMPORTANCE OF ADEQUATE PROTEIN (AMINO ACIDS) IN THE DIET.

Courtesy, Mendel: *Nutrition—The Chemistry of Life*, New Haven, Yale University Press, 1923.

orders are benefited by fasting. The *fasting treatment* has also been used in cases of diabetes mellitus and in the treatment of obesity.

In order to determine experimentally how the fasting metabolism differs from normal metabolism, proceed as follows: Ingest an ordinary mixed diet and collect your urine (see p. 1044) for a day. Measure the volume and analyze the sample for total nitrogen, ammonia, creatine, sodium chloride, total

<sup>91</sup> The chloride, phosphate, and acidity determinations were collected during one seven-day fast and the other data collected during a different fast on the same man.

phosphates, and acidity<sup>92</sup> (for methods see Chapter 31). For the next few days (three to seven as desired) ingest nothing but water and collect the urine accurately and analyze for the constituents enumerated above. Tabulate your results and compare them with those given in the table above.

FIG. 264. CURVE SHOWING INFLUENCE OF A DEFICIENCY OF LYSINE IN THE DIET.

Unpublished data from the senior author's laboratory.

**16. Influence of Protein (Amino Acid) Deficiency.** Certain of the amino acids which occur in proteins cannot be synthesized in the animal body. This subject is discussed on p. 1015. The importance of proper protein (amino acids) in the diet is illustrated in Fig. 263. The following experiment, which may readily be made using white rats as subjects, will clearly demonstrate the importance of the amino acid lysine.

**Demonstration of Lysine Deficiency.** Place two young white rats (40–60 g.) in separate cages. Feed one rat Diet 1 and the other Diet 2 as listed in the following table.

<sup>92</sup> A more accurate experiment may be carried out by ingesting a uniform diet of known composition (see p. 1047) for a few days before the fast.

LYSINE DEFICIENCY DIET

|                                 | <i>Diet 1</i><br><i>per cent</i> | <i>Diet 2</i><br><i>per cent</i> |
|---------------------------------|----------------------------------|----------------------------------|
| Rolled oats <sup>93</sup> ..... | 60                               | 60                               |
| Gelatin <sup>93</sup> .....     | 0                                | 10                               |
| Dextrin or starch.....          | 30                               | 20                               |
| Salt mixture.....               | 4                                | 4                                |
| Hydrogenated vegetable oil..... | 5                                | 5                                |
| Cod liver oil.....              | 1                                | 1                                |

The rat receiving Diet 2 will grow normally because of the high lysine content of gelatin. The animal receiving Diet 1 will fail to grow properly because of lysine deficiency. See Fig. 264.

III. MICROBIOLOGICAL DETERMINATION  
OF AMINO ACIDS

The widespread use of microorganisms for the assay of the vitamins in the B-complex group soon revealed their requirements for the amino acids. Extensive investigations followed and successful quantitative assays for 14 amino acids, using bacteria, appeared shortly. At least three amino acids may be determined with mutant strains of the mold *Neurospora* (see p. 1066), and one, L-lysine, with a specific decarboxylase. Of the amino acids recognized as physiological constituents, only norvaline, norleucine, and hydroxyproline have not been found essential for any organism yet investigated. The fundamental principle involved in microbiological assays is to measure the response of bacteria, yeasts, or molds to graded increments of the sample and of a standard solution added to media furnishing all the nutrients required by the microorganism except the amino acid (or other nutrient) under assay. The graded response may be measured by the increase in population of the microorganisms (i.e., turbidimetrically) or by their products of metabolism (acid or CO<sub>2</sub> production).

Microbiological methods are advantageous in that several amino acids may be determined in a single prepared hydrolyzate with the same microorganism with only slight modification of the basal medium. Only the natural or L-forms are biologically active, except in the case of aspartic acid, whose D- and L-isomers are equally available to *Lactobacillus delbrückii*. However, the L-forms are more expensive than the synthetic DL-mixtures, so that the latter are used in the basal medium and in the standard series when available. When substituting one form for the other, or when the hydrochlorides are used, appropriate adjustments should be made in the amounts employed. Microbiological methods are exceedingly simple compared to the chemical isolation procedures. Moreover, they are not subject to isolation losses since determinations are made directly on the hydrolyzates.

<sup>93</sup> Oat protein is low in lysine. Gelatin is relatively high in this amino acid (see p. 122).

Careful attention must be given to proper methods of preparing hydrolyzates for assay. Acid is known to destroy tryptophan and, in the presence of carbohydrate, tyrosine. Enzymatic digestion or hydrolysis with barium hydroxide should be employed for tryptophan assays, since hydrolysis with sodium hydroxide has been reported to give erratic results. Alkaline hydrolysis racemizes the amino acids, so that such treatment must be continued until the racemization is complete, and the values found multiplied by two. Unless there is complete assurance that

\* Snell: *Conference on Amino Acid Analysis of Proteins*, New York Academy of Sciences, 1945.

† The symbol + indicates that the amino acid is essential; ±, that some growth but not maximum growth occurs in its absence; and —, that the amino acid is not essential.

‡ Asparagine and glutamine were essential for growth, and supplied the organism with these amino acids.

no amino acid loss occurs during the preliminary preparation of hydrolyzates, caution should be observed in applying such analytical data to the composition of the intact protein.

The qualitative amino acid requirements of six lactic acid bacteria are shown in the table above. These microorganisms have been employed in the quantitative determination of 14 amino acids. To facilitate the application of these methods, a typical procedure is described below, and pertinent data regarding the preferred methods of preparation of the hydrolyzates, the concentrations of the amino acids at half-maximum and at maximum growth, and the nature of the responses measured are

MICROBIOLOGICAL DETERMINATION OF THE AMINO ACIDS

\* Samples are hydrolyzed ten hours at 120° C.  
† These microorganisms may be obtained from the American Type Culture Collection, Washington 6, D. C., under the following numbers: *Streptococcus faecalis*, No. 9790; *Lactobacillus casei*, No. 7469; *Leuconostoc mesenteroides* P-60, No. 8042; *Lactobacillus arabinosus* 17-5, No. 8014; *Lactobacillus delbrückii* LD5, No. 9595. Prepared culture media for microbiological assay of the amino acids may be obtained from H. M. Chemical Co., Ltd., Santa Monica, California; Difco Laboratories, Inc., Detroit 1, Mich.  
‡ Alkali racemizes tryptophan. Though hydrolysis with sodium hydroxide has been found satisfactory by some investigators, others [Woolley and Sebrell; *J. Biol. Chem.*, 157, 141 (1945)] have obtained erratic results. The latter prefer enzymatic digestion which avoids possible variable racemization or destruction of tryptophan, or hydrolysis with barium hydroxide. Indole and anthranilic acid can replace tryptophan for *L. arabinosus* and should be removed from hydrolyzates by ether extraction at pH 4.0.  
§ Alkaline hydrolysis racemizes tyrosine. Thus, values should be multiplied by 2. Acid hydrolysis of samples containing appreciable amounts of carbohydrate should be avoided because the resultant humin formation is accompanied by a loss of tyrosine.

summarized in the table on p. 1063. References are made to the original publications for further details.<sup>93a</sup>

**1. Microbiological Determination of Isoleucine, Leucine, and Valine (Method of Shankman):**<sup>94</sup> **Principle.** Isoleucine, leucine, and valine are determined by measurement of the growth stimulation of *Lactobacillus arabinosus*. Samples are prepared for assay by the microhydrolytic procedure of McMahan and Snell,<sup>95</sup> employing 10 per cent hydrochloric acid. Each amino acid is determined separately by omitting it from the basal medium.

**Preparation of the Sample.** Weigh into a pyrex test tube an aliquot of the sample containing 100 mg. of protein. Add 1 ml. of 10 per cent hydrochloric acid<sup>96</sup> and seal the tube in an oxygen flame. Heat for 10 hours in an autoclave at 15 lb. pressure, or in an oven at 120° C. Cool, open the tube, and wash out with approximately 95 ml. of water. Adjust with 4 N sodium hydroxide to pH 6.8 to 7.0 and dilute to a concentration<sup>97</sup> of approximately 7.5 µg. of L-valine, 15 µg. of L-leucine, or 10 µg. of L-isoleucine per ml.

**Preparation of Basal Medium.** The composition of the basal medium is given in the following table:

COMPOSITION OF BASAL MEDIUM FOR THE ASSAY OF LEUCINE, ISOLEUCINE, AND VALINE

(The amounts shown are for the preparation of 500 ml. of basal medium)

|                          |         |                                  |         |
|--------------------------|---------|----------------------------------|---------|
| Glucose.....             | 5 g.    | L(−)-Leucine.....                | 100 mg. |
| Sodium acetate.....      | 3 g.    | DL-Isoleucine.....               | 100 mg. |
| Salt solution A.....     | 5 ml.   | DL-Valine.....                   | 100 mg. |
| Salt solution B.....     | 5 ml.   | L(−)-Cystine.....                | 50 mg.  |
| Adenine.....             | 5 mg.   | DL-Methionine.....               | 50 mg.  |
| Guanine.....             | 5 mg.   | L(−)-Tryptophan.....             | 17 mg.  |
| Uracil.....              | 5 mg.   | L(−)-Tyrosine.....               | 17 mg.  |
| Thiamine.....            | 50 µg.  | DL-Phenylalanine.....            | 50 mg.  |
| Riboflavin.....          | 100 µg. | L(+)-Glutamic acid.....          | 200 mg. |
| Nicotinic acid.....      | 100 µg. | DL-Threonine.....                | 100 mg. |
| Biotin.....              | 0.2 µg. | DL-Alanine.....                  | 100 mg. |
| Pyridoxine.....          | 50 µg.  | L(−)-Asparagine or aspartic acid | 200 mg. |
| Pantothenic acid.....    | 50 µg.  | L(+)-Lysine.....                 | 100 mg. |
| p-Aminobenzoic acid..... | 5 µg.   | L(+)-Arginine.....               | 25 mg.  |

For use in the assay tubes, omit from the basal medium that amino acid for which analysis is being made. Adjust to pH 6.6 to 6.8 with 4 N NaOH after

<sup>95</sup> McMahan and Snell: *J. Biol. Chem.*, 152, 83 (1944).

<sup>96</sup> Reagent grade concentrated hydrochloric acid solution contains approximately 35 per cent hydrochloric acid.

<sup>97</sup> Estimate the approximate concentrations of the amino acids present from the composition of the test material.

**preparation.** Store in the refrigerator and arrange storage flask with a siphon so that the amount required for the day's work may be readily obtained.

The amino acids may be weighed out directly or may be prepared as stock solutions in water, containing the desired amount in a few ml. Where necessary, a little hydrochloric acid may be used to aid in solution. Store the stock solutions in the refrigerator.

Salt solution *A* contains 25 g. each potassium monohydrogen phosphate and potassium dihydrogen phosphate, in 250 ml. water. Salt solution *B* has the following composition: 10 g. magnesium sulfate heptahydrate, 0.5 g. sodium chloride, 0.5 g. ferrous sulfate heptahydrate, and 0.5 g. manganese sulfate tetrahydrate, in 250 ml. water. Add a few drops of hydrochloric acid to solution *B* to keep from precipitating.

Prepare stock solutions of adenine, guanine, and uracil, containing 1 mg. per ml. Solution is aided by heating in the presence of a few drops of hydrochloric acid. Store in the refrigerator, and renew at frequent intervals.

Prepare stock solutions in water of thiamine, calcium pantothenate, and pyridoxine, containing 100  $\mu\text{g.}$  per ml. Store in the refrigerator and renew at frequent intervals. Prepare the riboflavin stock solution in 0.02 N acetic acid, to contain 100  $\mu\text{g.}$  per ml. Store as above, and in addition keep from exposure to light.

Stock solutions of nicotinic acid (100  $\mu\text{g.}$  per ml.) and biotin (2  $\mu\text{g.}$  per ml.) are prepared in 50 per cent ethyl alcohol. The stock solution of *p*-aminobenzoic acid (50  $\mu\text{g.}$  per ml.) is prepared in glacial acetic acid, and stored in a dark-glass bottle.

**Procedure.** Carry stab cultures<sup>98</sup> of *Lactobacillus arabinosus* 17-5 on yeast extract-dextrose-agar (Difco) and subculture monthly. After transfer, incubate the cultures at 30° C. for 24 to 48 hours, and then hold in the refrigerator. Prepare the inoculum for the assay tubes by transfer from the stock culture to a sterile centrifuge tube of the *complete* basal medium, containing all the amino acids listed. Incubate the inoculum at 30° C. for 24 hours before use. Centrifuge aseptically and wash 3 times by suspending in sterile 0.9 per cent saline and centrifuging. Finally suspend the cells in 30 ml. of saline.

**Assay.** Pipet into pyrex test tubes 0, 0.25, 0.50, 0.75, 1.0, 1.5, 2.0, 3.0, 4.0, and 5.0 ml. aliquots of the test extract. Add to each tube 5 ml. of basal medium lacking the particular amino acid to be determined, and sufficient distilled water to make a total volume of 10 ml. Prepare a similar series of standards containing the amino acid to be assayed, employing a pure solution of the appropriate amino acid in place of the test extract. Optimal concentrations are 15  $\mu\text{g.}$  DL-valine or L-leucine per ml. or 20  $\mu\text{g.}$  DL-isoleucine per ml. Plug the tubes with cotton and sterilize in an autoclave at 15 pounds pressure for 15 minutes. After cooling to room temperature, add one drop (0.03 ml.) of inoculum to each tube and incubate at 30° C. for 72 hours.

Transfer the contents of each tube to a 125-ml. Erlenmeyer flask, using a constant volume of distilled water as a wash. Titrate the lactic acid produced with 0.05 N sodium hydroxide using bromothymol blue as the indicator.

---

<sup>98</sup> American Type Culture Collection, No. 8014.

**CALCULATION.** For each amino acid assayed, plot the titrations for the standard series in ml. of 0.1 N sodium hydroxide against  $\mu\text{g.}$  of the standard used. From the appropriate curve, estimate the amount of each amino acid assayed per tube. Calculate the concentration per ml. of test extract. Determine the amino acid content of the test sample from the values obtained from not less than five of the tubes which do not vary by more than  $\pm 15$  per cent from the average. Synthetic DL-mixtures contain 50 per cent of the biologically active enantiomorph. If the racemic mixture was used as the standard, multiply the value obtained by one-half.

In Fig. 265 is shown a standard curve obtained with DL-valine, during the assay of a  $\beta$ -lactoglobulin preparation for that amino acid. The method of calculation is illus-

FIG. 265. TITRATION OF LACTIC ACID PRODUCED BY *Lactobacillus arabinosus* GROWN AT DIFFERENT LEVELS OF VALINE SUPPLEMENTATION.

trated in the table on p. 1067. Results are expressed as per cent of valine in the protein constituent of the material assayed.

There is some evidence that in addition to a proper balance of the essential amino acids, it may be necessary to supply certain peptide linkages in the dietary to insure satisfactory utilization of protein nitrogen. Thus, it has been demonstrated in rat assays that omission of a new factor, strepogenin, from a dietary including a hydrolyzate containing all of the essential amino acids in satisfactory quantities was responsible for a poor biological response. This factor, believed to be a peptide, is a growth stimulant for *Lactobacillus casei* and *Streptococcus lactis*. A preliminary method of assay has appeared based upon the growth of the former microorganism.<sup>99</sup>

**2. Use of *Neurospora* Mutants.** In 1941 Beadle and Tatum<sup>100</sup> reported the production of biochemical mutants in the red bread mold *Neurospora* by irradiation with ultraviolet and x-rays. These mutants are unable to

<sup>99</sup> Sprince and Woolley: *J. Exp. Med.*, **80**, 213 (1944).

carry out certain specific chemical reactions which are normally possible to the unmutated or wild-type strain. For example, the untreated mold is able to synthesize all the components of protoplasm it needs (vitamins, amino acids, etc.) on a medium containing only sucrose, nitrate, inorganic salts, and biotin. Various mutant strains have been obtained which are unable to grow without the addition of certain specific vitamins or amino acids to the medium, i.e., the strain has lost the ability it at one time

| 5.0                                         | 8.6                                   | 72.7                                                               | 14.5                                         |

Calculation:  
 $15.3 \times \frac{1}{2} \times 750 = 5.74$  mg. of L-valine per 100 mg. protein in sample.

\* The theoretical nitrogen content of  $\beta$ -lactoglobulin is 15.6 per cent. 0.107 g. contains 100 mg. of protein.

possessed to synthesize that particular vitamin or amino acid. It is believed that this loss of specific biochemical power is due to the loss of a single gene, which would ordinarily control the particular reaction which no longer occurs in the mutant.

The implications of these remarkable findings are obviously widespread, not only in the field of genetics but also in many other ways, one of which is in the field of microbiological assay. The *Neurospora* mutants with specific nutritional defects can be used for microbiological assay of amino acids and other nutrients just as has been described for the use of certain bacteria. For example, Horowitz and Beadle<sup>101</sup> have described a *cholineless* strain of *Neurospora*, i.e., a mutant which cannot synthesize choline and is therefore unable to grow without the presence of added choline in the medium. These authors have described a method for the microbiological assay of choline by the use of this strain. The procedure is substantially identical in principle with that described on p. 1064 for the

<sup>101</sup> Horowitz and Beadle: *J. Biol. Chem.*, **150**, 325 (1943). See Chapter 35, "Choline."

microbiological assay of amino acids, except that growth response is followed by drying and weighing the mold mycelium. Comparison is made in terms of a standard curve obtained with known amounts of choline. Methods have also been described for the assay of certain amino acids (methionine, leucine, arginine) by the use of the proper *Neurospora* mutants, and in general this versatile phase of microbiological assay appears to be just beginning in so far as future application is concerned.

Another contribution of this work is to facilitate knowledge concerning gene action, and the reactions controlled by genes. If, as has been suggested, each step in a biochemical reaction is under the control of a single gene, studies of the various mutants should permit a better understanding of the intermediate stages in biochemical reactions. For example, by this method of approach the progressive reaction ornithine  $\rightarrow$  citrulline  $\rightarrow$  arginine, postulated by Krebs and Henseleit in connection with urea synthesis in mammalian liver (see p. 1039) has been shown to occur in distinct gene-controlled steps in *Neurospora*. While this does not necessarily mean that the reaction occurs in this way, or even occurs at all, in higher cells, it at least indicates the possibility of it so doing. There is no doubt that further studies of this type will add significantly to our knowledge of the fundamental chemical processes of protoplasm.

#### IV. EXPERIMENTS ON CARBOHYDRATE METABOLISM

**1. Hyperglycemia Produced by Carbohydrate Ingestion.** The average glucose content of normal blood is somewhat less than 0.1 per cent. This is increased (hyperglycemia) after the ingestion of carbohydrate food. The increase is noted more quickly after the ingestion of monosaccharides than after the ingestion of the more complex carbohydrates. After the ingestion of 100 g. of glucose the increase in the sugar of the blood sometimes occurs in three minutes.

(a) **INFLUENCE OF GLUCOSE.** In the morning before breakfast, or at least three hours after breakfast, determine the normal sugar content of your blood by means of some accurate micromethod (see Chapter 23). Ingest 100 g. of glucose dissolved in 250 ml. of water, and again determine the blood sugar level at intervals of 5, 15, and 30 minutes, and one, two, and three hours. (Plot a curve similar to the one shown in Fig. 266.) The urine may also be examined for sugar at intervals of one hour after the sugar ingestion.

Repeat the experiment on another day using 250 g. of glucose and compare the results with those obtained after the ingestion of 100 g. Explain your findings. If desired, this experiment may be combined with the one on "Alimentary Glucosuria," below.

(b) **INFLUENCE OF STARCH.** Repeat the experiment as given above for glucose except that 170 g. of white bread or 100 g. of starch made into a paste<sup>102</sup> are substituted for the 100 g. of glucose.

The experiment may be repeated as described above, using an increased amount of starch.

The various experiments may be conducted on patients suffering from diabetes mellitus if such are available and instructive data collected. The alimentary hyperglycemia will generally be slower in reaching its maximum and will be more prolonged than in the case of normal subjects. In some instances after the diabetic has ingested

<sup>102</sup> In making starch paste, rub up the dry starch in a mortar with cold water, pour the suspended starch granules into boiling water, and stir.

100 g. of glucose the blood sugar does not reach its maximum until a period of two hours has elapsed. The blood sugar also returns to its former level more slowly than in the case of normal individuals.

FIG. 266. BLOOD SUGAR AS INFLUENCED BY DIET.

A, glucose; B, starch; C, starch and fat; D, fat.

**2. Experiments on Alimentary Glucosuria.** According to Folin and Berglund, the sugar of normal urine consists of a motley variety of carbohydrate products and carbohydrate derivatives including di- and polysaccharides. These are believed to arise from foreign, unusable carbohydrate materials present in grains, vegetables, and fruits and from decomposition products due to cooking, canning, and baking of food. The ingestion of pure glucose, fructose, maltose, dextrin, or starch does not normally give rise to glucuresis, but the ingestion of impure products or of an ordinary carbohydrate meal increases the sugar of the urine. So also may lactose and galactose.

**Procedure.** On arising at 7:00 A.M., the student should empty his bladder and discard the urine voided. He should then drink one glass of water but eat no food. At 8:00 A.M., the bladder is again emptied and the urine kept for analysis. The student then immediately drinks 200 g. of pure glucose dissolved in about 500 ml. of water. Urine specimens are collected again at 9:00, 10:00, and 11:00 A.M. Test each specimen for sugar by Benedict's qualitative reduction test. Determine sugar in each specimen according to the method of Folin and Svedberg (see Chapter 31).

Other students should go through the same procedure with the exception that for glucose there should be substituted 200 g. of cane sugar, 200 g. of commercial dextrin, 200 g. of pure dextrin-starch,<sup>103</sup> 100 g. of pure lactose, a dozen graham crackers with water only, two baked apples, bread and butter, meat with water only, or a large dish of pure gelatin without added sugar.

This experiment may be made more complete by making determinations of blood sugar at short intervals as described in Exp. 1, p. 1068. If desired, data on glucosuria, hyperglycemia, and carbohydrate in feces (see below) may be collected from one experiment.

**3. Effect of Exercise on the Composition of the Urine.** After strenuous exercise the urine volume generally decreases, while the acidity and ammonia increase. The

<sup>103</sup> Dextrin-starch mixture may be prepared by boiling 200 g. of starch in 900 ml. of water, cooling to 50° C., adding a little malt extract, and allowing to digest until completely liquefied.

phosphate and lactic acid excretion increase and the chloride excretion decreases. The maximum effect usually is obtained in 20 minutes. Normal values should be restored in about an hour.

**Procedure.** The subject who has had no food for several hours is given 50 ml. of water every 15 minutes throughout the experiment, beginning for example at 12:00 noon. At 12:00 the bladder is emptied and urine specimens collected every 15 minutes thereafter. At 1:00 the subject engages in strenu-

FIG. 267. CURVES SHOWING INFLUENCE OF EXERCISE ON COMPOSITION OF THE URINE.

Courtesy, Wilson, *et al.*: *J. Biol. Chem.*, 65, 755 (1925).

ous exercise for 2–3 minutes. Running up and down stairs for this period will suffice. In the urine specimens determine lactic acid, phosphate, total acidity, chloride, ammonia, and pH. (For methods, see Chapter 31.) Plot curves of amounts of these constituents per 10-minute specimen against time to show the effect of exercise on urine composition. The blood sugar may also be determined at intervals and the influence of the exercise noted. Curves from a typical experiment are shown in Fig. 267.

**4. The Effect of Insulin on the Blood Sugar Level.** See the experiment described on p. 769.

**5. Influence of Carbohydrate Deficiency.** Carbohydrates occupy a very prominent place in the diet of man. That they are not *essential* dietary constituents, at least for the white rat, may be shown by the following experiment.

**Demonstration on Carbohydrate Deficiency.** Use young white rats as subjects, feeding one rat Diet 1 and another rat Diet 2 as given in the following table:

CARBOHYDRATE DEFICIENCY DIET

|                                                | <i>Diet 1</i><br><i>per cent</i> | <i>Diet 2</i><br><i>per cent</i> |
|------------------------------------------------|----------------------------------|----------------------------------|
| Casein.....                                    | 55                               | 20                               |
| Butter fat.....                                | 30                               | 15                               |
| Lard.....                                      | 15                               | 10                               |
| Starch or dextrin.....                         | 0                                | 55                               |
| Yeast, dried, <sup>104</sup> gram per day..... | 0.4                              | 0.4                              |

Both rats will grow normally in spite of the practical absence of carbohydrates in Diet 1. In the case of man, the withdrawal of carbohydrates is followed by ketosis (see p. 1073). This ketosis is absent or much less pronounced in the case of the white rat.

**6. Isolation and Determination of Liver Glycogen.** This exercise serves to illustrate the conditions for the manufacture and storage of liver glycogen by the animal organism, to provide some liver glycogen for study, and to show how tissue glycogen is quantitatively determined.

**Procedure.** Students may work in pairs. Prior to the experiment, transfer a 6-ml. portion of 30 per cent KOH to each of two 50-ml. centrifuge tubes, stopper the tubes with a rubber stopper, and weigh on an analytical balance. Suspend the tube on the balance by means of a copper wire fastened around the tube just below the pouring lip. Take care that the alkali does not come in contact with the rubber stopper.

Each group of four students will be supplied with a rat. Half the animals dispensed will have been starved and the other half fed. Remove a rat from its cage gently to avoid exciting it. Stun it by a blow on the head and decapitate it quickly. Immediately remove the liver, weigh quickly to the nearest 0.1 g., and cut into two approximately equal portions, one for each pair of students. Mince the liver portion immediately and transfer samples of the minced liver to each of the two centrifuge tubes (0.7 to 1.0 g. samples from fed rats and 1 to 1.5 g. samples from starved rats). Stopper the tubes and weigh again. The difference between this weight and the original weight of the tube plus the KOH solution will give the weight of liver sample used. Remove the stoppers and place the tubes upright in a boiling water bath for 15 to 20 minutes, agitating the solution occasionally to ensure thorough disintegration.

At this point each pair of students should exchange one of the two tubes for one from another pair of students that represents a rat of opposite type. Thus each group will have one glycogen preparation from a fed rat and one from a fasted rat. Add 7 ml. 95 per cent alcohol to each tube, mix by tapping, and immerse in the water bath until boiling just begins (care must be taken to avoid loss by sudden foaming). Allow the tubes to cool at room temperature for about 2 hours. Centrifuge, decant and discard the supernatant fluid, drain and wash the precipitates twice with 5-ml. portions of 60 per cent alcohol by centrifuging, decanting, and draining as before. Expel the

<sup>104</sup> The yeast is fed separately, 0.4 g. to each rat. It may be fed in the form of a powder or as tablets. The only carbohydrate present in Diet 1 is the very small amount in the dried yeast.

last traces of alcohol by immersing the tubes in boiling water just long enough to dry the glycogen. Compare the relative amount of glycogen obtained from the fed animal with that from the fasted animal. To each tube add 10 ml. distilled water and stir until a uniform suspension is obtained. Pipet 5 ml. of the suspension into a clean test tube, add 5 ml. 2 N sulfuric acid solution, insert a small funnel in the mouth of the test tube to minimize loss by evaporation, and heat in a boiling water bath for 3 to 4 hours to hydrolyze the glycogen. Cool, add a drop of phenol red indicator, and neutralize cautiously with 1N NaOH, with constant stirring; a volume of about 10 ml. should be required. Transfer the neutralized solution quantitatively to a 50-ml. or 100-ml. volumetric flask, dilute to volume with water, and mix. Analyze this solution for glucose by the Somogyi-Shaffer-Hartman method (p. 571), using the volume of aliquot that will contain not less than 0.1 mg. or more than 2.0 mg. of glucose, calculated on the assumption that the glycogen content of the liver from the fed animal is approximately 10 per cent on a wet weight basis, and that from the starved animal is 0.2 per cent (it may be zero). Calculate the liver glycogen content as grams of glucose per 100 g. of liver, and report results to the instructor. In your discussion of the experiment, briefly discuss the factors which influence glycogen storage and depletion. Use the remaining glycogen suspension which was not hydrolyzed for performance of the iodine test (p. 281) and the saliva test (p. 281).

## V. EXPERIMENTS ON FAT METABOLISM

**1. Fat Utilization.** This may be determined in a manner entirely analogous to that used in the determination of protein utilization (see p. 1047). The fat may be determined by the Saxon method (see p. 454). It is claimed when moderate amounts of fat are fed that the fat of the feces is largely independent of the diet. Therefore, in order to secure accurate information regarding the utilization of food fat, it is said to be necessary to determine the fecal fat on a nonfat diet. There may possibly be a fat excretion from the intestine but much of the lipide of the feces is found in cellular structures (bacteria, epithelial cells, etc.). (See Chapter 21.)

**2. Fat in Feces.** A normal adult will digest and absorb at least 90 per cent of the fat in the diet when the amount ingested does not exceed 100 g. If the diet contains an excessive amount of fat, e.g., 300 g. per day, considerable appears in the feces. In pancreatic diseases and such conditions as are accompanied by a decrease in bile flow, the digestion and assimilation of fat is lessened.

**Experiment.** (a) Ingest an ordinary mixed diet containing an average amount of fat per day, e.g., 75–100 g. Collect a stool and examine it microscopically as directed on p. 449. (b) Now ingest a diet containing an excessive quantity of fat, e.g., 300 g. per day. Separate the feces and subject a representative sample of the feces from the high fat diet to microscopical examination. (c) If it is desired, the fat may be extracted from some of the stool by applying the principle involved in the quantitative determination of fat in the Saxon method (see p. 454). Evaporate the ether extract and identify the fat in the residue by tests given in Chapter 3.

**3. Influence of Fat (Fatty Acid) Deficiency.** Although it has often been demonstrated that fats are not essential constituents of the diet from the energy standpoint, Burr and Burr have shown the essential nature of certain unsaturated fatty acids (see discussion on p. 1004). The following experiment demonstrates the characteristics of a deficiency of essential fatty acids in the rat.

**Experiment.** Two groups of rats, weaned at three weeks, are placed in individual cages and fed the following diet: purified casein<sup>105</sup> 24, sucrose 72.1, salt mixture (McCollum-Davis, see Appendix) 3.9. Supplementing this diet, 0.65 g. of dried ether-extracted yeast upon which is dried 2 drops of an ether extract containing the nonsaponifiable fraction of 70 mg. cod-liver oil, is fed daily. To each rat in one group 10 drops of lard are given daily. Water is supplied ad lib., and if desired, the quantity consumed may be measured.

In about 70 to 90 days the symptoms of the deficiency will begin to appear in the fat-free group. The legs, especially the hind legs, become scaly and swollen, the tail becomes spotted and ridged and finally necrotic (Fig. 268), the hair on the back becomes filled with dandruff and tends to fall out, and degeneration of the kidneys sets in, as may be observed from the bloody urine. The renal lesions are the immediate cause of death. In the females, ovulation becomes irregular and finally ceases.

FIG. 268. NECROSIS OF THE TAIL OF A RAT ON A FAT-FREE DIET.

Courtesy, Burr and Burr: *J. Biol. Chem.*, 82, 345 (1929).

The deficient animals eat the same amount of food but drink twice as much water as the controls. Before the deficient animals reach a moribund condition, their diet may be supplemented with a small amount of an oil or fatty food, to test the curative properties of the fatty acid molecules.

The above procedure can be employed quantitatively for the bioassay of the essential fatty acids present in foods.<sup>106</sup> Weanling male rats from litters of which the mothers have been on a low-fat diet are placed on a fat-free diet until depleted, as determined by a constant body weight for 3 weeks. This requires a period of approximately 12 weeks. The rats are then divided into the following groups: negative control group; groups to determine reference growth curve (which receive 10, 20, or 50 mg. methyl linoleate daily); groups to receive unknown fat at several levels (25 and 50 mg. per day for cottonseed and similar oils, 250 and 500 mg. per day for margarines and butter). The assay period is continued for 8 weeks. The potency of the unknown fat can then be estimated from the log dose:gain-in-weight relationship, as is done in the standard procedure for bioassay of vitamin A.

**4. Ketosis.** Ketosis may be induced in a normal person by the ingestion of a carbohydrate-free diet. The origin of ketosis is discussed on p. 1007. The intensity of ketosis

<sup>105</sup> Reprecipitated curd casein is washed until free from chlorides, extracted repeatedly with alcohol, and finally extracted for one week with ether, and dried at 35° C. For detailed directions see Burr and Burr: *J. Biol. Chem.*, 82, 345 (1929).

<sup>106</sup> Deuel, Greenberg, Anisfeld, and Melnick: *J. Nutrition*, 45, 535 (1951).

may be evaluated by determination of the excretion of ketone bodies in the urine (ketonuria). The following table shows the data obtained in an actual case of the withdrawal of carbohydrate food from the diet of a normal man (Von Noorden).

KETOSIS ACCOMPANYING CARBOHYDRATE WITHDRAWAL

| Day | Diet                           | Excretion of Acetone Bodies Calculated as $\beta$ -Hydroxybutyric Acid |
|-----|--------------------------------|------------------------------------------------------------------------|
|     |                                | grams                                                                  |
| 1   | Protein, fat, and carbohydrate | None                                                                   |
| 2   | Protein and fat                | 0.8                                                                    |
| 3   | Protein and fat                | 1.9                                                                    |
| 4   | Protein and fat                | 8.7                                                                    |
| 5   | Protein and fat                | 20.0                                                                   |
| 6   | Protein, fat, and carbohydrate | 2.2                                                                    |

**Experiment.** Ingest an ordinary mixed diet for 1 day. Follow this by a period of 2 to 4 days in which no digestible carbohydrate is eaten. (A diet of meat, eggs, butter, agar-agar, and water has a very low digestible carbohydrate value.) Collect the urine for each day of the experiment, examine it qualitatively for acetone bodies (see tests, Chapter 29). If present, determine the total acetone bodies quantitatively (for methods see Chapter 31). The blood may also be examined (see Chapter 23). Did the withdrawal of carbohydrate food cause a ketonuria?

VI. ADEQUATE vs. OPTIMAL NUTRITION; THE DIETARY EFFICIENCY OF MILK

The foregoing experiments have demonstrated that certain factors must be present in a diet if it is to be deemed *adequate*. But such a diet, although it qualifies under all required nutritional standards, may be improved upon. We thus form what may be termed an *optimal* diet. To demonstrate the difference between an *adequate* and an *optimal* diet proceed as follows:

Place two white rats from the same litter, each weighing 35–45 g., in separate cages. Feed one rat an *adequate* diet (see below) and the other an *optimal* diet (see below).

| Adequate Diet            |    | Optimal Diet             |    |
|--------------------------|----|--------------------------|----|
| Whole wheat.....         | 82 | Whole wheat.....         | 66 |
| Whole milk (powder)..... | 17 | Whole milk (powder)..... | 33 |
| Sodium chloride.....     | 1  | Sodium chloride.....     | 1  |

It will be noted that dry milk constitutes only *one-sixth* of the adequate diet whereas it makes up *one-third* of the optimal diet. Give the animals water ad lib. and weigh them at least twice a week. Continue the experiment for at least 10 weeks, plotting the growth curve of each animal and keeping an accurate record of the food eaten (see Appendix for methods of recording data). If it is desired to investigate the relationship of these diets to reproduction, two rats of opposite sex may be used in each test and caged together.

The rat (or rats) receiving the *optimal* diet should grow more rapidly than the animal or animals receiving the *adequate* diet. If the experiment embraces the question of reproduction it will be found that the rats on the optimal diet have greater success in

the rearing of young and that the offspring grow better during the nursing period than do the offspring of the rats ingesting the *adequate* diet.

In a comprehensive series of observations on these diets by Sherman and associates it has been found that the animals fed the optimal diet mature earlier and live longer. In common with other data secured from tests with albino rats these findings may be applied directly to the human dietary, and afford a very striking demonstration of *the remarkable nutritive efficiency of milk*.

Various other elements are also present in traces; these are sometimes called as a group the *trace elements*. In many instances their nutritional significance if any is obscure. In addition to copper, manganese, zinc, and iodine, which may be considered trace elements of known nutritional significance, this group includes the elements aluminum, fluorine, silicon, lithium, bromine, arsenic, lead, molybdenum, vanadium, and possibly others. Each of these elements is in fact a mixture of *isotopes*, elements that have identical chemical properties but differ in certain physical properties (see Chapter 32, "Isotopes").

The elements which make up the animal body are obtained from various sources. Carbon, hydrogen, and oxygen are supplied to the body by carbohydrates, fats, and proteins, and by water and the oxygen of the air; nitrogen, as well as a considerable proportion of phosphorus and sulfur, are supplied by proteins; the remaining elements are supplied by the mineral constituents of natural foodstuffs, by common salt, and to some extent by the minerals of drinking water.

About 90 per cent of the total oxygen of the animal body and about 70 per cent of the total hydrogen are present together in the form of water, which makes up roughly two-thirds of the total body weight. The remaining oxygen and hydrogen, along with all the nitrogen, most of the carbon

PROXIMATE CHEMICAL COMPOSITION OF AN ADULT HUMAN BODY

Adapted from the data of Mitchell, Hamilton, Steggerda, and Bean (*J. Biol. Chem.*, **158**, 625 (1945)). The subject was an adult male, aged 35, estimated to have been in reasonably good nutritional state at the time of death, which was due to an acute heart attack. The body was obtained from the Department of Anatomy of the University of Illinois College of Medicine, and had been preserved only by freezing until the dissection for analysis was begun about 6 weeks after death. Approved analytical methods were used.

† Somewhat enlarged.  
‡ Somewhat congested.

and sulfur, and some of the phosphorus, are found in the organic compounds of the body (carbohydrates, lipides, proteins, etc.). These compounds comprise about 90 per cent of the total solid matter of the animal body, the remaining 10 per cent (about 3.3 per cent of the total body weight) being largely inorganic. The inorganic elements essential for

animal life include sodium, potassium, calcium, magnesium, phosphorus, iron, copper, chlorine, iodine, cobalt, manganese, zinc, and possibly others.

The relative amounts of water, organic material, and inorganic elements ("ash") characteristic of the body as a whole do not necessarily represent the composition of the individual tissues and organs of the body, where wide variation may be encountered, not only from tissue to tissue but for a particular tissue under varying normal and pathological conditions. These differences between the various parts of the animal body in this respect are illustrated by the data in the table on p. 1078.

The term "proximate" refers to an analysis in terms of fundamental components but not necessarily in terms of the elements themselves. Fresh tissues or tissues from different animal species may vary more or less from the values given in the table. The weight of the ash is slightly higher than the actual weight of mineral elements present, including as it must the carbon and oxygen of carbonates, the oxygen of phosphates and sulfates, etc.

The absence of carbohydrate from the table is to be noted. If the carbohydrate content is estimated by difference, it cannot account for more than a few per cent of the total body weight. This emphasizes the fact that in animal tissues as a whole, carbohydrate is present in limited amount, despite the high carbohydrate content of the animal diet—in contrast to plant tissues, where carbohydrate may make up the major portion of the solid matter present. Another factor which enters into the picture is that much of the carbohydrate in animal tissues readily undergoes post-mortem changes, i.e., glycogen and glucose are converted to lactic acid, etc., so that a precise estimation of carbohydrate content requires special technical treatment.

## WATER

Water is the most abundant compound in the animal body, making up approximately two-thirds of the total body weight, although the various tissues within the body may differ significantly in water content (see table, p. 1078). Other organisms, e.g. the jelly-fish, may have a much higher proportion of water. Water furnishes what has been called "the aqueous milieu within which life processes occur." Water is more essential than food in the sense that an individual can survive much longer when deprived of food than when deprived of water. According to Thorpe, death usually results when about 20 per cent of the body water is lost. For experiments illustrating the need for water in the diet, see p. 1057.

Water possesses a number of physical and chemical properties which promote its physiological utility. The high solvent power of water permits the formation of a variety of true and colloidal solutions, within which reactions may occur at a much more rapid rate than if a solid phase were concerned. The high dielectric constant of water promotes ionization, thus facilitating reaction occurrence and velocity. Water itself enters into a great many of the reactions of biological material (hydrolysis, oxidation, reduction, etc.) and appears to catalyze other reactions in which it plays no apparent part. The lubricating action of water is important in con-

nection with such physiological functions as swallowing and the role of the various internal fluids of the body (synovial, peritoneal, pleural, etc.).

Water is a good heat insulator, and at the same time appears to be of major importance in the control of heat loss from the animal body. The heat required to convert 1 g. of water to water vapor at room temperature is approximately 0.6 Cal. Du Bois found in one instance that the amount of water lost by vaporization from the skin and lungs of a normal resting man under ordinary conditions of temperature and humidity was about 680 g. per day. The heat loss associated with this vaporization represented about one-quarter of the total daily heat loss. Other means of heat loss include radiation and conduction; as the environmental temperature rises toward that of the animal body (37° C.), these latter means become relatively ineffective and heat loss by vaporization of water becomes proportionately greater.

The significance of water in the animal body<sup>1</sup> has two general aspects: (1) the relation between water entering the body and that leaving it, i.e. the water balance, and (2) the distribution of water between the various water-containing fluids of the body.

**Water Balance.** The sources of body water include (1) the fluids of the diet, (2) the solids of the diet, which contain more or less water, and (3) the water produced by the oxidation of material within the tissues. The major channels of water excretion include (1) the lungs, (2) the skin, (3) the kidneys (urine), (4) the intestinal canal (feces), (5) in the lactating female, the milk, and (6), to a minor extent, the tears. The relative significance of these various factors may be illustrated by the following table.

WATER BALANCE OF A NORMAL INDIVIDUAL

| Source                        |      |                   | Excretion  |      |                   |

| Totals.....                   | 2500 | 100               |            | 2500 | 100               |

Normally an individual is in water equilibrium, i.e., water gain equals water loss with respect to all sources. A water intake in excess of the ability of the body to excrete water may be toxic (water intoxication); a water loss which exceeds water intake may lead to dehydration, and if sufficiently prolonged, to death.

<sup>1</sup> For a review, see Abbott: *Am. J. Med. Sci.*, **211**, 232 (1946). See also Hawk: "The relationship of water to certain life processes and more especially to nutrition," *Biochem. Bulletin*, **3**, 420 (1914); Hawk: "Water as a Dietary Constituent," in *Endocrinology and Metabolism* Vol. III, London and New York, D. Appleton and Co., 1924.

Wide variation from the values given in the table is encountered under a variety of physiological and pathological conditions. Water intake by a normal person is largely a matter of individual choice or habit; it has been amply demonstrated that copious water drinking produces no harm and even if taken with meals promotes digestion owing to stimulation of glandular secretions. Water excretion through the skin as perspiration may be significantly increased at the expense of other channels, e.g. the urine, during severe exercise in a hot environment. Pathologically, the main channels of water loss, and the extent each may be involved, are as follows: by vomiting, up to 5 liters; overventilation, 1 to 2 liters; excessive perspiration, 10 to 15 liters; diarrhea, up to 5 liters. In diabetes insipidus, daily urine volumes of 30 liters or more have been observed, with a correspondingly large water intake.

Water excreted by the body through any channel except the lungs is invariably accompanied by electrolytes, chiefly sodium and chloride. The symptoms of excessive water loss (dehydration) are due to the loss of both water and electrolytes, and both water balance and electrolyte balance must be restored if the condition is to be alleviated. If, after prolonged profuse sweating, only water is restored to the body by drinking, neuromuscular spasms (cramps) may occur due to failure to replace the electrolytes lost in the sweat. Workers in a high-temperature environment and persons competing in athletic events have found that the addition of common salt to the drinking water will obviate this tendency.

Water excretion by the kidneys appears to be under the control of hormones from the posterior pituitary and the adrenal cortex. Absence or ineffectiveness of the "antidiuretic" principle of the posterior pituitary is believed to be the lesion in diabetes insipidus, although some balance with the anterior pituitary must be acting here, since the production of diabetes insipidus by experimental lesions of the posterior pituitary requires the presence of an intact anterior pituitary. The nerve fibers of the hypothalamic portion of the brain also appear to be of some importance in this connection. It is possible that, in the absence of the anti-diuretic hormone, the tubular cells of the kidneys to a greater or lesser extent lose their ability to reabsorb the 99 per cent or more of the approximately 150 liters of glomerular filtrate produced in the kidney per day.

With regard to cortical hormones, of the pure principles thus far obtained (see Chapter 26), deoxycorticosterone is effective in maintaining normal water and electrolyte balance, as is the "amorphous fraction" of the cortical hormones. It is uncertain here whether the effect is primarily on the excretion of water or electrolytes, if indeed any distinction between these two can be made. This may also be true with respect to the pituitary principle. It serves to emphasize the fact that water excretion and electrolyte excretion are closely connected and should not be considered separately.

**Distribution of Water in Body Fluids.** The water of the body tissues and fluids is usually divided for consideration into two phases: (1) an extracellular phase, subdivided into (a) plasma (5 per cent of total body weight, or about 3 liters in a 70-kg. man), and (b) interstitial fluid, comprising about 15 per cent of the total body weight, or about 10

liters in an adult; and (2) an intracellular phase, making up about 50 per cent of the total body weight, or about 35 liters. Various methods, not all of which give the same result, have been used to establish this distribution of the body water and to follow variations in health and in disease. For example, a common basis for the determination of interstitial fluid volume is to determine the dilution of a known amount of injected material such as thiocyanate, sulfate, chloride, sucrose,<sup>2</sup> etc., which is assumed to distribute itself evenly throughout the extracellular water but not to penetrate the cells, at least under the experimental conditions. Suitable corrections for the amount present in the plasma, and the amount excreted, must of course be made. The use of heavy isotopes such as deuterium and tritium and of radioactive isotopes, e.g. radio-sodium, radio-chloride, and radio-sulfate, is of considerable value.<sup>3</sup> See Chapter 32.

The factors determining the distribution of water between the various fluid "compartments" of the body are not known with certainty, but they appear to be largely osmotic and related to electrolyte concentration, possibly modified by differences in permeability of ions to various membranes. The role of the plasma proteins in the water equilibrium between the blood and tissues has been discussed in Chapter 22. The role of inorganic ions may be visualized by the following necessarily inexact illustration. If it is assumed for example that the interstitial fluid contains sodium chloride in isotonic concentration, the presence of approximately 9 g. of sodium chloride will permit the retention of 1 liter of water, since sodium chloride in 0.9 per cent solution is isotonic. Loss of sodium chloride will necessitate an equivalent loss of water to keep the remaining fluid isotonic, and excess sodium chloride in the tissues will result in the presence of a larger volume of water for the same reason.

There appears to be an equilibrium between the various fluid compartments, to provide for the maintenance of a normal water content in the most essential phase. For example, the water content of the interstitial fluids may be decreased by 20 per cent or so without any detectable change in the water content of the plasma. Thus the water content of the plasma is not necessarily a reliable guide to general dehydration as some have assumed, at least in the early stages.

The inorganic compounds of the body exercise a great diversity of vital functions in the animal economy. The calcium phosphate-carbonate complex that forms the basis of osseous tissue gives to the bones and teeth their rigidity and hardness. Because of their influence on such phenomena as permeability of cell membranes, hydrogen-ion and osmotic equilibria, solubility of proteins, etc., the inorganic salts dissolved in the body fluids affect the contraction of muscle, the irritability of the nervous system, enzyme activities, water balance, and the secretion of digestive juices, perspiration, and urine. Certain of the inorganic elements, e.g. phosphorus, sulfur, iron, etc., are combined in the molecules of biologically important compounds such as glutathione, lecithin, hemoglobin and other proteins, etc.

<sup>2</sup> Dean, Schreiner, and Robertson: *J. Clin. Invest.*, **30**, 1463 (1951).

<sup>3</sup> See Winkler, Elkington, and Eisenman: *Am. J. Physiol.*, **139**, 239 (1943); Walser: *Proc. Soc. Exp. Biol. Med.*, **79**, 372 (1952); Moore: *Science*, **104**, 157 (1946).

It has been demonstrated that inorganic elements must be available in the animal diet not only in adequate amount but also in proper balance with respect to one another. For example, a high intake of potassium salts results in increased elimination of sodium and chlorine, adequate dietary calcium is necessary for retention of potassium, and in cases of vitamin D deficiency, too high or too low ratios of calcium to phosphorus in the diet lead to serious impairment of bone structure.

In the following pages are considered some of the metabolic aspects of inorganic elements and compounds. Quantitative methods for the determination of various inorganic elements in blood and urine have been described in Chapters 23 and 31; the occurrence and significance of these elements in the urine are discussed in Chapter 28.

## SODIUM

This element is present to a considerable extent in the diet and in the body fluids of the animal organism, invariably in the form of the sodium ion,  $\text{Na}^+$ , and in the diet at least, for the most part as sodium chloride. However, the sodium ion is a physiological entity whose function within certain limits is relatively independent of whatever anions (chloride, bicarbonate, lactate, phosphate, proteinate, etc.) are associated with it.

The adult human body contains about 100 g. sodium, distributed almost entirely in the extracellular fluids (blood plasma, interstitial fluid) of the body. On the average, about 4 to 5 g. sodium are ingested per day in the ordinary diet, corresponding to about 10 g. sodium chloride, which is the major form in which this element is ingested. Practically all of this ingested sodium is excreted by way of the urine. On diets low in sodium the urinary excretion falls to a very low level, so that the daily sodium requirement is considerably in excess of the amounts ordinarily ingested, and is commonly covered by the amount of sodium chloride (table salt) in the diet.

Carnivorous animals receive adequate salt from the animal tissues which constitute their food. The food of herbivorous animals is relatively low in sodium, and is high in potassium, the ingestion of which causes an increased urinary excretion of sodium. This loss of sodium induces a craving for this element, which in nature may be satisfied by such animals traveling long distances to salt licks, while domestic cattle are furnished with salt blocks. In the case of human subjects, the addition of salt to the diet makes it possible to eat with relish larger amounts of vegetable foods. Lactating cows not given a salt supplement yield milk of low sodium chloride content and may suffer otherwise. It has been shown in rat experiments that sodium deficiency unfavorably affects the appetite, the normal increase in weight, the storage of energy, and the synthesis of fat and protein. On a diet otherwise normal but of restricted sodium content (0.002 per cent), rats show retarded growth and disturbances of the eyes and reproductive function, with death ultimately ensuing. Rats may have their sodium needs satisfied by diets containing as little as 0.1 per cent of sodium chloride.

It has been shown by the use of radioactive sodium that this element is absorbed exceedingly rapidly from the gastrointestinal tract, some absorp-

tion apparently taking place even from the stomach—somewhat surprising in view of the relatively restricted absorptive capacities of this organ. Radioactive sodium ( $\text{Na}^{24}$ ) has also been used as a means of determining the volume of extracellular fluid in the animal body, on the assumption (which appears to be reasonably valid) that the sodium ion is distributed evenly or in a predictable way throughout the extracellular fluids of the organism and is virtually absent from the body cells.

The major functions of the sodium ion in the animal body appear to be in connection with osmotic-pressure regulation and acid-base balance, although other possible functions such as a catalytic effect on enzyme activity, though as yet undiscovered, cannot be excluded. The role of sodium in osmotic pressure regulation and acid-base balance is best understood by a consideration of the electrolyte distribution of a typical body fluid (blood plasma) as shown herewith.

#### APPROXIMATE ELECTROLYTE DISTRIBUTION OF NORMAL HUMAN BLOOD PLASMA

|                                                    | “Bases” |     |     |     | “Acids” |           |                |             |
|----------------------------------------------------|---------|-----|-----|-----|---------|-----------|----------------|-------------|
| Ion:                                               | Na      | K   | Ca  | Mg  | =       | Cl        | $\text{HCO}_3$ | Pr + Others |
| Concentration:                                     | 154     | + 5 | + 5 | + 3 | =       | 106       | + 28           | + 17 + 16   |
| (milliequivalents<br>per liter of<br>plasma water) |         |     |     |     |         | 167 = 167 |                |             |

The numerical values are to be considered as approximations only, subject to more or less wide variation under both normal and pathological conditions. As a matter of fact, the ionic concentration of an element in a biological fluid is somewhat difficult to define with exactness, since what is ordinarily measured is the total amount of element rather than that fraction which is ionized (see discussion of calcium, p. 1088). Nevertheless, the relationship shown above serves to bring out several fundamental facts.

In the first place, it must be true that the sum of all the cations present (Na, K; etc.) equals the sum of all the anions (Cl,  $\text{HCO}_3$ , etc.). This is evident only if concentrations are expressed in terms of milliequivalents rather than milligrams. This is one reason for the increasing use of the former term in connection with such substances as sodium, chloride, bicarbonate, etc., in their relation to physiological processes. For example, if bicarbonate is replaced by chloride in plasma, this replacement is on the basis of ion for ion (i.e., equivalent for equivalent) rather than gram for gram. The equivalent concentration of a monovalent ion may be obtained by dividing the weight of ion present by the equivalent (combining) weight of the ion; for milliequivalents, both weights are expressed in milligrams. Thus if sodium is present to the extent of 354 mg. per 100 ml., or 3,540 mg. per liter, the milliequivalent concentration per liter is  $3,540/23 = 154$  milliequivalents (mEq.). For a divalent ion such as  $\text{Ca}^{++}$ , the equivalent weight is the combining weight divided by 2, since one Ca ion is equivalent to two monovalent anions.

From the data on electrolyte distribution, therefore, it can be seen

that the sodium ion is the chief cation of blood plasma, and this is true also for the other extracellular fluids of the body. Within the cells, sodium is present in relatively low concentration, being replaced largely by potassium and magnesium.

The division of the various ions of plasma into "bases" and "acids" deserves some clarification, since this usage is rare in general chemistry though quite common in physiology and medicine. The plasma (and the tissue fluids in general) are essentially neutral in reaction, and remain so under all conditions compatible with life. When an acid such as lactic acid enters into or is produced within a neutral buffered physiological fluid, to all intents and purposes the hydrogen ion of the acid disappears in the formation of water or other un-ionized molecule. The fluid still remains essentially neutral in reaction, and the only evidence that acid has been present is found in the increased amount of the acid anion—e.g., the lactate ion in this instance. This increased acid anion content is at the expense of such buffer anions as bicarbonate, phosphate, proteinate, etc., originally present. Thus the entrance of acid is reflected not by any marked change in pH, but by alteration in the relative amount and distribution of the various anions present. The anions therefore represent the "acid" portion of the electrolytes. An analogous situation prevails with respect to base, the entrance of which, within the framework of a neutral solution, will be evidenced almost entirely by an increase in cation (e.g. Na) content. Naturally, other factors enter into acid-base balance within the body, as is evident from the discussion in Chapter 24, but the concept of acid-base balance reflected in part by the kind and distribution of anions (acids) and cations (bases), within an essentially neutral solution, is of considerable value in an understanding of all phases of this subject. From what has been said, it can be seen that sodium is the chief base of the plasma, and of the extracellular fluids in general.

Another aspect of sodium-ion concentration which is of importance is in connection with osmotic pressure regulation. The total osmotic pressure of a biological fluid such as the blood plasma is equal to the sum of the osmotic effectiveness of all the ions present. Thus the plasma corresponds osmotically to a solution 0.167 M (167 milliequivalents per liter of plasma water) with respect to an electrolyte such as NaCl, which is assumed to be completely dissociated in solution to yield two ions, or to a solution of a nonelectrolyte which is approximately 0.33 M ( $2 \times 0.167$ ). The *osmolar* concentration of plasma is therefore approximately 0.33. Note that of the total osmotically effective bases of plasma, sodium makes up approximately 92 per cent ( $\frac{154}{167}$ ). Thus changes in the osmotic pressure of plasma (and in general of the extracellular fluids of the body) are largely due to, and may be caused by, changes in the concentration of sodium present. It is true that under stress a loss of sodium may be compensated for to a small extent by an equivalent increase in potassium, but the ability of the organism to substitute *bases* in this manner is relatively restricted (in contrast to the wide variation in anion distribution which may occur) and any major loss of sodium from the body, as in Addison's disease, and prolonged diabetic ketosis, leads to a significant lowering of the osmotic pressure of the body fluids, and therefore water loss

(dehydration). Restoration is not complete until both the lost base and the lost water are replaced.

The role of sodium in acid-base balance is secondary to its role in maintaining the total osmotic pressure of the body fluids. That portion of the body sodium equivalent to the bicarbonate present (i.e., about 28 milliequivalents per liter of plasma water) represents most of the available base of the plasma which can be used for the neutralization of entering acids, and in conjunction with carbonic acid determines the pH of blood (see Chapter 24). It is more correct however, to regard acid-base changes in terms of the anions present rather than in terms of sodium. Thus one may have an acidosis or alkalosis in terms of variation in plasma bicarbonate and  $\text{CO}_2$  tension without significant changes in sodium content.

The sodium ion has an effect on irritable tissues such as muscle which does not appear to be related to osmotic forces, and which is counteracted by the presence of the calcium ion, in the proportion of about 1 to 2 calcium ions per 100 sodium ions. This is the basis for the use of such "physiologically balanced" solutions as Ringer's, Tyrode's, etc., rather than isotonic saline alone, in experiments involving the maintenance of function of isolated animal tissues or organs.

The excretion of sodium has been discussed on p. 963. On an ordinary diet urinary sodium amounts to about 3 to 5 g. per day, corresponding to 10 to 12 g. expressed as sodium chloride, but wide variations naturally can be expected. On a low-salt diet and in starvation, urinary sodium chloride excretion falls to very low levels. The activity of the antidiuretic hormone of the posterior pituitary (see p. 775) is sensitive to the availability of corticosterone and deoxycorticosterone, elaborated by the adrenal cortex. As a result, a deficiency of these steroid hormones is followed by a loss of sodium and chloride in the urine and retention of potassium, although the causative relationship has been questioned.<sup>4</sup> The restriction of dietary sodium chloride is widely advocated in essential hypertension and cardiac disease.

## CHLORINE

This element is found in biological material exclusively in the form of the chloride ion;<sup>4a</sup> the biological significance of postulated organic chlorine compounds, such as chlorolipides, has as yet to be conclusively demonstrated. In the diet chloride is found largely as sodium chloride, the daily intake approximating 6 to 7 g., representing about 10 g. of sodium chloride, but wide variation in this respect is encountered, depending as it does upon dietary habits. The adult human body contains approximately 100 g. of chloride, found largely in the extracellular fluids of the body, but present to some extent in red blood cells and to a lesser extent in the other cells of the tissues.

Although a close relationship exists between chloride and sodium in

---

<sup>4</sup> Fourman, Reifenshtein, Kepler, Dempsey, Bartter, and Albright: *Metabolism*, 1, 259 (1952).

<sup>4a</sup> A notable exception to this rule is the antibiotic Chloromycetin (chloramphenicol), which contains chlorine in organic combination.

certain physiological processes, the chloride ion has a number of functions which are peculiar to it and which are essentially independent of sodium ion functions. Thus it is the chief anion of the gastric juice, being present there in approximately the same concentration as in the blood, at least before dilution or other modification of the gastric juice, and accompanied by the hydrogen ion in substantially equivalent amount, rather than by sodium as in the plasma and extracellular fluids of the body. The chloride of gastric juice is apparently derived ultimately from blood chloride (see Chapter 14), and is normally reabsorbed during later stages of digestion. Loss of gastric juice chloride by vomiting, or in pyloric or duodenal obstruction, may lead to the development of an alkalosis due to bicarbonate excess, since the lost chloride is replaced in part at least by bicarbonate. It is interesting to note that on chloride-deficient diets there is no change in the output of chloride in the gastric juice, while chloride excretion by other channels, such as the urine and the perspiration, may be markedly decreased.

Another specific function of the chloride ion is in connection with the *chloride shift* in the blood during the carriage of carbon dioxide (see Chapter 24) whereby the bicarbonate content of the blood plasma is significantly increased by exchange with plasma chloride, which enters the red cells.

Chloride is likewise concerned in osmotic pressure regulation, making up about two-thirds of the total anions of blood plasma and occupying a similar position in the other extracellular fluids of the body. The role of chloride in this connection, however, is subject to somewhat greater variation than the role of sodium, since to a certain extent the organism can exchange chloride ions for other anions within the framework of a normal osmolar concentration of total anions. This ability to replace chloride ions by other ions is more restricted, however, than for the other major anion of the plasma, the bicarbonate ion, over half of which can be replaced, for example by the lactate ion under certain conditions.

The chloride ion is an activator of salivary amylase, but this action is not specific for chloride and may be due in part to the effect of strong electrolytes in general on the solubilities of such proteins as globulins. Radioactive chloride ( $\text{Cl}^{38}$ ) has been used for studies on the volume of the interstitial extracellular fluid of the body.

Chloride present in the diet in excess over that required by the body is excreted, chiefly by way of the kidneys. Excreted chloride usually is accompanied by excess sodium or potassium unless there exists a need for conserving base, in which case the ammonium ion accompanies the chloride ion to a variable extent. Factors controlling the excretion of chloride are similar to those concerned with the excretion of sodium and potassium. On a chloride-deficient diet, or in fasting, the chloride excretion may amount to but a trace. However the excretion by normal adults averages about 10 to 15 g. per day expressed as sodium chloride.

## POTASSIUM

This element, like sodium and chlorine, is also present in plant and animal tissues entirely as the potassium ion. The adult human body con-

tains about 250 g. potassium, present almost entirely in the cells rather than in the extracellular fluids as with sodium. While normal human blood plasma contains only about 5 milliequivalents of potassium per liter of water, almost the entire cation content of red cells is made up of potassium (about 170 milliequivalents per liter of cell water). Thus potassium is the major "base" of the body cells, and apparently subserves in the cells the same general functions relating to osmotic pressure regulation and acid-base balance that have already been described for sodium in the extracellular fluids of the body. This is not the only function of potassium, however; it has been shown to aid in the enzymatic transfer of phosphate from ATP to pyruvic acid, for example (see p. 994); and the toxic effects of a significantly elevated plasma potassium level (potassium poisoning) can hardly be ascribed to osmotic forces alone. The potassium ion has an effect on muscular irritability which, like that of sodium, tends to antagonize the effect of the calcium ion. Nevertheless, under conditions of severe dietary salt restriction, calcium appears highly important in supporting the potassium content of tissue.<sup>5</sup>

The abundance of potassium in plant foods and in meat precludes the danger of a deficiency of this element in a mixed diet. From 1 to 3 g. is commonly excreted in the urine per day on such a diet. Growth in rats may be retarded by reducing the daily potassium allowance below 15 mg. in the male and 8 mg. in the female; this difference may be due to differences in growth rate. Potassium requirement varies considerably in the different animal species. Prolonged consumption of a potassium-deficient diet may result in failure of the animal to respond to a correction of the deficiency. Potassium deficiency in man is associated with weakness and muscular paralysis, accompanied by a fall in the plasma potassium level; in animals hypertrophy of the heart and kidneys has been noted. In Addison's disease the excretion of potassium falls and plasma potassium rises, with the reverse changes in urinary and plasma sodium, indicating a function of the adrenal cortex in this connection. The administration of sodium chloride alone will sometimes alleviate the symptoms of the disease, apparently permitting the organism to restore the altered relation between sodium and potassium retention and excretion. It has been claimed that the symptoms associated with removal of the adrenal cortex may be reproduced experimentally by measures which increase the plasma potassium level to about twice the normal value.

## CALCIUM

Calcium is an essential constituent of all living cells. Its mode of action is not clear but it appears to play a part in decreasing the permeability of cell membranes and the irritability of cells in general. Its effect on neuromuscular mechanisms is shown in higher animals by the development of hyperirritability and tetany as a result of a decline in the calcium content of the blood. Such a fall is observed in tetany following removal of the parathyroids, symptoms becoming noticeable when the calcium-ion concentration falls below 3 mg. per 100 ml. (total calcium below 7 mg.).

---

<sup>5</sup> Eppright and Smith: *J. Biol. Chem.*, **118**, 679 (1937).

Normal values are 9 to 11 mg. total or 4.25 to 5.25 mg. of ionized calcium. In fatal hyperparathyroidism,  $\text{Ca}^{++}$  values of 7 mg. (total calcium 16 mg.) have been noted. McLean and Hastings find the calcium of plasma nearly all accounted for as calcium ions and calcium bound with protein, an equilibrium existing between the two forms. The parathyroids appear of prime importance in regulating the calcium content of the blood. The mechanism of this action is not clear.

Vitamin D improves the utilization of calcium for calcification and other purposes. There is convincing evidence that vitamin D promotes calcium absorption; there is also some evidence that it may act on the calcification process itself. The mechanism of vitamin D action is obscure. Any relation between vitamin D and parathyroid action is, at most, indirect. The action of vitamin D in calcium metabolism is discussed further in Chapter 35. Since calcium salts within the intestinal tract are more soluble at acid reaction than in neutral or alkaline solution, absorption of calcium is promoted by high gastric acidities, by acid-containing diets in general, and by diets containing lactose which lead to lactic acid fermentation in the intestines. Amino acid products of protein digestion may promote the absorption of calcium, possibly by the formation of soluble complexes. Other as yet unknown factors may also be concerned.

We are also much in the dark as to the nature of the calcification process as it occurs in bones and teeth. It appears to depend upon an adequate inorganic phosphate concentration of the blood plasma as well as upon the  $\text{Ca}^{++}$  of the plasma, and these are maintained through a balance between absorption from the intestines and excretion by the intestines and the kidneys. One view is that we have a simple chemical or physicochemical equilibrium between blood and bone, the blood being commonly supersaturated with respect to calcium phosphate and carbonate, with cartilage possessing a certain selective action. Another view is that calcification involves an active chemical process in the bone cells, such as the liberation of inorganic phosphate from organic phosphates through the action of phosphatase. The subject of calcification is discussed further in Chapter 9.

**Calcium Requirement.** The recommendation of the National Research Council is 0.8 g. per day for adults. There is a rather wide zone of calcium intakes over which different individuals can maintain or approximate equilibrium; adaptation to lower intakes has also been demonstrated. The question has even been raised whether or not the adult human male requires dietary calcium.<sup>6</sup> Sherman found 16 per cent of American dietaries to fall below 0.45 g. The growing child requires considerably more calcium than the adult. Similarly increased amounts are needed by women during pregnancy and lactation. Otherwise a negative balance for calcium may result and the drain upon the calcium of the bones of the mother becomes excessive. Because of the large store of calcium in the bones the adult does not suffer so soon from calcium deprivation as the child. A lactating cow may lose as much as 20 per cent of its total supply of calcium without seriously interfering with milk

---

<sup>6</sup> Hegsted, Moscoso, and Callazos: *J. Nutrition*, **46**, 181 (1952).

production. In the growing child, however, any interference with the calcium supply leads to impaired calcification of the bones, as in rickets, as well as to slower growth of the body in general. It must be borne in mind that the child at birth is calcium-poor, i.e., the bones are incompletely calcified. The greater flexibility of the bones facilitates delivery, but the need of the newborn for calcium is necessarily more critical on this account.

Milk is of supreme importance in maintaining a proper calcium level in the diet. Every child should receive along with other foods a quart of milk (containing about 1.1 g. calcium) each day. Milk is recommended in supplying calcium, because of its high content of calcium, the available form in which this is present (utilization about 30 per cent) and because milk has otherwise a high nutritive value. Milk contains about 120 mg. of calcium per 100 g., cottage cheese contains about 100 mg. Of other foods, eggs are useful, containing 70 mg. per cent, mainly in the yolk; as are also green vegetables, cabbage or lettuce supplying about 45 mg. per cent of calcium. Some green vegetables, like spinach, though high in calcium, are not so satisfactory, since much of their calcium exists as oxalate and is not readily utilized by the body. In certain foods, such as some cereals, the presence of phytic acid (inositol hexaphosphoric acid) impedes calcium and magnesium absorption, since this substance forms an insoluble compound with calcium and magnesium. This effect can be readily overcome by adding calcium carbonate to the diet, as for example by incorporation into bread. Bread has about 30 mg. per cent of calcium, and meat on the average about 10. The utilization of calcium is improved by vitamin D, an adequate supply of which should therefore be insured.

The subject of calcium excretion has been discussed in Chapter 28. Most of the excreted calcium is found in the feces. This fecal calcium presumably represents unabsorbed dietary calcium. There is an intestinal excretion of calcium which may amount to 0.5 g. or more per day; most if not all of this appears to be reabsorbed. The many factors which influence the absorption and excretion of calcium have led some to doubt the validity of calcium balance studies as an index to calcium requirement unless these various factors can be subjected to rigorous control.

The urinary output of calcium depends upon the nature of the diet but averages about 0.1 to 0.3 g. per day for normal adults.

## PHOSPHORUS

Since the greater part of the phosphorus of the body is associated with calcium in bone, the metabolism of these two elements is to a considerable extent parallel and follows that of the osseous tissues. Phosphorus, however, is abundant also in many of the softer tissues of the body and plays many important roles in life processes. Through the intermediary formation of lecithins it is concerned with fat metabolism. Through the formation of hexosephosphates, of adenylic acid, and of creatine phosphate, it plays a primary role in the carbohydrate metabolism of animals as well as in fermentation processes. Phosphates play a role in the neutrality regulation of the organism (see p. 818). They are concerned with the absorption of sugars from the intestine and the reabsorption of glucose in the

kidney tubules. Phosphorus is a constituent of the phospholipides present in all tissues and which are especially abundant in nervous tissues. It is present in nucleoproteins of the chromatin material of cells and in phosphoproteins such as casein. It has been suggested that most of the phosphorus, as well as the fat of milk, arises from the lecithin of the blood of the lactating animal.

Many studies of phosphorus metabolism have been made using radioactive phosphorus; this isotope also has some use in the treatment of disease (see p. 983). The important conclusions regarding phosphorus in its relation to bone and teeth formation which have resulted from the use of radioactive phosphorus have been presented in Chapter 9. For a further discussion of phosphorus in its relation to calcium metabolism and vitamin D, see Chapter 35.

**Phosphorus Requirement.** The National Research Council states that the daily phosphorus allowance for children and for women during pregnancy and lactation should be fully equal to the calcium allowance. The allowance for other adults should be 50 per cent higher than the calcium allowance (see Table, p. 1108). Four per cent of American dietaries have been found to fall below the minimum phosphorus requirement, the danger of deficiency being less than in the case of calcium, and yet a matter of some concern. The phosphorus content of the diet is most readily maintained at a proper level through the liberal use of milk, a quart of milk a day containing 0.88 g. of phosphorus being recommended for children. In addition to milk (93 mg. of phosphorus per 100 g.) good sources of phosphorus are meat (average 175 mg. per cent), eggs (180 mg.), cheddar cheese (610 mg.), nuts (400 mg.), whole cereals (as whole wheat, 375 mg.), while white flour and polished rice are much lower in phosphorus (about 90 mg.). The phosphorus in the bran of cereals (phytic acid) is utilized with some difficulty but, in general, the form of phosphorus in the diet is of little practical importance since in any case, as the result of the digestive processes, the phosphorus is absorbed in inorganic form. Too high a ratio of calcium to phosphorus in the diet, however, is unfavorable to phosphorus absorption. A diet high in beryllium or strontium also hinders phosphorus absorption and gives rise to a form of rickets.

## MAGNESIUM

Magnesium is an indispensable constituent of all living cells. The daily requirement for magnesium has been estimated to be about 0.43 g. for adults. Magnesium is present in such amount in plant foods and in meat that there is little possibility of the diet being inadequate with regard to this element.

About 71 per cent of the magnesium of the body is present in the bones. In muscle magnesium exceeds calcium in amount. In blood, where the reverse is true, the magnesium content is very constant. This is true also of the body as a whole, the concentration of magnesium remaining constant at about 0.045 per cent during growth, whereas calcium and phosphorus tend to increase in percentage. Excessive intake of magnesium gives rise to an increased excretion of calcium in the urine, and vice versa.

Like calcium, magnesium depresses nervous irritability, but to a greater

extent. A level of magnesium in the blood of 20 mg. per cent produces anesthesia, apparently by action on the central nervous system, whereas injections of calcium salts have a wakening effect. Magnesium ions are necessary for the action of many enzyme systems, particularly those concerned in carbohydrate and fat metabolism in muscle and other tissues. The mode of action of the magnesium ion in these instances is not known. Magnesium ions inhibit the activity of adenosinetriphosphatase, the enzyme which splits phosphate from ATP. It has been suggested that this may be related to magnesium anesthesia.

Diets extremely low in magnesium (1.8 parts per million) have been fed to young rats; under these conditions serum magnesium drops to 0.5 mg. per cent and there is marked vasodilation and hyperexcitability, leading to tetany and death. There is a rise of cholesterol of the blood and a corresponding decrease in free fatty acids, perhaps representing a disturbed metabolism of fat. There is also a marked decalcification of the skeleton which recalls the fact that grass tetany of cattle is associated with a low magnesium content of the blood.

Intestinal absorption of magnesium salts does not present a nutritional problem because of the relative solubility of the magnesium salts and their abundance in the diet. The excretion of magnesium has been discussed in Chapter 28. The action of magnesium sulfate in the duodenum in bringing about emptying of the gallbladder is employed in clinical diagnosis and therapy.

## IRON

Iron exists in the body chiefly in the heme portion of the hemoglobin of the red blood cells. It is also found, however, in plasma in combination with serum globulin and as an indispensable constituent of various oxidation-reduction enzymes essential for the life of cells in general. Among the heme-containing enzymes are catalase, peroxidase, the cytochromes and cytochrome oxidase, and probably others. The action of these enzymes is inhibited by cyanide, which apparently combines with the iron. Iron is also found in the liver in the form of a compound called ferritin. Ferritin is an iron-containing protein, the protein portion of which has a molecular weight of about 500,000, and the iron is considered to be present in the form of colloidal  $\text{Fe}(\text{OH})_3$  interspaced in the crystal lattice of the protein. The full significance of ferritin in nutrition remains to be elucidated.

Young animals (of all species so far studied) placed on a pure milk diet at the time of weaning develop a severe anemia. Addition of purified iron salts alone to the diet does not cure the condition, but does so if supplemented with very small amounts of copper salts. It is well established that the animal organism cannot convert the iron of the diet into hemoglobin unless very small amounts of copper are also present. There are a few instances in the literature where this has also been demonstrated in the case of human nutritional anemia. In the majority of human nutritional anemias, however, a copper deficiency does not exist and the anemia is due simply to iron deficiency. These nutritional anemias are not to be confused with the anemia of folic acid deficiency (see Chapter 35) or with pernicious anemia or other anemias due to increased blood destruction or disturbances of the blood-forming organs.

**Iron Requirement.** The recommended daily allowance of iron as given by the National Research Council is 12 mg. per day for adults (15 mg. per day in pregnancy), and 6 to 15 mg. per day for children, depending upon age. It has been estimated that for infants 0.5 mg. per kg. body weight per day is necessary to insure retention of iron. The form of the iron in the diet must also be considered. Anemia due to iron deficiency is not uncommon in women and preschool children. Hence general adequacy of this element in the diet cannot be assumed. Infants are born with a high level of hemoglobin iron and with an additional iron reserve in their livers which is later used for hemoglobin formation to supplement the low iron content of their milk diet. If continued beyond the normal lactation period such a diet leads to the development of a nutritional anemia. Children ordinarily require supplementary iron-containing foods by the time they are one year old. There is some evidence that the administration of iron to normal children and young adults, or increasing the iron intake above the usual levels by other means, will consistently produce a slight but significant (about 10 per cent) increase in the blood hemoglobin content.

Milk contains from 0.07 to 0.1 mg. iron per 100 g. This small amount of iron appears to exist in a readily assimilable form. Most foods appear to contain two forms of iron: heme iron which is not utilizable and nonheme forms which are available. Metallic iron or any of the ordinary iron salts may be used to supply iron. It has been shown<sup>7</sup> that under certain conditions ferrous compounds are somewhat better utilized than ferric compounds. Eggs contain 3 mg. iron per 100 g. of food, all of the iron being available. Lean muscle meats contain about the same amount, 50 per cent of which is available. Beef liver or heart contain about 8 mg. per cent of iron, about 60 per cent of which is available. Spinach contains about 3.6 mg. iron but like the iron of blood, alfalfa, and oysters this appears to be less than 25 per cent available. The minimum amount of iron which must be added to milk for maximum hemoglobin regeneration is said to be 0.0007 per cent.

The absorption and excretion of iron have been the object of much study. Relatively little is known about the mechanism of iron absorption, but it is known for example that the action of copper in promoting iron utilization is not related to iron absorption. There is some indication that the absorption of iron may be influenced by the state of the body iron stores. Studies with radioactive iron have shown that iron may be absorbed very rapidly, appearing in the red blood cells in about four hours. However it takes about a week for the complete conversion of absorbed iron into hemoglobin.

Very little iron is ever excreted. Only 1 to 3 mg. per day is found in the urine, with more in the feces, but this latter probably represents for the most part unabsorbed iron of the diet. Iron split off from the hemoglobin of the red cells after their destruction appears to be retained within the body and used over again. The chief need for iron appears to arise in infants on a milk diet, or in others after blood loss as by hemorrhage or during menstruation.

## COPPER

Although copper has long been known as a constituent of such compounds as the hemocyanin of the blood of certain lower organisms, the first demonstration that copper played a vital part in the animal organism was in connection with the conversion of dietary iron to hemoglobin, as described on p. 1092. Since that time, copper has been shown to be an essential component of certain enzymes such as tyrosinase and ascorbic acid oxidase, and a copper-containing protein (hemocuprein) has been isolated from animal blood. Animals placed on a copper-deficient diet soon lose weight and die, but death is not due to the concomitant anemia, since an equally intense anemia due to simple iron deficiency may be maintained for a long time. Thus copper is an essential element in the animal body, but the precise role still remains obscure.<sup>8</sup> Some studies have demonstrated that copper is associated with the activity of certain oxidation-reduction enzymes in tissues.

The amounts of copper required per day are extremely small; for an adult only about 1 to 2 mg., whereas a child requires only 0.05 mg. per kg. of body weight. The adult human body contains about 0.1 g. of copper. Copper appears generally to be present in the ordinary mixed diet in adequate amounts, so that the possibility of a copper deficiency is limited. Perhaps because of this fact, there have been relatively few demonstrations of copper deficiency in man.

## IODINE

The adult human body contains about 25 mg. iodine, about 15 mg. of which is in the thyroid. The daily allowance recommended by the National Research Council is about 0.003 mg. per kg. body weight. It is needed for the production of thyroxine and a deficiency leads to the condition of simple goiter. Ocean water is relatively rich in iodine, as is also the dust formed in the atmosphere from the drying of the salt spray, which dust is carried inland by the winds, where the rains dissolve it and carry it into the soil which thus becomes enriched with iodine. Where the distances from the sea are greater or mountain barriers intervene, this does not occur; at the same time iodine is being leached out of the soil, which thus becomes low in iodine. In such regions, including the Great Lakes region and the Alpine regions of Europe, the vegetable foods grown in the iodine-poor soil are poor in iodine, as is also the drinking water, and goiter is prevalent. In Japan goiter is very rare, in part because of the use in the diet of seaweed which is very high in iodine. Sea foods such as fish and oysters are rich in iodine. Good sources are also vegetables from sea coast districts. Fair amounts are also found in the fat of milk. In goiter regions, however, such foods should not be depended upon but should be supplemented with potassium iodide. A few drops of 10 per cent iodide solution given every two weeks would cover the requirement, since some storage of ingested iodine occurs. The most

---

<sup>8</sup> Glass: *Copper Metabolism*, Baltimore, Johns Hopkins University Press, 1950; Marston: *Physiol. Revs.*, **32**, 66 (1952).

satisfactory method for insuring an adequate intake of iodine without danger of overdosage is to use table salt to which has been added one part per 100,000 of iodine as sodium iodide. Such salt is widely sold. Care must be taken in the administration of iodine to persons with hyperactive thyroids. Studies with radioactive iodine indicate that this element is rapidly taken up from the blood by the thyroid gland, with significant differences in this respect between normal, hyperthyroid, and hypothyroid individuals (see also p. 983). Iodides also appear to be selectively concentrated and excreted by the salivary glands in man.

Variations in the iodine content of the blood show a relation to thyroid disease, but the results obtained are somewhat irregular. The normal range of serum iodine content is from 5 to 12  $\mu\text{g.}$  per 100 ml. About 85 per cent of the serum iodine is bound to proteins, chiefly albumin. This constitutes the *protein-bound* iodine of the serum, the concentration of which is of diagnostic value regarding the level of thyroid function.<sup>9</sup> The normal level of serum protein-bound iodine is from 4 to 8  $\mu\text{g.}$  per cent. A thyroid hyperplasia has been produced in rabbits by feeding cabbage. Various synthetic compounds are known, such as thiouracil and thiourea (see pp. 771–2) which exert a specific depressing effect on thyroid secretion and have proved useful in the treatment of thyroid disease.

## SULFUR

Strictly speaking the metabolism of sulfur does not come under the head of inorganic metabolism, since only an insignificant part of the sulfur ingested is in inorganic form, by far the greatest proportion being combined in protein molecules as the amino acids cystine and methionine. Proteins of foods vary in sulfur content from 0.4 to 1.6 per cent, with an average of about 1 per cent. The sulfur-containing amino acids and their metabolism are discussed in Chapter 33.

The end product of sulfur metabolism is taurine or sulfuric acid; the latter is either immediately neutralized and excreted as inorganic sulfate in the urine or may be first conjugated with phenol, glucuronic acid, or indoxyl. On the average, about 1.0 g. sulfur is excreted daily in the urine.

Certain sulfur compounds have important biological interest, e.g., thiocyanate in saliva and other fluids, taurocholic acid in bile, ergothioneine of the blood corpuscles, and glutathione present in all cells and concerned with oxidation processes. These substances are discussed elsewhere in this book, as are also the properties and metabolism of the sulfur-containing amino acids and the various forms of urinary sulfur.

## MANGANESE

There is considerable evidence that manganese in small amounts is a dietary essential. Rats placed on a manganese-deficient diet show a retardation of growth and reproductive failure in both male and female. The arginase activity of the liver of the manganese-deficient rat is lower than normal; *in vitro* addition of manganese ions restores the enzymatic ac-

---

<sup>9</sup> Salter, Bassett, and Sappington: *Am. J. Med. Sci.*, **202**, 527 (1941).

tivity. Other isolated enzyme systems are known to be activated by manganese ions in small amount. In the case of the growing chick, a manganese deficiency is associated with the development of perosis (bone malformation). Studies with radioactive manganese indicate that the chief channel of excretion is through the liver into the bile. It has been suggested that the daily diet of children should provide from 0.2 to 0.3 mg. manganese per kg. of body weight.

## OTHER ELEMENTS

**Fluorine.** Fluorine is found widely distributed in animal and plant tissues, in very small concentration. When added to the diet in small amount, it is excreted in proportion to the intake. Individuals on a normal diet containing no added fluorine excrete about 0.3 to 0.5 mg. per day; this presumably represents the amount ordinarily present in the diet. In certain parts of the world the soil contains sufficient soluble fluoride so that the drinking water, and food grown on the soil, contain enhanced amounts of fluorine relative to other localities. Individuals living in such communities are prone to develop "mottled enamel" (dental fluorosis), an unsightly condition of the teeth. At the same time, the incidence of dental caries in these communities is in general much lower than elsewhere. The concentration of fluorine in water claimed to be effective in the prevention of caries, approximately 1 p.p.m., is said to be below the level which will cause dental fluorosis. A fluorine level of 6 p.p.m. apparently has no harmful effects on the bones. The fluoride ion in significant concentration (0.01 M) is an enzymatic poison for tissues, and fluoride salts are used commercially as ingredients of animal poisons. (For a further discussion of fluorine, see Chapter 9.)

**Cobalt.** Cobalt is present in plant and animal tissues in small amount, and there is conclusive evidence that it is an essential element in animal nutrition. It is present in vitamin B<sub>12</sub> (see p. 1209). Certain diseases of cattle and sheep have been attributed to a cobalt deficiency, and respond to cobalt therapy. In cattle, cobalt dietary deficiency is accompanied by a microcytic hypochromic anemia, rapid loss of weight, absence of estrus, abortion, and low milk yield. In the case of sheep disease the cobalt is effective orally but not when injected. It has been shown that cobalt increases the synthesis of vitamins B<sub>6</sub> and B<sub>12</sub> in the rumen of sheep. The administration of cobalt salts to rats and rabbits produces a marked polycythemia; the reason is not known. Studies with radioactive cobalt indicate that absorption and elimination take place rapidly, with the kidney the main channel of excretion.

**Zinc.** There is definite evidence that zinc is an essential element in animal nutrition. Rats on a diet low in zinc show a marked delay in intestinal absorption and a retarded growth rate. Zinc is a constituent of highly purified carbonic anhydrase, the enzyme important in the formation and decomposition of carbonic acid (see pp. 362 and 685). The zinc content of carbonic anhydrase is about 0.2 to 0.3 per cent, i.e., very similar to the iron content of hemoglobin (0.34 per cent). Zinc is also a constituent of crystalline (but not of amorphous) insulin. Whether zinc plays any significant role in connection with the action of insulin or carbonic anhydrase

is not known, nor has any specific function been ascribed to zinc in animal nutrition. However, zinc is said to enhance the action of the follicle-stimulating hormone (FSH) and of the luteinizing hormone (LH) of the anterior pituitary.

**Trace Elements.** Various other elements found in traces in biological material are of uncertain significance. Aluminum has a wide distribution in animals and plants but is not known to be essential, nor does any aluminum added to food during cooking in aluminum utensils have any demonstrable effect on nutrition. However, it has been demonstrated<sup>10</sup> that female albino rats fed biscuits made with a tartrate baking powder gave evidence of a distinct nutritional advantage over rats from the same litter which were fed biscuits made with an alum baking powder. This advantage was apparent from the standpoint of reproduction as well as from that of growth.

Boron is essential for plants but apparently has no significance in animal nutrition. The position of arsenic as a trace element is debatable. Silicon is found in plant and animal tissues but its function is unknown. Bromine has no normal or pathological significance aside from its known pharmacological effects. Selenium may be taken up by plants and thus become transferred to animals where it has a toxic effect which is counteracted by methionine. Molybdenum is an essential component of the enzyme xanthine oxidase.

**Acid-forming and Base-forming Foods.** Certain foods, such as vegetables and fruits, on burning outside or inside the body leave an ash or residue in which the basic elements (sodium, potassium, calcium, and magnesium) predominate; whereas cereals, meat, and fish foods leave an ash in which the acid-forming elements (chlorine, phosphorus, and sulfur) predominate. Such foods are spoken of as base-forming and acid-forming foods, respectively, and will influence the acid-base balance of the body and the acidity of the urine. Sulfur, while present in foods chiefly in neutral form in the sulfurized amino acids, is oxidized in the body to yield sulfuric acid and is hence an acid-forming element. High-protein foods are hence generally acid-forming. On the other hand, the citrus fruits contain citric acid and acid potassium citrate, the citrate radicals of which are completely metabolized in the body like carbohydrate, leaving behind potassium, which is one of the bases of the body (see p. 1084). Hence many "acid" fruits are base-forming. Grape juice is much less effective than orange juice in reducing urine acidity because the tartaric acid it contains is not completely oxidized but is eliminated to a certain extent in the urine as such. Prunes, plums, and cranberries contain quinic acid. This is excreted in the urine chiefly in the form of hippuric acid (a conjugate of benzoic acid and glycine) which increases the acidity of the urine. With the exception of foods containing incompletely oxidizable organic acids, the acid-forming or base-forming value of foods may be calculated by obtaining the differences between the equivalents of normal acid, calculated from the content of sulfur, chlorine, and phosphorus (considering

---

<sup>10</sup> Hawk, *et al.*: Unpublished. For abstract see Philip B. Hawk and Collaborators: *Researches and Writings*. Published privately, 1942.

phosphoric acid as divalent) and of normal alkali calculated from the content of sodium, potassium, calcium, and magnesium. A table of the acid- or base-forming value of various foods will be found in Appendix IV.

Through the use of considerable amounts of potatoes or other vegetables or of fruits such as oranges, it is possible to lower the acidity of the urine markedly or even to make it alkaline. Naturally reduction in the amount of acid-forming foods has a similar tendency. Increase of urinary acidity above the usual levels is less readily brought about. Reduction in the acidity of the urine by increasing the solubility of uric acid therein may reduce a tendency to formation of uric acid calculi in the urinary bladder. A certain balance between acid-forming and base-forming foods may be otherwise desirable, since too much acid-forming food might under certain circumstances be a drain upon the fixed base of the body. Fortunately, however, the body has ordinarily a marked ability to protect itself from excess acid formation, through ammonia production and in other ways. It is not clear, therefore, that a harmful effect is produced by a preponderance of acid-forming foods provided mineral, vitamin, and other dietary requirements are met.

## EXPERIMENTS ON INORGANIC METABOLISM

**1. Salt-free Diet.** The effect of a salt-deficient diet upon the metabolic processes is reflected in the composition of the urine as shown by the following experiment.

**Procedure.** Ingest an ordinary mixed diet containing an ample salt content for a period of two days. Follow this period by the ingestion of a diet which has had its salt content reduced to a very low value. Sugar and olive oil or nonsalted butter may supply the bulk of the calorific part of the diet and dialyzed egg white or casein or commercial protein preparations, e.g., plasmon, gluten, or glidine may supply the protein. Ingest such a diet for three days. (This is an acid-forming diet, p. 1097.) Collect the urine and analyze for chloride, titratable acidity, ammonia, and total nitrogen. Compare the data from the normal days with those obtained when the salt-free diet was ingested.

**2. Salt-rich Diet.** On an ordinary mixed diet a normal adult will daily excrete 10–15 g. of chloride, expressed as sodium chloride, in the urine. On a salt-free diet this excretion decreases, whereas if the diet contains an excessive quantity of sodium chloride this excess will be promptly excreted in the urine. Normal feces contain very little sodium chloride even after excessive sodium chloride ingestion (see Exp. 3, below).

**Experiment.** Ingest an ordinary mixed diet for two days. On each of the following two days take a similar diet plus a weighed amount (e.g., 10 g.) of sodium chloride in divided doses. Collect the urine for the four days in 24-hr. samples, preserve and analyze for sodium chloride (for methods see p. 955). What proportion of the added chloride was recovered?

**3. Inorganic Elements in the Feces.** The salts of sodium and potassium are almost completely absorbed from the intestine. Hence the alkali metals and chlorides are excreted mainly in the urine and are found only in very small amounts in the feces even when large amounts are ingested. With calcium, magnesium, iron, and phosphate, conditions are different. Ordinarily about 90 per cent of ingested calcium and

over half of the magnesium are eliminated by way of the feces. From 20 to 30 per cent of the phosphorus ingested is usually found in the feces.

**Experiments.** (a) Ingest for a period of three days an ordinary mixed diet without added salt and containing no milk. Separate the feces for the period (see p. 1046) and retain a portion of the well-mixed feces for analysis.

(b) Proceed as above with the exception that there is added to the mixed diet 10 g. of common salt and a quart of milk (containing about 1.1 g. Ca, 0.1 g. Mg, 1.4 g. chloride expressed as sodium chloride, and 1.0 g. P). Mix the feces well and reserve part for analysis.

Ash 10 g. samples of the feces from the above diets. Dissolve with the aid of a little dilute nitric acid, filter, and make up to 100 ml. Determine in aliquot portions of this solution: (1) Chlorides. (2) Calcium and magnesium. (3) Phosphorus. (For details of analytical methods see Chapter 31.) Calculate the percentages of the added Ca, Mg, P, and Cl which are recovered from the feces.

For a more detailed study of chloride excretion combine this experiment and Exp. 2, above.

4. "*Alkaline Tide.*" For a time after a meal the normal acid reaction of the urine may be changed to neutral or alkaline. This has been explained as due to the production of a temporary alkalosis because of the secretion of the acid gastric juice. The presence of an alkaline tide has been used as an indication of the secretion of hydrochloric acid in the stomach in cases where it was desirable to avoid passing the stomach tube. The urinary ammonia excretion may also serve a similar purpose.

**Experiment.** Ingest an ordinary mixed diet. Urinate just before dinner and note the reaction of the urine to litmus. If acid, determine the hydrogen-ion concentration by the method given on p. 871. (If alkaline, discard the urine and make the test on another day.) After eating a heavy dinner (meats) collect the urine at intervals of half an hour and take the reaction to litmus and determine the hydrogen-ion concentration as before. Did your urine change in reaction after the meal and if so how long a period elapsed between the meal and the occurrence of the maximum change in reaction?

5. *Hydrogen-ion Concentration of the Urine as Influenced by the Ingestion of Acid-forming and Base-forming Foods.* It has been demonstrated that vegetables and fruits, on burning, leave an ash in which the basic elements (sodium, potassium, calcium, and magnesium) predominate, whereas cereals, meats, and fish foods leave an ash in which the acid-forming elements (chlorine, sulfur, and phosphorus) predominate.

The acid- or base-forming potentialities of various foods are given in the Appendix. Potatoes, oranges, raisins, apples, bananas, and cantaloupes are important base-forming foods. Among the most important acid-forming foods are found rice, whole-wheat bread, oatmeal, meats, and eggs. Certain fruits, e.g., cranberries, prunes, and plums, yield a basic ash but are acid-forming foods. For further discussion see p. 1097.

On a mixed diet the hydrogen-ion concentration of the urine has been found to average about pH 6.0. Base-forming foods decrease the acidity and the ammonia content of the urine, while acid-forming foods have the reverse effect.

**Experiment.** Ingest a uniform diet consisting of milk, crackers, butter, peanut butter, and water in desired quantities for a period of three days. Follow this by a period of six days during the first three of which considerable quantities of acid-forming foods (see Appendix) are added to the diet. During the

second half of the period (days four to six) add an abundance of base-forming foods to the diet. Distilled water should be used for drinking purposes and a uniform volume should be ingested daily. Collect the urine in 24-hour periods, preserve, and analyze for hydrogen-ion concentration, titratable acidity, and ammonia (for methods see Chapter 31). Compare your results with those tabulated in the table below.

REACTION OF URINE AS INFLUENCED BY DIET<sup>11</sup>

| Determi-<br>nation                   | Basal<br>Diet <sup>12</sup> |           | 1                                                    | 2                                       | 3                                                         | 4                                                            | 5                                             | 6                                                          |

**6. Hydrogen-ion Concentration of the Urine as Influenced by Alkali Ingestion.** The ingestion of certain organic salts of the alkalies, e.g., sodium citrate and sodium bicarbonate, causes an increase in the pH of the urine. The ingestion of acids (either organic or inorganic) or acid salts, e.g. sodium dihydrogen phosphate, decreases the pH of the urine. The alkalies are much more effective in producing changes in reaction than are the acids. The influence of ingested alkali (sodium bicarbonate) is shown in the table on p. 1101 containing data submitted by Henderson and Palmer.

Blatherwick reported a decrease in ammonia nitrogen output from 0.256 g. to 0.072 g., and accompanying decreased acidity under the influence of bicarbonate ingestion (25 g. in two days).

**Experiments: Influence of Alkali.** Ingest a uniform diet consisting of milk, crackers, butter, peanut butter, and distilled water for a period of two days. During the next two days take the same diet and ingest 24 g. of sodium bicarbonate between meals (12 in A.M. and 12 in P.M.). Collect the urine in 24-hr.

<sup>11</sup> Tabulated from data reported by Blatherwick (*Arch. Int. Med.*, 14, 409 (1914)). Experiments all made on the same subject (B).  
<sup>12</sup> Basal diet No. 1 contained 100 g. graham crackers, 25 g. butter, 400 ml. whole milk ingested at each of the three daily meals. One apple and one soft-boiled egg added at supper. In diet No. 2 whole-wheat crackers were substituted for the graham crackers.  
<sup>13</sup> This day was preceded by NaHCO<sub>3</sub> ingestion for three days and by rice ingestion for four days.  
<sup>14</sup> This diet followed immediately after the diet of prunes (see 5).

INFLUENCE OF INGESTED SODIUM BICARBONATE ON HYDROGEN-ION

periods and analyze it for titratable acidity, hydrogen-ion concentration, and ammonia. Compare your results with those shown in table above.

If desired, the bicarbonate may be given in one dose of 8 to 12 g. and the urine collected in hourly specimens for the next 5 hours and each specimen analyzed. Data from such experiments are shown in table above.

**7. Influence of Calcium Deficiency.** A demonstration of the harmful effect following the elimination of calcium from the diet may readily be made if the diets listed below be fed to young white rats.

**Procedure.** Place two young white rats (40–60 g.) in separate cages and feed the diets given in the following table. Make frequent body-weight determinations. The rat receiving Diet 2 will show normal growth. The rat receiving Diet 1 will fail to show normal gains in weight. This diet is deficient in calcium. See Figs. 269 and 270.

|                                     | Diet 1   | Diet 2   |
|-------------------------------------|----------|----------|
|                                     | Per Cent | Per Cent |
| Beef liver (steamed and dried)..... | 20.0     | 20.0     |
| Casein.....                         | 10.0     | 10.0     |
| NaCl.....                           | 1.0      | 1.0      |
| KCl.....                            | 1.0      | 1.0      |
| CaCO <sub>3</sub> .....             | 0.0      | 1.5      |
| Dextrin or starch.....              | 65.0     | 63.5     |
| Butter fat.....                     | 3.0      | 3.0      |

**8. Influence of Ultraviolet Radiation on Inorganic Metabolism.** Ultraviolet radiation has calcium-depositing properties. See p. 1248.

**Procedure.** Place three young white rats (litter mates) weighing 50–60 g., in individual cages, and supply ad lib. a rachitogenic diet such as described in Chapter 35. Keep the rats in a dark or dimly lit room, but subject one to an hour's exposure to direct sunlight at about noon each day, and expose another to 1 minute's irradiation at a distance of 2 feet from an ultraviolet lamp. After 4 weeks examine the leg bones roentgenographically or by the line test (see p. 1265), and perform bone ash analyses on the dried, fat-free bones.

FIG. 269. GROWTH CURVE OF RAT WITH AND WITHOUT CALCIUM AND PHOSPHORUS IN THE DIET.

Unpublished data from the senior author's laboratory.

FIG. 270. SKELETONS OF TWIN ALBINO RATS SHOWING INFLUENCE OF CALCIUM DEFICIENCY.

Courtesy, Sherman and MacLeod: *J. Biol. Chem.*, 64, 429 (1925).

**9. Influence of Iron and Copper Deficiency.**<sup>15</sup> The anemia caused by the ingestion of milk as the sole article of diet may be cured by the addition of an iron (and copper) supplement.

**Procedure.** Place three young white rats (litter mates) on a milk diet and perform hemoglobin determinations weekly on blood obtained by clipping off the tips of the tails. After the hemoglobin has dropped to half its original value, feed one rat a daily supplement of 0.25 mg. of Fe (as ferric chloride) and another rat 0.25 mg. of Fe (as ferric chloride) and 0.05 mg. of Cu (as copper sulfate). Continue the third animal on the original milk diet without Fe or Cu supplement. Continue weekly determinations and compare the condition of the three animals, noting especially the color of the tails, ears, and eyes.

## Vitamins and Deficiency Diseases<sup>1</sup>

In 1881 Lunin, a pupil of Bunge, recognized that a diet consisting only of purified protein, carbohydrate, fat, and minerals would not sustain life. When such diets were supplemented with certain natural foods, notably milk, normal growth and well-being of the experimental animals were restored. These findings were in accord with earlier demonstrations of the curative value of citrus fruit juices in scurvy, a disease contracted by sailors, soldiers, prisoners, and others who subsisted on limited fare. They also coincided with observations by the Dutch physician Eijkmann in 1897 that beriberi or polyneuritis, a disease resulting from the prolonged consumption of polished rice, could be cured by supplementing the diet with rice polishings or extracts thereof. These and similar studies suggesting the presence of indispensable substances in natural foods were brought to a head by Hopkins (1912) who called them "accessory food factors." The work of Osborne and Mendel and of McCollum (1913) established beyond doubt the presence of these factors in milk. Funk (1912) introduced the term *vitamine* in the belief that he had isolated one of these factors and established that it possessed the properties of an amine. The final *e* has since been dropped inasmuch as these substances as a class are not related to amines.

A vitamin is a potent organic compound, occurring in minute proportions in natural foods, which must be available to the animal organism from the diet or other sources in order that a specific metabolic process or reaction may proceed normally. The "other sources" referred to in this definition are, for example, ultraviolet irradiation of precursors of vitamin D in the skin or bacterial synthesis of certain vitamins of the B group in the intestinal tract. Unlike amino acids, vitamins do not enter into the tissue structure. Vitamins are exogenous, hormones endogenous. Compounds which may be vitamins for some species may be synthesized by others and hence behave, in effect, as hormones.

With the rapid advancement of our knowledge of the chemical constitution of the vitamins, it is not surprising that structurally related chemical derivatives, both natural and synthetic, should be discovered which exhibit typical physiological activity, though perhaps in varying degree. For these, the term *vitamers* has been suggested. Naturally occurring

---

<sup>1</sup> The rapid strides being made in this field require that special attention be paid to the date of publication of material on this subject. Important books and review articles on the general subject of vitamins are cited in the Bibliography at the end of this chapter.

vitamin D exists in various chemical forms; and what was previously regarded as vitamin A in plant sources is now known to consist of various carotenoids, principally  $\beta$ -carotene, which function as precursors of the vitamin. Hence a distinction should be made between *vitamin activity*, which indicates certain specific biological properties, and the *vitamins per se*, which refer to definite chemical entities, of which there may be several exhibiting similar biological activity.

Some vitamins are characterized by species specificity; i.e., they are required by certain species of animals and not by others. For example, vitamin C is necessary in the diet of man, guinea pigs, and monkeys, but dogs, rats, and other species are able to synthesize it. Hence for these species vitamin C may be regarded as a hormone. To a certain extent the physiological requirement of various species of animals for vitamins may be met by bacterial synthesis in the rumen or intestinal tract. This process, however, does not signify that these species do not require the nutrient in question.

The vitamins are recognized biologically by their absence rather than by their presence; that is, the characteristic symptoms of each vitamin deficiency must be produced in order that the effect of the vitamin in question can be demonstrated. In addition to (and probably secondary to) their role in the prevention of specific deficiency symptoms, each of the vitamins participates to a greater or less degree in the promotion of growth. Our knowledge of the physiological *modus operandi* of the known vitamins is not far advanced. It is known, however, that most of the vitamins participate in enzymic reactions of a highly complex nature. Vitamins may be precursors of enzymes, as thiamine is of cocarboxylase or niacin of coenzymes I and II; or they may be substrates, as vitamin A is of rhodopsin.

The condition induced by the absence of a single vitamin from the diet is called an *avitaminosis*, e.g., avitaminosis B<sub>1</sub>; if the deficiency is multiple, the term *polyavitaminosis* is applied. Many observations, particularly on the effect of deficiency or dosage of one vitamin on the storage or excretion of another, suggest the need for balanced proportions of certain dietary essentials. Until more is known about the specific mechanism of the action of individual vitamins, however, it will be difficult to establish the significance of such interrelationships.

The present list of vitamins cannot be regarded as complete, but it is probable that from the standpoint of human nutrition all the major vitamins have been identified. The table on p. 1106 summarizes the common names of the vitamins, and their principle *vitamers*—i.e., structurally related compounds possessing qualitatively similar activity. Some question has been raised as to the justification for including choline or inositol among vitamins, since such compounds are present in the foods in more than trace quantities. Nevertheless, they do not form a material part of body tissue, and functionally they conform to the definition of vitamins stated above.

Concurrent with the advances in isolation and identification of the vitamins, chemical and physical analytical procedures have been evolved for determining the content of almost every vitamin. More recently,

## SUMMARY OF PRINCIPAL COMPOUNDS WHICH POSSESS VITAMIN ACTIVITY

| <i>Vitamin</i>         |                                                                                 | <i>Principal Vitamers</i>                                                                                                      |                                                                                                                                       |

RECOMMENDED DAILY DIETARY ALLOWANCES<sup>2</sup>  
REVISED 1953

DESIGNED FOR THE MAINTENANCE OF GOOD NUTRITION OF HEALTHY PERSONS IN THE U.S. WHEN CONSUMED IN VARIED DIETS OF COMMON FOODS. ALLOWANCES ARE CONSIDERED TO APPLY TO PERSONS NORMALLY VIGOROUS AND LIVING IN TEMPERATE CLIMATE

*Food and Nutrition Board, National Research Council*

*Fat.* While a requirement for certain unsaturated fatty acids (the linoleic and arachidonic acids of natural fats) has been amply demonstrated with experimental animals, the human need for these fatty acids is not known. . . . Several factors make it desirable (a) that fat be included in the diet to the extent of at least 20 to 25 per cent of the total calories, and (b) that the fat intake include essential unsaturated fatty acids to the extent of at least 1 per cent of the total calories. At higher levels of energy expenditure, e.g., for a very active person consuming 4500 calories and for children and adolescent persons, it is desirable that 30 to 35 per cent of the total calories be derived from fat.

*Water.* An ordinary standard for diverse persons is 1 ml. for each calorie of food. . . . At work or in hot weather, requirements may reach 5 to 13 liters daily. Water should be allowed *ad libitum*, since sensations of thirst usually serve as adequate guides to intake except for infants and sick persons.

*Sodium Chloride.* Average intake of sodium chloride (salt) for the normal adult is 7 to 15 g. daily. . . . The requirement for sodium chloride is increased by environmental and climatic conditions associated with increased sweating. Under unusual conditions, such as doing heavy work in a hot climate, 10 to 15 g. daily, or even more, may be required with meals and in drinking water. However, after acclimatization to heat the sodium content of sweat is greatly reduced and the allowance for salt can be near to normal.

*Phosphorus.* Phosphorus allowances should be at least equal to those for calcium in the diets of children and of women during the latter part of pregnancy and during lactation. For other adults the phosphorus allowances should be approximately 1.5 times those for calcium. When the calories are obtained largely from cereals, computation of the total phosphorus intake may be misleading because phytin phosphorus may be poorly utilized unless the supply of vitamin D is adequate.

*Copper.* The requirement for copper for adults is about 1 to 2 mg. daily. Infants and children require approximately 0.05 mg. for each kg. of body weight. The requirement for copper is approximately one-tenth that for iron.

*Iodine.* The requirement for iodine is small, probably about 0.002 to 0.004 mg. daily for each kg. of body weight, or a total of 0.15 to 0.30 mg. daily for the adult. . . . Especially important in *adolescence* and *pregnancy*.

*Vitamin B<sub>6</sub> Group.* Vitamin B<sub>6</sub> is essential for human nutrition. . . . The daily intake should approximate about 2 mg.

*Folic acid.* It seems probable that dietary intakes of the order of less than a mg. per day can be expected to cover any nutritional needs for folic acid activity.

*Biotin.* Intestinal synthesis of this vitamin is extensive and tends to prevent the development of deficiency. . . . Biotin is needed by the human body and cannot be synthesized metabolically.

*Pantothenic Acid.* The amount of pantothenic acid consumed daily with 2500 calories of good diet is approximately 10 mg.

*Vitamin K.* Available evidence warrants increased attention to the vitamin K intake of the mother during the latter part of pregnancy. . . . A daily oral dose of 1 mg. should be satisfactory. . . . A suitable amount for the mother preceding delivery is 1 mg. administered parenterally; this amount will stabilize the prothrombin level of the infant until food is taken. A suitable amount for the infant after birth is 1 mg. for a single dose. In fact it has been shown that a single dose of 10 to 20  $\mu$ g. is adequate to cover the first 5 days. The daily requirement of the infant is approximately 1  $\mu$ g.

<sup>2</sup> In planning practical dietaries, the recommended allowances can be attained with a variety of common foods also providing other nutrient requirements less well known; the allowance levels are considered to cover individual variations among normal persons as they live in the United States subjected to ordinary environmental stresses common thereto. [For a proper understanding of the foundations underlying this Table of Recommended Daily Allowances, reference should be made to the original source.]

<sup>3</sup> These calorie recommendations apply to the degree of activity for the reference man and woman described in the original text. For the urban "white-collar" worker they are probably excessive. In any case, the calorie allowance must be adjusted to the actual needs of the individual as indicated by his weight and height. [Adjustment for environmental temperature should also be made.]

<sup>4</sup> The recommendations for infants pertain to nutrients derived primarily from cow's milk or commercial milk preparations. There should be no question that human milk is the most desirable source of nutrients for infants, although expected intakes may not provide the recommended levels of certain nutrients; e.g., protein, calcium, and riboflavin.

microbiological procedures have been developed (particularly for the vitamins of the B group) based on the propagation of various bacteria, yeasts, or molds in special media in which one of these vitamins is the limiting factor.

The conditions employed in the nonbiological assay procedures, especially in the preliminary extraction or hydrolysis of the samples, are of course not necessarily equivalent to the conditions to which such foods may be subjected in the gastrointestinal tract. Therefore vitamin *content* as determined by chemical analysis may not always coincide with vitamin *potency* as measured by feeding tests. Correlation of animal assays of foods with nonbiological assays suggests that the full content of vitamins is usually, but not always, biologically active under the experimental conditions employed. The assessment of vitamins in foods in terms of their physiological availability for man is a field of investigation which needs more intensive exploration.

It is important when using tables of the distribution of vitamins in foods, such as that presented in Appendix III, to bear in mind that most of these data are based on assays for total vitamin content rather than for available vitamin content in the physiological sense. For example, in tables spinach, whose "vitamin A" is due to the activity of carotenes, or butterfat, whose "vitamin A" is due to a mixture of carotenes and preformed vitamin A, are usually presumed to have been evaluated biologically; and whenever possible the interpretation of nonbiological assays is made in the light of existing animal-assay data.

When referring to food-composition tables it must be recognized that uniformity is the exception rather than the rule. Such factors as soil, climate, season, varietal differences, and period of harvesting (which affect plant foods) or composition of the feed, age at slaughter, and duration of lactation (which affect animal foods), as well as storage, transportation, processing, "refining," and culinary losses, account for a several-fold range of variation in the vitamin content of natural foods. Hence the values given in tables must be regarded as indicative of expected orders of magnitude rather than absolute vitamin contents.

Under the provisions of the Food, Drug and Cosmetic Act, the Food and Drug Administration established standards of minimum daily requirement for certain of the major vitamins (and minerals) to serve as a basis for proper labeling of foods intended for special dietary uses. These values are presented as a guide to the interpretation of such labeling but are not to be confused with the table of recommended daily allowances prepared by the Food and Nutrition Board of the National Research Council reproduced in its latest (1953) revision on p. 1108. The latter is intended to furnish "desirable goals toward which to strive in planning diets and food supplies." It provides for variations in requirements due to sex, age, activity, and the physiological demands of pregnancy and lactation. Individual needs may deviate significantly from these allowances owing to differences in body weight, glandular activity, gastrointestinal disturbances, and many other conditioning factors.

The term "major vitamins" is sometimes applied to thiamine, riboflavin, niacin, ascorbic acid, and vitamins A and D, for which fairly reliable knowledge exists as to human requirements; it is generally be-

lieved that if diets are devised to supply adequate amounts of these vitamins, sufficient quantities of all other vitamins (somewhat presumptuously called "minor") will be present. This view is questionable and merely reflects current ignorance as to the essentiality and quantitative requirements for such vitamins which, it is hoped, future research will correct.

Whether a given food, as prepared for consumption, is a poor, fair, good, or excellent source of the vitamins or of other dietary essentials must be judged by the size of the usual portion and the frequency with which it is consumed. The Council on Foods of the American Medical Association<sup>5</sup> tentatively adopted the following standards for determining the significance of a source of a dietary essential:

1. In general, when one-tenth of the day's requirement for an average man is furnished in a portion which can be easily eaten in one day, the food may be regarded as a "fair" source.

2. When one-tenth of the day's requirement is contributed by an amount of the food which at the same time furnishes not more than 200 calories, the food may be classed as a "good" source.

3. When one-tenth of the day's requirement is furnished by a food which appears in the diet practically every day, and in which the portion contributing one-tenth of the essential furnishes not more than 100 calories, the food may be classed as "excellent."

4. When a food is not one which can be easily eaten in amounts to furnish one-tenth of the day's requirement, or is one eaten infrequently, or both, and the amount required for one-tenth of the day's allowance of the essential furnishes more than 200 calories, the food is a negligible or poor source.

## VITAMIN A

**Physiological and Clinical Aspects of Vitamin A.** Vitamin A was first recognized by the failure of rats to grow on diets lacking in natural fats and oils. At about the time of cessation of growth the eyes become hemorrhagic, keratinized, and later infected. This condition, known as xerophthalmia, is associated specifically with deficiency of vitamin A, hence the name *antiophthalmic* (or *antixerophthalmic*) vitamin (Fig. 271). Interruption of growth (Fig. 272) and lowered resistance to bacterial infection are secondary results of a specific disturbance in the metabolism of epithelial membranes resulting from vitamin A deficiency. This is deduced from the fact that keratinization is observed in the sublingual and submaxillary glands, and in the respiratory, alimentary, and genito-urinary tracts, as well as in the cornea and conjunctiva. Similar involvement of the oral and pharyngeal mucosa is responsible, at least in part, for the diminution of food consumption and consequent loss in weight. The formation of urinary and renal calculi observed after vitamin A depletion is probably also a sequel to the metaplastic changes in the epithelial membranes. Similar alterations in mucosal epithelium are followed by bacterial invasion and consequent infections of the sinuses, middle ear, and other areas. However, vitamin A has no specific or immunologic value in the treatment of the common cold. A form of dryness of the skin (xerosis) and a follicular hyperkeratosis (phrynoderma) are among the

symptoms of avitaminosis A found in man as well as in animals. A variety of skin diseases characterized by these symptoms have responded to vitamin A therapy (see p. 1290). Suggestions have been made to name vitamin A “anti-infective”<sup>6</sup> or “antikeratinic,”<sup>7</sup> but these terms have not been adopted because their implications are too broad. Inanition accompanying severe vitamin A depletion may contribute in no small degree to the lowered resistance to bacterial invasion. The primary specific effect of lack of vitamin A, however, is the “substitution of stratified keratinizing epithelium for normal epithelium in various parts of the respiratory tract, alimentary tract, eyes and paraocular glands, and the genito-urinary tract” (Wolbach).

There is evidence that lack of vitamin A may produce degenerative changes in the myelin sheath. Since the lack of vitamin A interferes with the process of ovulation, an adequate dietary supply of this vitamin is necessary for normal fertility. It has been demonstrated in rats that a liberal allowance of this vitamin is conducive to longevity.

In addition to its role in maintaining the normal epithelium of the eye and paraocular glands, vitamin A plays a critical part in the process of vision. The characteristic pigments of the retinal rods and cones are conjugated carotenoid proteins known respectively as rhodopsin and iodopsin. According to Wald<sup>8</sup> they differ only in respect to their opsin or protein moieties (called scotopsin and photopsin, respectively). The specific carotenoid common to both is a *cis* isomer of retinene. The range and degree of sensitivity of the rods to light (scotopic vision) is determined by the absorption spectrum of rhodopsin, whereas that of the cones (photopic vision) is determined by the absorption spectrum of iodopsin.

The chemical changes in the visual cycle involving rhodopsin are shown in the following diagram.

In the pigment epithelium of the rods a *cis* isomer of vitamin A alcohol is oxidized to the corresponding vitamin A aldehyde, retinene. This reaction is reversible and is mediated by alcohol dehydrogenase in the presence of cozymase (DPN). The protein opsin, acting as an aldehyde trapping agent, combines stoichiometrically and spontaneously with retinene in the dark to form rhodopsin or visual purple. This is the basis of

dark adaptation. Light induces a series of photochemical changes in rhodopsin, beginning with bleaching of the purple pigment on the release of the visual impulse, and ending with the formation of all-*trans*-retinene and its isomerization. For each molecule of retinene formed two sulfhydryl groups are liberated, and in the reverse reaction two free HS groups are provided by opsin.

The resynthesis of rhodopsin is isomer-specific, requiring a *cis* isomer of retinene (probably 3-*cis* or neoretinene B) for the formation of which the corresponding *cis* isomer of vitamin A is withdrawn from the circulation. Equilibrium reactions involving the isomerization of *trans*-retinene or vitamin A to *cis* forms take place elsewhere in the body, probably in the liver.

The reversible synthesis of rhodopsin has been reproduced *in vitro* by Hubbard and Wald<sup>9</sup> using the four-component system vitamin A (natural or *cis* isomers), cozymase, alcohol dehydrogenase, and opsin.

Since some vitamin A is lost in the visual cycle, deficiency of the vitamin results in a diminution of visual acuity, i.e., the ability to see in subdued light. This condition is known as nyctalopia<sup>10</sup> or night blindness and is the earliest sign of vitamin A deficiency in man, though it may result from other causes. Dark adaptation is the term applied to the adjustment of the visual threshold to darkness after exposure of the eyes to light. Quantitative measurement of the visual threshold—i.e., the light intensity required to elicit a visual sensation—is made by photometric instruments which measure the rate of restoration of visual acuity following stimulation by a light source of standard intensity.<sup>11</sup>

Severe outbreaks of vitamin A deficiency in humans are rare and of limited geographic distribution. The incidence of ophthalmia is relatively high for example in China, Labrador, and India. An acute epidemic among Danish children during World War I was attributed to the substitution of margarine for butter, which was largely exported. The fortification of margarine with vitamin A is now a common practice in most countries where it is sold.

Twenty to 25 units of vitamin A per kg. body weight suffice to maintain a normal visual threshold in most species studied. This amount will also maintain the normal estrus cycle in the rat, although storage in the liver does not occur until approximately four times this level is reached. Liberal allowances of vitamin A, among other factors, tend toward optimum, as distinguished from adequate, nutrition (see p. 1074). In experiments on the rat, Sherman and his associates have shown that by feeding several times the dose of vitamin A sufficient to prevent deficiency symptoms, the reproductive period of females as well as the longevity of both sexes could be prolonged.

The efficiency of absorption of vitamin A in different species is influenced by the nature and quantity of the diluent and by the state of the

\* Butler: *Commercial Fisheries Rev.*, April 1946, p. 13.

vitamin, i.e., whether carotene, preformed, free, or esterified.<sup>11a</sup> The recommended daily allowances of vitamin A for various sex and age groups are incorporated in the table on p. 1108. These values are based on a consensus obtained under the sponsorship of the National Research Council. An outline of the clinical symptoms of vitamin A deficiency is given in the American Medical Association syllabus on p. 1290.

**Storage of Vitamin A.** When young animals, previously fed a diet containing vitamin A, are deprived of this vitamin, they continue to grow

<sup>11a</sup> Week and Sevigne: *J. Nutrition*, **39**, 233, 251 (1949); **40**, 563 (1950).

for a period dependent upon the amount of vitamin A which they have stored. The storage capacity for this vitamin is relatively greater in young animals, i.e., at the age of most rapid growth. The vitamin is stored principally in ester form in the liver and kidneys and to some extent in the lungs. At high levels of intake, rats store more vitamin A in the liver than in the kidneys, but at low intake levels the reverse is true. Liver storage is the basis of a bioassay for vitamin A.

**Distribution of Vitamin A.**<sup>12</sup> Preformed vitamin A occurs only in lipides of animal origin, whereas carotenoid precursors occur in the vegetable kingdom, where they are synthesized. The fat of milk may contain both carotenoids and vitamin A in variable proportions, depending on the animal's ration and the extent of conversion of the former into the latter. The chief natural foods of vitamin A value are butterfat (hence milk, cream, cheese, etc.), egg yolk, liver, and pigmented and leafy vegetables (e.g., carrots, tomatoes, pimientos, spinach, lettuce, alfalfa). Vegetable oils as a class are deficient in vitamin A although red palm oil may contain as much as 0.2 per cent of carotenoids. The liver oils of certain species of fish including the shark (notably the soupfin species), swordfish, halibut, mackerel, etc., are extremely high in vitamin A, some oils being several hundred times as rich as codliver oil, one of the earliest known and most abundant sources of both vitamins A and D. There are great variations within species due to storage with age, sex and reproductive phase, marine nutrition, temperature, etc. Natural fish-liver oils are refined or concentrated and blended to standard potencies for therapeutic or food use.

Certain unicellular marine organisms are able to synthesize vitamin A. These provide food for marine plankton, which are consumed by caplin and other small fish, which in turn are consumed by the larger species. The vitamin is also present to a smaller extent in the visceral and body oils of the cod, salmon, and certain other fish.

In the plant world vitamin A activity, being due to carotenoids, is closely associated with pigmentation; the green outer leaves of lettuce are richer than the white center leaves, green tips of asparagus are richer than "bleached" tips, sweet potatoes are richer than white potatoes, yellow corn than white, palm oil (red) than coconut oil. The milk of cows on green pasturage is higher in vitamin A than is the milk of stall-fed animals. No direct quantitative relationship exists between the color of butter or of fish liver oils and vitamin A potency since in animal fats such activity is due principally to the colorless preformed vitamin. (Commercial butter is often artificially colored.) The yellow pigment carotene possesses the physiological activity of vitamin A by virtue of its conversion into the vitamin in the intestinal wall. Hence carotene, or rather certain carotenoids, are provitamins or precursors of vitamin A. In addition to the carotene isomers (see below) other carotenoids which possess vitamin A activity in animals are cryptoxanthin of yellow corn and paprika, myxoxanthin and aphanin of algae.

The synthesis of provitamins A in plants has been shown to be accelerated by light radiations especially of short wavelength, although the

---

<sup>12</sup> For vitamin A values of foods, see Appendix III.

ultimate amount of vitamin formed is not increased. There is no evidence that the animal body can produce vitamin A *de novo*, except in the case of the pigeon.<sup>13</sup> Although synthesis of carotenes seems to parallel chlorophyll formation, the latter pigment does not possess vitamin activity.

The rate of intestinal absorption of vitamin A and its precursors varies in different species of animals and is influenced by the nature and content of fat in the diet. Excessive quantities of mineral oil inhibit absorption. The efficiency of converting carotenoids into vitamin A likewise varies with the particular compound as well as with the species; in general, rodents are most efficient, pigs and cattle less, and cats least, while the relative capacity of the human infant or adult in this respect remains to be determined.

**Chemistry of Vitamin A.**  $\beta$ -Carotene has been shown by Kuhn and Karrer to have the following structural formula:

In the animal organism cleavage occurs at the central double bond with the formation of the alcohol, vitamin A.

<sup>13</sup> Kon and Drummond: *Biochem. J.*, **21**, 632 (1927).

Hunter and Williams<sup>14</sup> claim to have effected this conversion by oxidation with hydrogen peroxide to give vitamin A aldehyde, and subsequent reduction to the alcohol. In the liver and other storage depots of the animal organism vitamin A exists in the form of fatty acid esters. The palmitate and acetate are produced commercially from either natural or synthetic sources.

It will be noted that the  $\beta$ -carotene molecule is symmetrical, containing two  $\beta$ -ionone rings, designated  $\beta^1$  and  $\beta^2$  respectively, bridged by a chain of four isoprene ( $\text{CH}_2=\text{C}(\text{CH}_3)-\text{CH}=\text{CH}_2$ ) units. The  $\alpha$  and  $\gamma$  isomers differ

in respect to the configuration of only one of the rings, the molecular formula of all of these isomers being  $\text{C}_{40}\text{H}_{56}$ . In place of the rings indicated above for  $\beta$ -carotene, certain other carotenoids differ only in respect to the rings as shown in the following tabulation.

|                                                                          | $\beta^1$ ring | $\beta^2$ ring |

At least one intact  $\beta$ -ionone ring is essential for vitamin A activity, since isomers or derivatives in which the only change is in both rings (e.g.,

<sup>14</sup> Hunter and Williams: *J. Chem. Soc.*, 554 (1945); Hunter: *Nature*, 158, 257 (1946).

lycopene or xanthophyll) are inactive. The conjugated double bonds in the side chain (or in the carotenoid bridge) make possible a large number of *cis-trans* isomers.<sup>15</sup> However not all of these stereoisomers exist in nature or have been produced synthetically, owing to steric hindrances. Twenty *cis-trans* isomers of  $\beta$ -carotene are possible and even larger numbers in the case of the asymmetrical compounds like  $\alpha$ - or  $\gamma$ -carotene. The stereoisomers are differentiated by their spectral-absorption characteristics in both the visible and ultraviolet wavelengths and by their chromatographic adsorption affinities.

It has been postulated that because of steric interference, only two of the four double bonds in the side chain of vitamin A assume *cis-trans* configuration, yielding four stereoisomeric forms, viz. all-*trans*-, 3-*cis*-, 5-*cis*-, and 3,5-di-*cis*-vitamin A. The isomers found in liver oils are principally all-*trans* (Fig. 273) associated with a *cis*-isomer (probably 5-*cis*) which has been crystallized<sup>16</sup> and designated "neovitamin A" (Fig. 274). Despite the functional differences between these isomers in the visual cycle (see p. 1113) the growth-promoting activity of neovitamin A for the rat appears to be approximately 80 per cent of that of crystalline all-*trans*-vitamin A.<sup>17</sup>

The approximate vitamin A activity for rats of certain important natural carotenoids relative to  $\beta$ -carotene is as follows:

|                                              |     |
|----------------------------------------------|-----|
| $\beta$ -Carotene (all- <i>trans</i> )       | 100 |
| $\alpha$ -Carotene (all- <i>trans</i> )      | 53  |
| $\gamma$ -Carotene (all- <i>trans</i> )      | 27  |
| Cryptoxanthin (all- <i>trans</i> )           | 57  |
| Neo- $\beta$ -carotene U (mono- <i>cis</i> ) | 38  |
| Neo- $\beta$ -carotene B (di- <i>cis</i> )   | 53  |
| Lycopene                                     | 0   |
| Xanthophyll                                  | 0   |

$\beta$ -Carotene is approximately twice as potent biologically as its naturally occurring isomers. It was believed that fission of the carotenoid molecules occurs at the central double bond yielding two molecules of vitamin A; there is evidence, however, that asymmetrical breakdown to the active  $\beta$ -ionone fragment of the molecule can also occur.

Since intestinal absorption, stability, and efficiency of conversion affect the biological activity of carotenoids, the estimation of vitamin A potency of plant foods from the relative content and activity of the individual pigments is not always reliable.

The previous international standard of vitamin A activity,  $\beta$ -carotene, has been replaced by crystalline vitamin A acetate. The International or USP unit is now defined as 0.30  $\mu$ g. of vitamin A alcohol, equivalent to 0.344  $\mu$ g. of the acetate. For the estimation of carotene the former standard has been retained; 0.6  $\mu$ g. of pure  $\beta$ -carotene is considered to have the

activity of one unit of vitamin A. It has been found however that the "crude carotene" of many plant foods (i.e., the pigment in the petroleum ether extract which absorbs light at 420 m $\mu$ ) has a vitamin A activity of about 1 USP unit per  $\mu$ g.

Vitamin A alcohol forms pale yellow crystals melting at 63–64° C. when deposited from ethyl formate solution or at 7–8° C. when methyl alcohol is the solvent. It forms esters but is not precipitated by digitonin, providing a means of separation from cholesterol which likewise occurs in the nonsaponifiable fraction of animal fats. The vitamin is distillable *in vacuo*, thus forming the basis for a process of concentration from fish liver oils; viz., Hickman's method of molecular distillation. Vitamin A forms colored compounds with certain condensing agents, one of which, antimony trichloride, produces an evanescent blue color (Carr-Price reaction) of sufficient intensity to afford a measure of its concentration. This color absorbs light maximally at 620 m $\mu$ , in contrast with the more stable greenish-blue color produced with carotene, which shows an absorption maximum at 590 m $\mu$ . For the analysis of foods or animal tissue containing both factors, the SbCl<sub>3</sub> reaction necessitates either correction for the differences in rate of color development and fading, or preferably, preliminary separation of the carotenes from preformed vitamin A.

Vitamin A is characterized by an absorption band in the ultraviolet with a maximum at 328 m $\mu$ . This forms the basis of the spectrophotometric method of estimating (preformed) vitamin A content.

In the absence of air, vitamin A is quite stable at high temperatures, but when exposed to air or oxygen it is readily destroyed. Aeration of cod-liver oil for 12 hours at 100° C. oxidizes the vitamin A, leaving the anti-rachitic potency unimpaired. Vitamin A appears to be more resistant to oxidation in its natural environment, probably because of the presence of protective antioxidants such as tocopherols, phospholipides, and possibly other agents. Certain phenolic substances, like hydroquinone and pyrogallol, are even more effective antioxidants, but their use is not permitted on toxicological grounds. Light, especially in the ultraviolet range, exerts a destructive influence upon vitamin A; hence the practice of dispensing fish liver oils in dark bottles and of conducting analytical operations in amber or red glassware.

### DETERMINATION OF VITAMIN A

In estimating vitamin A in natural products a distinction must be drawn between vitamin content and vitamin potency. Vitamin A activity is derived principally from the physiologically available amounts of preformed vitamin A, which may be present as free alcohol or as esters, and of the carotenoids, which vary in their individual potencies. Furthermore activity is influenced by the nature and content of fat in the diet and by the physical state of the carrier; for example, fine dispersions of vitamin A in aqueous media are absorbed more rapidly than is the vitamin in oily media.

Because of this distinction between vitamin A content, in the chemical sense, and biological activity of true vitamin A and related compounds, the bioassay continues to play an important function, especially in the

evaluation of foods whose vitamin activity is of multiple origin. In products whose vitamin A activity is derived from less complex sources, such as the crystalline alcohol or its esters, high-potency fish liver oils or  $\beta$ -carotene preparations, it is only necessary to establish correlation between values for vitamin content obtained by physical or chemical methods and the bioassay values to justify the use of the nonbiological procedures. Because of the small size of sample available, the analysis of blood and tissues for vitamin A is limited to the nonbiological methods.

## CHEMICAL METHODS

### Colorimetric Methods for Preformed Vitamin A and Provitamin

**A.** The carotenes are determined colorimetrically preferably after isolation by saponification, extraction, adsorption, and elution. Prediction of biological potency from the content of carotenoids is complicated by their individual differences in activity and absorbability. Chromatographic separation of the carotenoids and their identification and estimation from spectrophotometric absorption data afford a more accurate but involved basis for estimating the vitamin A activity of plant carotenoids.

Various color reactions have been proposed for the estimation of preformed vitamin A, especially in liver oils.<sup>18</sup> The most widely used reaction is that of Carr and Price.<sup>19</sup> When a solution of antimony trichloride in chloroform is added to a dilute solution of a vitamin A-bearing oil, a blue color appears which soon reaches a maximum intensity and then rapidly fades or changes to reddish-brown or other colors, varying with the individual oils. Under carefully controlled conditions the blue color persists long enough to make accurate readings possible. Glycerol 1,3-dichlorohydrin activated by distillation over antimony trichloride is also used as a colorimetric reagent for vitamin A, greater color stability being claimed for the reaction product.<sup>20</sup>

**Antimony Trichloride (Carr-Price) Reaction:** Into a dry test tube introduce 0.2 ml. of a 20 per cent solution of codliver oil in chloroform.<sup>21</sup> Add rapidly 2 ml. of a saturated solution of antimony trichloride in chloroform. Observe the color changes.

**Determination of Carotene (Provitamin A).**  $\beta$ -Carotene occurs in certain plant sources (e.g., carrots, alfalfa) relatively free from other carotenoids such as cryptoxanthin or lycopene. In these cases it may be determined by methods involving selective solvent extraction (phasic separation). Mixtures of hexane and acetone, methanol, or diacetone alcohol are widely used, since they permit partition of the carotenes from xanthophyll, chlorophyll, or other inactive pigments. When present

---

<sup>18</sup> These have been reviewed by Fisher and Bailey: *J. Assoc. Official Agr. Chem.*, **13**, 352 (1930); Bacharach and Smith: *Analyst*, **59**, 70 (1934), and others.

<sup>19</sup> Carr and Price: *Biochem. J.*, **20**, 497 (1926).

<sup>20</sup> Sobel and Werbin: *J. Biol. Chem.*, **159**, 681 (1945); *Ind. Eng. Chem., Anal. Ed.*, **18**, 570 (1946); *Anal. Chem.*, **19**, 107 (1947). Applications of this reagent to the determination of vitamin A in serum and milk have also been reported. Sobel and Snow: *J. Biol. Chem.*, **171**, 617 (1947); Sobel and Rosenberg: *Anal. Chem.*, **21**, 1540 (1949).

<sup>21</sup> The chloroform should be washed two or three times with its own volume of water, dried over anhydrous  $\text{Na}_2\text{SO}_4$ , decanted and distilled, and the first 10 per cent of the distillate rejected. During these processes the chloroform should be protected from light.

with other carotenoids,  $\beta$ -carotene is preferably separated by chromatography of a hexane solution.

**Extraction.** In the case of animal or dairy products containing fat, saponification and extraction is necessary. For this purpose the isolation of the unsaponifiable extract as described for vitamin A on p.1124 may be employed, but the residue after evaporating the ethyl ether should be taken up in an appropriate volume of hexane. Dried plant products or feed mixtures may simply be extracted for one hour under reflux with a mixture of acetone and hexane (3 + 7), using about 30 ml. per 2 g. of sample. After cooling, the extract is filtered through anhydrous sodium sulfate into a 100-ml. volumetric flask and made up to volume with hexane rinsings.

Other extraction methods have been described for special cases, e.g., those requiring cold extraction to avoid isomerization.<sup>22</sup>

**Chromatography.** In view of the predominance of  $\beta$ -carotene in most animal tissues or foods intended for human use, the method to be described, which actually measures total or "crude" carotenes, will generally be found satisfactory. For procedures effecting more complete resolution of the carotenes and their isomers the reader is referred to the literature.<sup>23</sup>

Insert a chromatographic adsorption tube (22 × 175 mm.) into a suction flask and plug the outlet orifice with a bit of glass wool. Introduce a mixture of equal parts of activated magnesia<sup>24</sup> and Hyflo Supercel<sup>25</sup> to a depth of 15 cm. with the aid of suction and a flat-surfaced tamping device; gently press the adsorbent down to a depth of 10 cm. Cover with a 1-cm. layer of anhydrous sodium sulfate.

Under continuous suction pour the extract into the adsorption column. (Always keep the top of the column covered with a layer of solvent.) Follow through with 50 ml. of acetone-hexane (1 + 9) to develop the chromatogram. Collect the eluate, which contains all the carotene, leaving the xanthophylls, chlorophyll, and oxidation products in the column. Transfer the partially evaporated eluate to a 100 ml. volumetric flask and make up to volume with acetone-hexane.

**Spectrophotometry.** The solution should have an absorbancy corresponding to 1–4  $\mu$ g. of carotene per ml. Read the optical density in a spectrophotometer at 436 m $\mu$ . Convert to "total carotenes" by means of a calibration chart prepared from graded concentrations of a standard solution of crystalline  $\beta$ -carotene;<sup>26</sup> or calculate from the following equation:

$$\frac{(-\log T) \times v \times 100}{196 \times L \times C} = \text{mg. carotene per 100 g. sample}$$

where  $(-\log T)$  is the optical density,  $v$  the final volume of eluate (100 ml.),  $L$  the cell depth in cm., and  $C$  the weight of the original sample.

<sup>22</sup> Beadle and Zscheile: *J. Biol. Chem.*, **144**, 21 (1942); Zechmeister and Polgar: *J. Am. Chem. Soc.*, **64**, 1856 (1942).

<sup>23</sup> Bickoff, *et al.*: *J. Assoc. Official Agr. Chemists*, **31**, 633 (1948); **32**, 766 (1949). These authors employ hydrated lime as an adsorbent to separate the carotene isomers.

<sup>24</sup> Micron Brand No. 2642, Westvaco Chlorine Products Co., Newark, Col.

<sup>25</sup> Johns-Manville Co., Chicago, Ill.

<sup>26</sup> The International Standard obtainable from USP Reference Standards, 46 Park Ave., N.Y. 16. Pure  $\beta$ -carotene or a mixture (90 per cent  $\beta$ , 10 per cent  $\alpha$ ) as supplied by General Biochemicals, Inc., Chagrin Falls, Ohio, may be used.  $\beta$ -carotene may be purified as follows: Dissolve 100 mg.  $\beta$ -carotene in 2 ml. chloroform, and reprecipitate with 20 ml. methanol. Filter, wash with a few drops of methanol, and dry in a vacuum desiccator.

**Determination of Preformed Vitamin A (Colorimetric Method of Oser, Melnick, and Pader):**<sup>27</sup> **Principle.** The blue color produced when vitamin A reacts with antimony trichloride in chloroform solution is measured photometrically. An internal standard (increment) is included to compensate for the effect of inhibitors or accelerators on the color development.

**Procedure: Preparation of the Unsaponifiable Fraction.** Perform all operations in amber glassware. Into an Erlenmeyer flask transfer a weighed sample, containing preferably at least 50 USP units of vitamin A. The sample may be weighed by difference from a weighing bottle furnished with a rod and stopper. Saponify by refluxing on a boiling water bath for 0.5 hr. with freshly prepared 0.5 N alcoholic potassium hydroxide, using 15 ml. for each gram of sample solids. Cool, and transfer to a separatory funnel, adding an equal volume of water as a wash. Extract four times with 75 ml. of freshly redistilled ether, and discard the aqueous phase. Wash the combined ether extracts once with 50 ml. of water, once with 25 ml. of 0.5 N aqueous potassium hydroxide, and then with 50-ml. portions of water till the last washing gives no color with phenolphthalein. Dry the ether extract with anhydrous sodium sulfate and evaporate to dryness on a water bath, removing the last few milliliters at room temperature with a stream of nitrogen. Dissolve the residue immediately in sufficient purified<sup>28</sup> chloroform to produce a concentration of from 5 to 15 USP units of vitamin A per ml. A turbid chloroform solution may be clarified with anhydrous sodium sulfate.

**Colorimetric Procedure.** A direct-reading photoelectric colorimeter with a 620-m $\mu$  filter is used for the measurements. Set the instrument at 100 per cent transmittance with a solution containing 1 ml. of chloroform and 9 ml. of antimony trichloride reagent.<sup>29</sup> To another tube add 1 ml. of the test solution and 9 ml. of chloroform, and read (*A*). To a tube containing 1 ml. of chloroform extract of the sample, add 9 ml. of antimony trichloride reagent rapidly from a blow-out pipet and measure the maximal blue color as indicated by the full swing of the galvanometer usually attained within 4 seconds (*B*). To another tube containing a 1 ml. aliquot of the test solution, with a micropipet add 0.1 ml. of a vitamin A standard<sup>30</sup> containing 10 USP units (or 3  $\mu$ g.) of vitamin A followed by 9 ml. of the antimony trichloride reagent. Measure the maximal color (*C*).

**CALCULATIONS.** Convert galvanometer readings, *G*, expressed in per cent transmittance, to photometric densities, *P.D.*, as follows:

$$P.D. = 2 - \log G$$

Then,

$$\frac{B - A}{1.01C - B} \times 10 \text{ USP units (or 3 } \mu\text{g.)} \times \text{dilution factor} \\ = \text{USP units (or } \mu\text{g.) of vitamin A per g. of sample.}$$

<sup>27</sup> Oser, Melnick, and Pader: *Ind. Eng. Chem., Anal. Ed.*, 15, 724 (1943); Oser, Melnick, Pader, Roth, and Oser; *ibid.*, 17, 559 (1945).

<sup>28</sup> Wash reagent grade chloroform three times with an equal volume of water and dry over anhydrous sodium sulfate. Redistil on the day used.

<sup>29</sup> A 25 per cent solution of antimony trichloride in dry chloroform. Filter if solution is turbid.

<sup>30</sup> The USP Reference Standard Solution of crystalline vitamin A acetate may be employed as the standard: the results are expressed in terms of vitamin A alcohol.

**Spectrophotometric Method.**<sup>31</sup> Since vitamin A is characterized by selective absorption in the ultraviolet, the intensity of absorption at the maximum (Fig. 275) serves as a measure of vitamin A content. Inasmuch as this region of the spectrum is beyond the visible range, spectrophotometric equipment is necessary. Adaptations of this method have been particularly useful in the assay of fish liver oils where the vitamin A

FIG. 275. ADVANTAGE OF PLOTTING EXTINCTION RATIOS RATHER THAN EXTINCTION COEFFICIENTS IN PRESENTING ULTRAVIOLET-ABSORPTION CURVES OF VITAMIN A SOLUTIONS.

1. Vitamin A acetate in ethyl laurate. 2. Oxidation of (1) by air. 3. Dilution of (1) 1:5 with ethyl laurate.

activity is due entirely to the vitamin *per se*. Greater accuracy is obtainable by the removal of interfering substances present in the saponifiable fraction, particularly in oils containing less than 15,000 units of vitamin A per gram.

The method involves the comparison of the absorption of ultraviolet radiation through the test solution containing vitamin A, with that absorbed by the solvent alone. Results are usually expressed in terms of the extinction coefficient<sup>32</sup> derived as follows:

$$E_{1\text{cm.}}^{1\%} = \frac{1}{cd} \log_{10} \frac{I}{T}$$

in which  $E_{1\text{cm.}}^{1\%}$  is the extinction coefficient,  $c$  is the concentration (in per cent),  $d$  the thickness of the cell (in cm.), and  $I$  and  $T$  the intensity of the

<sup>31</sup> For treatments of this subject, see Chapter 23; also Morton: *The Application of Absorption Spectra to the Study of Vitamins, Hormones and Coenzymes*, 2d ed. London, Hilger, 1942; Chapter 4 in Wokes: *Applied Biochemistry*, Baltimore, Wm. Wood and Co. (The Williams & Wilkins Co.), 1937; and *U.S. Pharmacopeia XIV*, 1950, pp. 756-8.

<sup>32</sup> "Specific absorbancy" in the terminology of modern optical physics.

“incidental” and transmitted light, respectively. For a discussion of the derivation of this equation see p. 512 *et seq.*

To be valid as a basis for estimating vitamin A content, the absorption curve from which the extinction coefficient at the peak (325 m $\mu$ ) is taken should be characteristic of the pure vitamin A absorption curve. Irrelevant absorption due to oxidation products of the vitamin or to other inactive substances may be evidenced by distortion of the vitamin A curve. This is more readily recognized when the curve is plotted without regard to concentration of the vitamin, i.e., on the assumption that the extinction coefficient at the maximum is equal to unity. The value at any other wavelength thus becomes an extinction ratio, i.e., the ratio of the extinction coefficient at that wavelength to that at the maximum (Fig. 275).

The conversion of the extinction coefficient (or “*E* value,” as it has been abbreviated) to vitamin A units is effected by multiplying by a conversion factor derived from observed ratios of biological potency to *E* value in fish liver oils. In practice such conversion factors have been found to vary over a wide range in different laboratories, owing to differences in the oils themselves, as well as to the errors inherent in both the biological and instrumental methods employed. On the basis of improved analytical techniques as well as theoretical considerations, it is now commercial practice to regard the factor 1900 multiplied by the extinction coefficient at the maximum for the typical vitamin A curve as giving the best estimate of vitamin A unitage.

**Determination of Preformed Vitamin A (Spectrophotometric Method):**

**Principle.** Vitamin A may be determined by measurement of the extinction coefficient of the characteristic absorption band in the ultraviolet region of the spectrum, whose maximum is in the region 325–328 m $\mu$ .

**Procedure: Preparation of Unsaponifiable Extract.** Throughout the entire determination avoid exposure to actinic light preferably by using amber or red glassware. Into a saponification flask introduce a weighed sample containing 250–400 expected units of vitamin A (but not more than 1 g. fat or oil). Add 30 ml. ethanol and 3 ml. 50 per cent (w/w) potassium hydroxide and reflux in all-glass apparatus for 30 minutes. Cool, add 30 ml. water, transfer to separatory funnel and extract 4 times with 30-ml. portions of ethyl ether.<sup>33</sup> Collect the ether extracts in another separatory funnel and wash by gently swirling with 50 ml. water. Remove the aqueous layer and repeat washings with gradually more vigorous shaking until the aqueous layer is no longer alkaline to phenolphthalein. Evaporate the ether extract to about 50 ml. on a water bath, add 5–10 g. anhydrous sodium sulfate, stir and allow to settle. Decant into a 100-ml. volumetric flask and make up to 100 ml. with several ether rinsings of the sodium sulfate. (The final rinsing should give a negative antimony trichloride reaction.) Evaporate 10–25 ml. of the ether extract to about 2 ml. Remove from water bath and blow off remaining ether with a stream of nitrogen or *in vacuo*. Take up the residue in sufficient isopropanol (99 per cent purity) to give an expected concentration of 8–15 units of vitamin A per ml. (i.e., to show an absorbancy of 0.4–0.8 at 325 m $\mu$ ).

<sup>33</sup> Peroxide-free and redistilled; discard first and last 10 per cent.

**SPECTROPHOTOMETRIC DETERMINATION AND CALCULATION.** Using quartz cuvettes, read the absorbancy of the isopropanol solution at 310, 325, and 334  $m\mu$ . The median wavelength is the absorption maximum of pure vitamin A alcohol in isopropanol, whereas the higher and lower are the wavelengths at which the absorbancy is  $\frac{6}{7}$  (i.e., 0.857) of the maximum. The absorbancy ratios  $A_{310/325}$  and  $A_{334/325}$  are frequently found to deviate by more than 1 per cent from 0.857 due to the presence of non-vitamin-A-absorbing materials. Assuming that such irrelevant absorption is linear within narrow wavelength limits (e.g.,  $\frac{6}{7}$  above and below the peak) the correction procedure devised by Morton and Stubbs may be applied.<sup>34</sup> In simplified form<sup>35</sup> this has been adopted into official USP and AOAC vitamin A assays.

$$A \text{ (corrected)} = 7A_{325} - 2.625A_{310} - 4.375A_{334}$$

in which  $A$  is the absorbancy at the indicated wavelength.

$\frac{A(\text{corrected})}{LC} \times 5.7 = \mu\text{g. vitamin A (per g. or other sample unit)}$  in which  $L$  is the length of the absorption cell in cm., and  $C$  the fraction of the sample unit per ml. of solution read.

$$\mu\text{g. Vitamin A} \times 3.33 = \text{International (USP) units}$$

**Comment.** This method is applicable chiefly to fish liver oils where the vitamin is present in comparatively high concentrations. Though a more accurate value is obtained by conducting the determination on the unsaponifiable fraction, oils of high potency may often be assayed with little error by dissolving them directly in isopropanol. For the analysis of foods that have been enriched with vitamin A, a blank test of an unfortified sample or of a sample in which the vitamin A has been destroyed by selective ultraviolet irradiation<sup>36</sup> is advised.

Agreement between the basically unrelated spectrophotometric and colorimetric procedures may be regarded as highly presumptive of the accuracy of the nonbiological determination. In fact the official assays for vitamin-A-bearing materials in the U.S. Pharmacopeia and the Association of Official Agricultural Chemists specify that for the spectrophotometric assay to be valid the colorimetric test must agree within a ratio of 1.00 to 1.30.

**Determination of Vitamin A and Carotene in Blood Serum (Colorimetric Method of Dann and Evelyn):**<sup>37</sup> **Principle.** Vitamin A and carotene are extracted from serum with ethyl ether after saponification with alcoholic potassium hydroxide. Carotene is determined colorimetrically in the extract by photometric measurement of the light absorption of a chloroform solution at 440  $m\mu$ , and preformed vitamin A by measurement of the light absorption at 620  $m\mu$  of the blue color produced by reaction of the vitamin with antimony trichloride.

<sup>34</sup> Morton and Stubbs: *Biochem. J.*, **41**, 525 (1947); **42**, 195 (1948).

<sup>35</sup> Oser: *Anal. Chem.*, **21**, 529 (1949).

<sup>36</sup> Little: *Ind. Eng. Chem., Anal. Ed.*, **16**, 288 (1944).

<sup>37</sup> Dann and Evelyn: *Biochem J.*, **32**, 1008 (1938). Vitamin A may also be determined in plasma or serum by the following procedure which avoids saponification: Add to the plasma slowly, while shaking, an equal volume of 95 per cent ethanol followed by 2 volumes of petroleum ether (b. pt. 40–60° C.). Stopper tightly and shake for 10 minutes. Centrifuge one minute at low speed. Evaporate an aliquot of the petroleum ether layer on a water bath (40° C.) in a stream of  $N_2$  heating finally at 70° C. for a few seconds. The residue is taken up in ethanol-free chloroform for colorimetric determination. (Kimble: *J. Lab. Clin. Med.*, **24**, 1055 (1939); Yudkin: *Biochem. J.*, **35**, 551 (1941).)

**Procedure.** To 10 ml. of serum in a small flask add an equal volume of 95 per cent ethyl alcohol and 2 ml. of a 60 per cent aqueous solution of potassium hydroxide. Boil for 3 minutes. Pour the mixture into 10 ml. of water in a separatory funnel, and wash the flask with two 15-ml. portions of water, followed by two 25-ml. portions of ether, adding the washings to the separatory funnel. Shake the funnel vigorously for 1 minute, then allow the phases to separate. Discard the aqueous (lower) layer. Wash the ether phase by shaking vigorously with 10 ml. of water, then twice gently with 25 ml. of water. Filter the ether solution through a layer of anhydrous sodium sulfate on a sintered-glass filter. Wash the residue with 20 ml. of ether, combining the wash with the filtrate. With the aid of a stream of nitrogen, evaporate the ether solution to dryness on a hot water bath. Take up the residue in 10 ml. of chloroform in the absorption cell of a photoelectric colorimeter.

Measure the light absorption of the solution at 440  $m\mu$ , setting the instrument at 100 per cent transmittance with pure chloroform. Calibrate the instrument by measuring the absorption of standard solutions of C.P.  $\beta$ -carotene in chloroform containing 0.2, 0.4, 0.6, 0.9, 1.2, 1.5, 1.8, 2.1, 2.5, and 3.0  $\mu\text{g.}$  per ml. Plot photometric densities against concentrations of carotene. From the graph, determine the concentration of carotenoids per ml. in the chloroform extract of the unknown, and multiply this value by 100 to obtain the concentration per 100 ml. of serum.

Place the cell in a hot water bath and evaporate off the chloroform with the aid of a stream of nitrogen. The latter provides an inert atmosphere and prevents oxidation of vitamin A. Take up the residue in 1.7 ml. of chloroform. Place the cell in the photoelectric colorimeter equipped with a 620  $m\mu$  filter, set at 100 per cent transmittance with 10 ml. of a solution containing 1.7 ml. of chloroform and 8.3 ml. of antimony trichloride reagent (see p. 1124). Rapidly add 8.3 ml. of antimony trichloride reagent to the unknown and determine the maximal extinction. Calibrate the instrument by conducting the test on pure solutions of vitamin A in chloroform<sup>38</sup> containing 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 6.0, 8.0, and 10.0  $\mu\text{g.}$  per 1.7 ml.

**CALCULATION.** Plot photometric density against concentration of vitamin A per 1.7 ml. Determine the concentration in the chloroform extract of the unknown, and multiply this value by 10 to obtain the concentration of apparent vitamin A per 100 ml. of serum. This value must be corrected for the interference of carotenoids which react with antimony trichloride to produce a blue pigment. The color produced by 1  $\mu\text{g.}$  of preformed vitamin A is approximately equal to that of 20  $\mu\text{g.}$  of  $\beta$ -carotene. Determine the true concentration of vitamin A by means of the formula

$$A - \frac{C}{20} = \mu\text{g. vitamin A per 100 ml. of serum}$$

where  $A$  is the concentration of apparent vitamin A and  $C$  that of carotene, both expressed per 100 ml. of serum.

**Interpretation.** The normal vitamin A level for blood serum is 15 to 60  $\mu\text{g.}$  (approximately 50 to 200 USP units) per 100 ml. The principal carotenoids in blood serum are carotene and xanthophyll, which are present in a relatively fixed proportion.<sup>39</sup> Under these conditions, measurement of

<sup>38</sup> Crystalline vitamin A acetate as contained in the USP Reference Standard. This ester is more stable than the free alcohol. On a molar basis the acetate and the free alcohol have equal chromogenicity with antimony trichloride.

<sup>39</sup> Clausen and McCoord: *J. Pediatrics*, 13, 635 (1938).

total carotenoids, which is necessary for the determination of total vitamin A activity, would be a good practical index of carotene content. Chromatographic analysis, however, has demonstrated that the true carotene content varies from 10 to 50 per cent of the total carotenoid.<sup>40</sup> The normal total carotenoid range in blood serum is 100 to 300  $\mu\text{g}$ . expressed as  $\beta$ -carotene.

### BIOLOGICAL METHODS

Since no single chemical or physical method for estimating vitamin A activity is sufficiently specific for all compounds and mixtures possessing vitamin A activity, the biological assay remains fundamentally the most reliable means for determining vitamin A potency and is the basis against which the more precise nonbiological procedures must be evaluated. Many of the limitations of bioassays are removed when they are planned to measure not only the response of animals to dosage of the test material but to known dosage of some standard of reference. By balancing the distribution of test animals among assay and control groups with respect to strain, litter origin, sex, age, and body weight, and standardizing the environmental factors, diet, feeding, dosing conditions, etc., it is possible to reduce the error of biological assay to a minimum. The assay can be set up according to a statistical design to permit control of these variables, and also to provide a measure of the limits of precision of the estimate and the extent to which individual factors such as sex, litter, etc. contribute to the total variance. An essential feature of bioassays in which responses are quantitatively graded to dosage is that the slope of the dose:response curve (plotted logarithmically) must be reasonably parallel to that of the reference curve. Otherwise the standard and unknown preparations are likely to be qualitatively different; e.g., the unknown may be contaminated with a substance that is toxic or inhibits absorption. The effect of departure from parallelism may be measured in an assay designed to permit factorial analysis of variance.

The curative method for assaying vitamin A is based on depleting young rats of their reserves of this vitamin and determining the relative growth responses of groups of these animals receiving daily supplements of the test material or of the vitamin A standard. The basal diet fed throughout the depletion and assay periods should be complete with respect to all nutrients required by the rat except vitamin A. Serious error may be caused by failure to include in the basal vitamin-A-free diet a sufficient amount of vitamin E (tocopherol), since the responses of the animals may be influenced by differences in the antioxidant content of the assay and reference materials.

The U.S. Pharmacopeia<sup>41</sup> method for vitamin A is a "rat-curative" assay and is most generally employed for the evaluation of food and pharmaceutical products. As described, however, it is a minimal-potency assay (i.e., it provides for one assay and one reference group), and therefore permits only the statement that the assay material contains "less

---

<sup>40</sup> Wohl: *Dietotherapy, Clinical Application of Modern Nutrition*, Philadelphia, W. B. Saunders Co., 1945, p. 225.

<sup>41</sup> XIVth Revision.

than" or "not less than" the unitage of vitamin corresponding to the administered dosage level. The method may be adapted to quantitative estimation of actual potency by feeding two or more dosage levels of the assay material and a similar number of dosage levels of the standard of reference (USP Reference Vitamin A Standard). The dosage interval—i.e., the ratio of each dose to the next lower dose—is constant in both assay and reference groups. The resulting data may be computed according to the analysis of variance, as illustrated by the example in Appendix VI,<sup>42</sup> to give an estimate of potency, the standard error of this estimate, and, most important of all, an objective indication of whether the assay is a valid basis for such estimation.

Biological methods have been described for vitamin A based on prevention rather than cure of the deficiency in rats, on keratinization of vaginal epithelium (which occurs at about the twenty-third day of depletion in young rats), and on the colorimetric determination of the vitamin A stored in the livers after controlled feeding periods.<sup>43</sup> The latter procedure is less adaptable than the curative rat-growth method to quantitative study since it requires the administration of massive doses of the vitamin.

**The U.S. Pharmacopeia biological assays for vitamins A and D are given in full on pp. 1261 and 1264, respectively.**

### THE VITAMIN B COMPLEX

Since the vitamin concept was first postulated, the initial group of three vitamins has expanded to more than 20 by virtue of the discovery of the multiple nature of previously known vitamins or the recognition, from biological experiments, that as yet unknown nutrients must exist. Most outstanding in this regard has been the branching out of the vitamin B complex, a group of water-soluble factors usually associated in nature with thiamine (the original vitamin B), rich sources being liver, yeasts, and brans. The possibility that the "antiberiberi vitamine" of Funk (also known as the antineuritic factor or water-soluble B) might be a complex was suggested by the work of Emmett and Luros<sup>44</sup> on the basis of differences in susceptibility to heat destruction. Smith and Hendrick<sup>45</sup> showed that autoclaved yeast, in which the antineuritic vitamin was destroyed,

still possessed supplementary value for rats receiving adequate amounts of vitamin B from oats or in the form of a vitamin B picrate. Goldberger,<sup>46</sup> in 1926, recognized that rats required not only the antineuritic vitamin ("B *sensu stricto*") but also another factor which he called P-P (pellagra-preventive). In 1927 the Accessory Factors Committee of the British Medical Research Council recommended the symbols B<sub>1</sub> and B<sub>2</sub> for the heat-labile (antineuritic) and the heat-stable components, respectively. (For a time vitamin B<sub>2</sub> was called G in the United States.) The erroneous belief that the latter was identical with the pellagra-preventive factor was corrected when distinction was drawn between human pellagra and canine blacktongue, on the one hand, and so-called rat pellagra on the other. Between the time that Jansen and Donath,<sup>47</sup> in 1927, isolated the crystalline antiberiberi vitamin from rice bran and R. R. Williams<sup>48</sup> synthesized it and gave it the name *thiamine* in 1936, evidence accumulated for the increasing complexity of the vitamin B group.

Kuhn, György, and Wagner-Jauregg<sup>49</sup> isolated the fluorescent compound ovoflavin from egg white, designating it vitamin B<sub>2</sub>. Their demonstration that this biologically active substance and similar flavins from milk and liver (lactoflavin and hepatoflavin) were identical, containing a ribose group attached to an isoalloxazine ring, caused them to adopt the common name *riboflavin* for vitamin B<sub>2</sub>.

Evidence for the existence of additional growth and antidermatitis factors for rats, pigeons, and chicks prompted the continued search for new vitamins in the B group, which in the years since 1927 has culminated in the identification and synthesis of at least ten additional vitamins. From the standpoint of human nutrition, one of the most significant is *nicotinic acid* (now called *niacin*), which was identified by Elvehjem, Madden, Strong, and Woolley,<sup>50</sup> in 1937 as the canine blacktongue factor. This compound had been known for many years and was actually isolated from rice polishings by Funk<sup>51</sup> in his effort to isolate "vitamine B." The therapeutic trial of nicotinic acid in human pellagra was rewarded with prompt and dramatic success.

Clinical experience with beriberi or pellagra has emphasized that these diseases are often associated with deficiencies of other nutrients than thiamine or niacin alone. Therapeutic administration of individual crystalline vitamins often reveals the presence of underlying deficiencies which respond to supplementary dosage with other vitamins of the B group or with rich sources of the vitamin B complex such as yeast or liver. In this connection it is significant that the relative proportions of the various members of the vitamin B group as found in natural sources, both plant and animal, are quite variable; for example, seeds and legumes are relatively higher in thiamine than in riboflavin, whereas in milk and leafy

vegetables the reverse is true. Processing by heat, exposure to light, or other destructive influences effect still further variations in the quantitative relationship of the B vitamins.

Bacteria present in the mammalian intestinal tract are capable of synthesizing various vitamins of the B group, noteworthy among them being biotin, folic acid, and pantothenic acid. Factors which influence such bacterial growth—e.g., nutrients in the diet of the host or bacteriostatic medication (like the sulfonamides)—may depress intestinal synthesis sufficiently to induce secondary deficiencies.

The use of microbiological assay procedures has aided materially in the discovery of additional factors in the vitamin B group which are essential for the nutrition of certain microorganisms or laboratory animals but whose role as vitamins for man is not yet established. Among these factors are *p*-aminobenzoic acid, thioctic (lipoic) acid, *L. citrovorum* factor, *L. bulgaricus* factor, and vitamin B<sub>T</sub> (the latter required by the mealworm *Tenebrio molitor*). Examples of microbiological assays are given under Riboflavin, Pantothenic Acid, Niacin, Vitamin B<sub>6</sub>, and Pteroylglutamic Acid. In principle, these methods are identical with the procedures for amino acid assay described in Chapter 33 and illustrated on p. 1064. A table outlining the conditions for extraction, hydrolysis, and optimal concentration for microbiological vitamin assays by selected methods is given on p. 1131.

## THIAMINE

The term "deficiency disease" was first applied to a condition known as beriberi, which was common in southeastern Asia and the islands of the Pacific Ocean. The similarity in pathology between this disease and polyneuritis observed in fowls restricted to a diet of polished rice, both of which could be cured by feeding the "silverskin" (i.e., pericarp and germ) of the grain, prompted Eijkman, in the Dutch East Indies, to investigate the subject from the nutritional standpoint. Eijkman produced beriberi in fowls on a diet of polished rice and prevented the syndrome by dietary means. His classic studies, reported in 1896–1897, paved the way for a host of other investigations which culminated in the formulation of a vitamin hypothesis. Besides those Oriental countries where polished rice is the main article of diet, other places in which beriberi has been observed are prisons or asylums, localities where the diet is apt to be restricted or faulty, and war-stricken countries.

After numerous attempts to isolate the vitamin by methods involving silver or lead precipitation, crystallization of a picrate, adsorption, etc., the vitamin was finally crystallized from rice polishings by Jansen and Donath in 1926, in the very laboratories in which the original studies were conducted by Eijkman, who was able, after thirty years, to confirm the antineuritic activity of the crystalline vitamin hydrochloride. A decade later the structure and synthesis of the vitamin were announced by R. R. Williams and his co-workers.

Clinical cases of thiamine deficiency in the Western Hemisphere are rare today. Subclinical cases of deficiency are probably more prevalent, arising from a limited intake of the vitamin or from increased require-

ments such as are observed in pregnancy or lactation. The neuritis observed in cases of chronic alcoholism has been claimed to result from diminished intake of food as well as insufficient thiamine to metabolize the alcohol consumed.

**Physiological and Clinical Aspects of Thiamine.**<sup>52</sup> Thiamine is essential for the growth and metabolism of all animals as well as of many plants and microorganisms. Deficiencies are characterized by a variety of

FIG. 276. EFFECT OF THIAMINE DEFICIENCY AND SUBSEQUENT CHANGE TO AN ADEQUATE DIET.

The spastic paralysis shown in the upper figure was cured (*below*) about 24 hours after addition of thiamine.

Smith and Munsell: *U.S. Dept. Agr. Circ. No. 84*, 1929. Courtesy, The Bureau of Home Economics, U.S. Department of Agriculture.

symptoms and clinically are often complicated by the effects of lack of other nutrients.

In thiamine deficiency (avitaminosis B<sub>1</sub>) a form of peripheral neuritis is manifested affecting both the sensory and motor nerves. During the early stages neuralgia and cramps of the calf muscles are common; as the condition advances the thigh muscles become weak and toe- and foot-drop develop along with hypesthesia. The acute disease, beriberi, may be of the dry type, in which cachexia, numbness, and paralysis are the primary symptoms, or of the wet type, associated with marked ("pitting") edema and paresthesia of the extremities. In animals the symptoms are

<sup>52</sup> Cowgill: "The Physiology of Vitamin B<sub>1</sub>," in *The Vitamins*, Chicago, American Medical Association, 1939; Vedder: "The Pathology of Beriberi," *ibid.*; Strauss: "The Therapeutic Use of Vitamin B<sub>1</sub> in Polyneuritis and Cardiovascular Conditions," *ibid.*

loss of muscular coordination, spastic movements, retraction of the head (opisthotonos), and paralysis (see Fig. 276). Recovery from the symptoms of polyneuritis is very rapid when thiamine is administered, especially by injection.

Debility and progressive decline in weight are observed early in vitamin B<sub>1</sub> deficiency as a result of anorexia (loss of appetite), one of the most striking symptoms of this deficiency disease. The loss of appetite, which is the main cause of growth failure, has been attributed to a general systemic disturbance rather than to diminished secretory functions of the digestive glands or to reduced gastric motility, although diminished motor function of the gastrointestinal tract is observed clinically in thiamine deficiency.

The rapid restoration of appetite following thiamine supplementation of avitaminotic subjects has been regarded as indicating a specific appetite-stimulating function of the vitamin. The anorexia of thiamine deficiency, however, is more probably explained by the impaired carbohydrate metabolism of cellular tissue in general. Attempts to explain the loss of appetite on the basis of lowered secretory or motor function or diminished basal metabolic rate have not succeeded.

In polyneuritis pathological changes in the tissues and organs of the body include cardiovascular and neural disturbances and atrophy of the endocrine glands and other vital organs, but hypertrophy of the adrenals. Prolonged deficiency results in cardiac failure and death. An outline of the clinical symptoms of thiamine deficiency is given in the American Medical Association syllabus on p. 1289.

Degeneration of the myelin sheaths of peripheral nerves and also of the ganglion cells of the brain and spinal cord is produced in experimental polyneuritis, but since similar findings are observed in starvation, even when the supply of thiamine is adequate, it is preferable to regard the primary neurological effect of the avitaminosis as a functional defect concerned with the physiology of the neurons.<sup>53</sup> The rapid recovery from neurological symptoms which follows thiamine therapy supports this view.

In 1937 Lohmann and Schuster<sup>54</sup> isolated from yeast a crystalline coenzyme, cocarboxylase, the pyrophosphate ester of thiamine. When this compound is bound to a specific protein (apoenzyme) from yeast, and a magnesium ion, an active enzyme (carboxylase) is formed which catalyzes the decomposition of pyruvic acid to acetaldehyde and carbon dioxide. Unphosphorylated thiamine has no cocarboxylase activity, although it can stimulate the action of cocarboxylase in alkali-washed yeast preparations. The pyrimidine portion of the vitamin with an intact amino group has similar properties. Substitution of the magnesium by other divalent ions or combination of the cocarboxylase with different specific apoenzymes may result in more than one form of the enzyme and in somewhat diminished biological activity.

Free thiamine is phosphorylated *in vivo* to cocarboxylase (or diphos-

---

<sup>53</sup> Wolbach: *J. Am. Med. Assoc.*, **108**, 7 (1937).

<sup>54</sup> Lohmann and Schuster: *Naturwissenschaften*, **25**, 26 (1937).

phothiamine) by liver and kidney tissue and to some extent by muscle and brain. The phosphorylating agent appears to be adenosine-5'-triphosphate (ATP).

In animal tissues, cocarboxylase plays a role in various reactions involving principally the decarboxylation of pyruvic and other keto acids. In the brain, cocarboxylase participates in the anaerobic dismutation of pyruvate to lactate and acetate, and their subsequent oxidation to carbon dioxide and water. In liver and other tissue cells, cocarboxylase is involved in the conversion of pyruvate to oxalacetate which combines oxidatively and irreversibly with another molecule of pyruvate to enter the tricarboxylic acid cycle. The oxidative decarboxylation of ketoglutarate to succinate and of pyruvate to acetoacetate, and the conversion of pyruvate to the acetyl group of acetyl-coenzyme A (see p. 1188), are additional examples of reactions found to be mediated by cocarboxylase.

It is not an exaggeration therefore to say that thiamine occupies a key position in at least the terminal stages of carbohydrate metabolism. In advanced thiamine deficiency both pyruvate and lactate accumulate in the blood whereas glycogen increases in the liver and heart muscle. Rats subsisting on diets of glucose or casein alone survive twice as long when thiamine is added.

Diphosphothiamine may be involved in the synthesis of acetylcholine and in the control of its hydrolysis *in vivo*. The activity of choline esterase of serum is strongly inhibited by cocarboxylase.

The average American diet has been estimated to contain 1.3 mg. of thiamine per day. Prior to bread and flour enrichment, the value was 0.8 mg. Moderate thiamine deficiency may be the root of many ill-defined nutritional disturbances, especially when anorexia is a symptom. Such cases respond readily to the therapeutic test; i.e., supplementation of the diet. The thiamine requirement is a function of sex, body weight, muscular activity, and other conditions. Diet, especially the intake of nonfat calories, is an important factor. The recommended daily allowances of thiamine are shown in the table on p. 1108. The remarkable tolerance for thiamine is indicated by the fact that 500 mg. have been taken daily for a month by normal people, without any objective symptoms. It is of interest in this connection that peripheral neuritis in chronic alcoholism has been attacked therapeutically on the hypothesis that the condition is due partly to a disturbance of the vitamin B<sub>1</sub>:nonfat calorie ratio.

It has been shown that lactating rats require an additional quota of antineuritic vitamin, in the absence of which the mother will neglect or destroy the litter. The vitamin may be supplied directly to the young, or indirectly through the mother's milk.<sup>55</sup>

Thiamine and its compounds are the only naturally occurring substances having vitamin B<sub>1</sub> activity for the higher species. Certain synthetic analogs have less biological potency; e.g., the compound having a methyl group in the 6-, rather than in the 2- position in the pyrimidine nucleus; the 2-ethyl, instead of the 2-methyl, compound is active for

---

<sup>55</sup> Sure: *J. Biol. Chem.*, **76**, 685 (1928); Sure and Walker: *J. Biol. Chem.*, **91**, 69 (1931); Macy, Outhouse, Graham, and Long: *J. Biol. Chem.*, **73**, 189 (1927),

*Phycomyces*; thiamine disulfide, a possible intermediate in the metabolism of thiamine, obtainable by mild oxidation of the vitamin, has full activity.

Thiamine may be inactivated both *in vitro* and *in vivo* by an enzyme, thiaminase, present in certain fish and shellfish (see p. 1284). The vitamin is hydrolyzed to 2-methyl-6-amino-5-hydroxymethyl pyrimidine and 4-methyl-5-hydroxyethylthiazole.

Pyriethamine, a mixture of derivatives which include the true pyridine analog of thiamine (i.e., 2-methyl-3- $\beta$ -hydroxyethylpyridine in place of the thiazole moiety), and oxythiamine, in which oxygen replaces the sulfur atom, are powerful thiamine antagonists (see Chapter 36).

**Storage and Synthesis of Thiamine.** The available evidence seems to indicate little capacity on the part of the animal body to store thiamine. It occurs both free and phosphorylated, somewhat higher concentrations being present in the heart, liver, and kidneys than in muscles and brain. It is possible to increase the thiamine content of the tissues by dietary means; however, their storage capacity is so limited that even under these circumstances only a few weeks' reserve can be maintained. It is thus important that the daily diet include an adequate supply of thiamine.

Whereas certain microorganisms can synthesize the vitamin, others require an external source; some utilize the thiazole and pyrimidine portions—e.g., *Phycomyces blakesleanus*—whereas others can synthesize one moiety and combine it with the other obtained from an external source. Thiamine is synthesized by all higher plants, though to only a limited extent in the dark.

Though all animals require thiamine, sheep and cattle do not need an external supply since the vitamin is synthesized in sufficient amount by bacteria in the rumen. Though thiamine is known to be synthesized by intestinal flora in rats and humans, the nutritional importance of this contribution is not known. Difficulties encountered in the production of experimental thiamine deficiency in humans subsisting on a diet low in thiamine have been attributed to the intestinal synthesis.

Thiamine and cocarboxylase have the same biological activity for higher animals. Thiamine can be phosphorylated by live yeast, by dried yeast, or by a phosphatase obtainable in the presence of hexosediphosphate, adenosinetriphosphate, and a specific protein. The vitamin may also be phosphorylated by certain bacteria. Liver and kidney, and to some extent muscle and brain, can perform the same function.

**Distribution of Thiamine.**<sup>56</sup> This vitamin is essentially of plant origin. There is no proof of its synthesis by the animal body proper although it is synthesized to some extent by bacteria in the intestinal tract. Its presence in such products as milk, eggs, and liver depends on the dietary supply of the animal. Of the various meats used for human consumption, pork muscle is the richest in thiamine. The ability to synthesize thiamine is possessed by plants and by lower forms of life; e.g., bacteria, molds, and yeasts. The latter are a potent natural source of this factor, as well as of other components of the vitamin B complex.

---

<sup>56</sup> For thiamine values in foods, see Appendix III.

Thiamine is widely distributed in the plant world, seeds, leaves, roots, stems, and fruits being recognized sources. In cereal grains as a class, thiamine is found in highest *concentration* in the germ or embryo, less in the bran, and least in the endosperm. The amount of thiamine in a milled grain such as flour depends on the proportion of each part of the grain present. Leaves and grasses (e.g., spinach, alfalfa, timothy hay, etc.) are rich sources of thiamine as are also beans, nuts, fruits, milk and egg yolk.

Vitamin B<sub>1</sub> may occur in natural materials as free thiamine, as a protein complex, as pyrophosphoric acid complex (cocarboxylase), and as a phosphorus-protein complex. In milk, the vitamin is present both as free thiamine and as the vitamin-protein complex. In brain and liver, it is found as cocarboxylase and as its protein complex. In wheat, thiamine occurs in the free form. In blood, it is present as the pyrophosphate in the cells and as free vitamin in the serum. Thiamine is excreted in the free form in the urine.

**Chemistry of Thiamine.** The efforts of many investigators to isolate pure crystalline thiamine from natural sources culminated in the work of Jansen and Donath (*loc. cit.*). They adsorbed an acid extract of rice polishings on clay, eluted with Ba(OH)<sub>2</sub>, and alternately precipitated (first with silver nitrate, then with phosphotungstic or silicotungstic acid) and decomposed with acid, finally obtaining a platinic chloride precipitate from which a crystalline thiamine hydrochloride was prepared. The procedure yielded about 1 part of the vitamin from 3,000,000 parts of rice polishings.

Analysis of the crystalline vitamin led to its synthesis by Williams and his co-workers in 1936,<sup>57</sup> which was soon followed by large-scale commercial production. Thiamine chloride is 3-(4'-amino-2'-methylpyrimidyl-5'-methyl)-5-β-hydroxyethyl-4-methylthiazolium chloride. Its hydrochloride, commonly called thiamine chloride, is

**Thiamine chloride hydrochloride**

Thiamine hydrochloride is a white crystalline solid. The crystals are stable at 100° C. for 24 hours but decompose when heated to the melting point of 249° C. The compound is hygroscopic and dissolves in water to form an acid solution which is optically inactive. One gram dissolves in 1 ml. of water, in 18 ml. of glycerol, in 100 ml. of 95 per cent alcohol, or in 315 ml. of absolute alcohol. It is insoluble in ether, acetone, chloroform, and benzene. The vitamin has a characteristic yeasty odor and taste.

<sup>57</sup> Williams: *J. Am. Chem. Soc.*, **58**, 1063 (1936); Cline, Williams, and Finkelstein: *J. Am. Chem. Soc.*, **59**, 1052 (1937); Williams: *Ind. Eng. Chem.*, **29**, 980 (1937). The synthesis of thiamine was also accomplished, at about the same time, by Todd and Bergel (*J. Chem. Soc.*, p. 364 (1937)) and by Andersag and Westphal (*Ber.*, **70**, 2035 (1937)).

Thiamine is a basic substance forming insoluble compounds with picric, phosphotungstic, and tannic acids and with salts of the noble metals. It is adsorbed from acid or neutral solution by fuller's earth, silica gel, or "Norit," and may be eluted by alkalization or treatment with quinine.

As the pH increases beyond neutrality, thiamine becomes unstable, especially at elevated temperatures. Heating at 100° C. in acid or neutral solution for one hour has little destructive effect but at higher temperatures gradual destruction takes place. However, at pH 3.5 or less the vitamin may be autoclaved at 120° C. with little loss. Oxidation is not the primary factor in this decomposition. Dried yeast when heated in an autoclave for several hours at 120° loses its thiamine activity but retains practically all of its riboflavin, this difference in thermolability being one of the earliest methods applied to the differentiation of the vitamin B complex.

The thiamine in foods is stable at cooking temperatures, though a considerable fraction is extracted and often discarded in the cooking water. In neutral or alkaline solution, thiamine exhibits spectrophotometric absorption maxima at 235 and at 267 m $\mu$ . Below pH 5.5 there is a single band at 246 m $\mu$ .

The principal ester of thiamine is the pyrophosphate, known as cocarboxylase or diphosphothiamine.

**Thiamine pyrophosphate (cocarboxylase)**

This compound differs from the free base in that it functions as a coenzyme in the decarboxylation of pyruvic acid. It is a white, crystalline compound melting at 242–244° C., and resembles thiamine itself in its susceptibility to mild oxidation and sulfite-cleavage.

Thiamine and its pyrophosphate are destroyed when treated with sulfite or nitrite owing to cleavage of the two-ring structure of the molecule. Both thiamine and cocarboxylase, when treated with mild oxidizing agents like potassium ferricyanide in alkaline medium, are converted to thiochrome, a blue fluorescent compound.

**Thiochrome**

Likewise both react with diazotized *p*-aminoacetophenone to produce red dyes. The reaction products obtainable from the free vitamin may be distinguished from those derived from the pyrophosphate by extraction

of the former with organic solvents in which the latter are insoluble. The thiochrome or diazotization reactions serve as the basis for analytical determination of the vitamin.

## DETERMINATION OF THIAMINE

Reliable chemical methods for the determination of thiamine are based on (a) measurement of the fluorescent compound, thiochrome, obtained by mild oxidation, and (b) the more specific but less sensitive diazotization reaction of Prebluda and McCollum. Colorimetric assays of various extracts and concentrates have been found to correlate well with bioassay results, whereas thiochrome values are somewhat low.<sup>58</sup> Thiochrome values have also been found to be low when compared with the results obtained in yeast fermentation studies and in rat-curative tests.<sup>59</sup>

For the chemical tests, the thiamine must first be extracted quantitatively from foods and biological materials by boiling with dilute acids. The vitamin is then freed from its natural complexes by the action of enzyme preparations containing phosphatases. This step, by hydrolyzing carbohydrates, also facilitates extraction. In order to accomplish complete extraction from materials rich in protein, digestion with proteolytic enzymes like pepsin is also employed. The extract of the free vitamin is then purified by passage of the solution through a column of zeolite, a synthetic adsorbent which removes thiamine and allows the passage of many undesirable materials. Reducing agents, heavy metals, and other compounds which interfere with the thiochrome and colorimetric reactions are discarded in the eluate. The vitamin is then eluted from the zeolite column in a relatively pure form with an acidified solution of potassium chloride.

In the thiochrome procedure the vitamin is oxidized by an alkaline solution of potassium ferricyanide to thiochrome. This fluorescent compound is extracted with isobutanol and determined photometrically. In order to correct for the presence of other fluorescent compounds which may be present in the final extract, a blank test is conducted in which the ferricyanide is omitted. Since the conversion to thiochrome is not quantitative and other oxidation products which do not fluoresce may be formed, care must be exercised to standardize the oxidation procedure and to employ a fixed amount of ferricyanide. Though thiamine pyrophosphate (cocarboxylase) also yields a blue fluorescent compound on oxidation with ferricyanide, the product is not extractable by butanol.

The assumption that the background fluorescence is independent of the treatment with ferricyanide may account for low values by the thiochrome procedure. This assumption is invalid when N<sup>1</sup>-methylnicotinamide is present,<sup>60,61</sup> since this compound fluoresces in the thiamine blank, but not when treated with ferricyanide. N<sup>1</sup>-Methylnicotinamide is a metabolite of niacin which, like thiamine, is adsorbed by and eluted from zeolite. It is partly responsible for erroneous results obtained in the

<sup>58</sup> Brown, Hartzler, Peacock, and Emmett: *Ind. Eng. Chem., Anal. Ed.*, **15**, 494 (1943).

<sup>59</sup> Hennessy, Wapner, and Truhlar: *Ind. Eng. Chem., Anal. Ed.*, **16**, 476 (1944).

<sup>60</sup> Najjar and Ketron: *J. Biol. Chem.*, **152**, 579 (1944).

<sup>61</sup> Mason and Williams: *J. Biol. Chem.*, **146**, 589 (1942); **140**, 417 (1941).

assay of urine by the thiochrome method. In the analysis of materials that yield clear solutions and low blanks, preliminary tests may justify omission of the adsorption-elution step (in both the standard and unknown). Examples of such materials are certain pharmaceutical preparations, enriched flour, meat extracts, and milk.

In the colorimetric procedure, the eluate from the zeolite is first added to a solution of phenol in alcohol to increase the sensitivity of the test. The solution is then made alkaline and diazotized *p*-aminoacetophenone is added. The mixture is allowed to stand while the red dye develops. The latter is then extracted selectively by xylene which leaves behind in the aqueous phase dyes produced by the coupling of the reagent with phenol, phosphorylated thiamine (if present), acid-base indicators, and other interfering compounds. Results obtained by the colorimetric procedure agree well with those obtained by biological assay.

Since many microorganisms require an external supply of thiamine for growth, microbiological methods may be employed for the determination of this vitamin. Caution should be exercised in the choice of microorganisms, however, since some can utilize portions of the thiamine molecule, or degradation products of the vitamin which are not biologically active for higher organisms. Successful microbiological assays have been conducted employing *Lactobacillus fermentum* 36, the growth of which, under the conditions of the test, is not stimulated by the pyrimidine or thiazole portions of the thiamine molecule, either alone or together. Results obtained by yeast fermentation methods are erroneous if the pyrimidine portion is present, since it stimulates yeast fermentation. Correction for this interference may be made by conducting a test on a sulfite-treated sample in which the thiamine is inactivated.<sup>62,63</sup>

Coccarboxylase may be determined specifically and directly by measurement of the carbon dioxide produced by decarboxylation of pyruvic acid by yeast cells previously washed free of coccarboxylase.<sup>64</sup>

Human thiamine deficiency, both clinical and subclinical, may be diagnosed by several biochemical procedures. These involve measurement of the concentration of thiamine, coccarboxylase or pyruvic acid in the blood or urine. Since the levels of these compounds may fluctuate widely depending on the dietary intake for several days immediately preceding the test, a more reliable diagnosis is made when the response to a test dose of the vitamin is measured. A simple and reliable diagnostic test<sup>65,66</sup> involves colorimetric measurement (see p. 1144) of the urinary excretion of thiamine in the 4-hour period following intramuscular injection of 0.35 mg. of the vitamin per square meter of body surface, 12 hours after the last meal. Normal individuals excrete more and deficient subjects less than 50 $\mu$ g. of thiamine during the 4-hour period.

## CHEMICAL METHODS

**1. Modification of the Fluorometric Method of Hennessy and Cerecedo:<sup>67</sup>**

**Principle.** The thiochrome method for the determination of thiamine involves extraction of the vitamin, dephosphorylation, purification by adsorption-elution, and oxidation. The fluorescent thiochrome is extracted with isobutanol and determined fluorometrically. For a general discussion of fluorometry see Chapter 23.

**Procedure: Preparation of Sample.** Extract a sample containing not more than 2 g. of solids by refluxing for 0.5 hour with 75 ml. of 0.1 N sulfuric acid. Cool to 40° C. If the material is rich in protein, add 0.5 g. of pepsin and incubate over night at 37° C. Bring to 100° C. and then cool. Add 10 ml. of 1.8 M sodium acetate and adjust the pH to 4.5 if necessary. Add 0.5 g. of "Taka-Diastase" and incubate overnight at 37° C., or 3 hours at 45–50° C. Cool. Dilute to 100 ml. with distilled water, and filter.

Pass an aliquot of the filtrate containing approximately 3–5 µg. of thiamine through a base-exchange tube<sup>68</sup> containing a column of activated zeolite.<sup>69</sup> Wash the column twice with 20-ml. portions of distilled water. Elute the vitamin with 25 ml. of 25 per cent potassium chloride in 0.1 N hydrochloric acid. Mix the eluate.

Pass a standard solution containing 5 µg. of thiamine in acidulated water (pH 4.5) through a separate column, and elute as above.

**Fluorometric Procedure.** Pipet a 5-ml. aliquot of the eluate into each of two 30-ml. separatory funnels. Specially prepared separatory centrifuge tubes, (see Fig. 277) are particularly valuable for this purpose. To one, the test (*T*), add 3 ml. of potassium ferricyanide solution.<sup>70</sup> Add 16.5 ml. of isobutanol to both, then 3 ml. of 15 per cent sodium hydroxide to the other, the blank (*B*). Shake the funnels for 1.5 minutes, centrifuge, and discard the aqueous phases. Clarify the isobutanol layers by shaking with approximately 1 g. of anhydrous sodium sulfate, transfer to cuvettes, and read in a fluorometer equipped with appropriate filters.<sup>71</sup> Use an aqueous solution of quinine sulfate containing 0.2 µg. per ml. in 0.1 N sulfuric acid to check the setting of the instrument.

FIG. 277.  
SEPARATORY-  
CENTRIFUGE  
TUBE.

Scientific Glass  
Apparatus Co.,  
Bloomfield,  
N. J.

<sup>67</sup> Hennessy and Cerecedo: *J. Am. Chem. Soc.*, **61**, 179 (1939); Hennessy: *Ind. Eng. Chem., Anal. Ed.*, **13**, 216 (1941).

<sup>68</sup> The base-exchange tube contains a reservoir at the upper end having a capacity of approximately 30 ml., followed by a tube of 5 to 6 mm. internal diameter approximately 14 cm. long. At the lower end is a capillary of such diameter that when the tube is charged, the rate of flow will be approximately 1 ml. per minute.

<sup>69</sup> Approximately 50 mesh "Decalso." Activate the zeolite by stirring with four 10-volume portions of 3 per cent acetic acid for 10 minutes each. Between the second and third acid wash, treat for 15 minutes with 5 volumes of 25 per cent potassium chloride solution. Wash the zeolite with water till free of chloride, then with alcohol, and ether. Dry in air and store in a sealed bottle. Place a pledget of glass wool over the upper end of the capillary, and pour a water suspension of 2 g. of the activated zeolite into the tube.

<sup>70</sup> Dissolve 30 mg. of potassium ferricyanide in 100 ml. of 15 per cent sodium hydroxide.

<sup>71</sup> The fluorometer should be equipped with an ultraviolet light source and a filter with a transmission peak at 3700 Å. Between the glass cuvette and the photocell, insert a secondary filter with a transmission peak at 4600 Å. Since thiochrome is unstable to light, make the measurements rapidly and in a semidark room.

CALCULATION. Calculate the thiamine content of the sample employing the formula:

$$\frac{T_u - B_u}{T_s - B_s} \times \frac{1}{5} \times \frac{25}{A} \times \frac{100}{G} = \mu\text{g. thiamine per g. of sample}$$

$T_u$  equals the galvanometer reading obtained with the isobutanol extract of the unknown treated with ferricyanide;  $T_s$  is the corresponding value obtained with the standard;  $B_u$  and  $B_s$  are the galvanometer readings obtained in the blank tests conducted on the unknown and standard respectively;  $A$  is the volume of the unknown solution passed through the column; and  $G$  is the weight of sample taken for analysis.

**2. Colorimetric Method of Hochberg, Melnick, and Oser:<sup>72</sup> Principle.** The red pigment formed in the reaction between thiamine and diazotized *p*-aminoacetophenone is measured in a photoelectric colorimeter. The method involves the preparation of a clear extract of the free vitamin, adsorption on and elution from a zeolite column, reaction with diazotized *p*-aminoacetophenone, extraction of the red pigment with xylene, and comparison with a standard similarly treated. The method is applicable to the determination of thiamine in urine. Here the extraction and enzymic hydrolysis are omitted, and the urine samples, after adjustment of the pH to 4.5, are passed directly through the zeolite column.

The use of large samples for analysis makes the colorimetric method sufficiently sensitive for the determination of thiamine in most products. However, it is not recommended for the assay of materials rich in protein but low in thiamine. Because large samples are taken for analysis, high concentrations of adsorbable amino acids are released which interfere with the retention of thiamine on the zeolite column.

**Procedure: Preparation of the Extract.** Weigh out a sample containing at least 20  $\mu\text{g.}$  of thiamine.<sup>73</sup> Reflux for 30 minutes with 150 ml. of 0.05 N sulfuric acid, cool to 50° C., and add 10 ml. of 1.8 M sodium acetate solution. Adjust the pH to 4.5 if necessary. Add 1 g. of "Taka-Diastase," and incubate the suspension 3 hours at 45–50° C. or preferably overnight at 38° C. Cool and dilute to 200 ml. Filter.

The apparatus used for the purification and concentration of the extract is shown in Fig. 278 (p. 1175). A glass funnel is sealed to the top of a condenser. This is connected by means of a ground glass joint to a zeolite filter. The latter is a tube having an internal diameter of 8 mm. for a length of 12 cm. beyond the joint, followed by a constricted portion about 4 mm. in diameter. A plug of glass wool is placed above the constriction and the tube is filled with treated zeolite<sup>74</sup> to a height of 10 cm. This requires about 3 g. of the adsorbent. The zeolite filter is fastened to the bottom of the condenser by two 2-inch steel springs, joined to glass hooks. At the bottom of the apparatus is a 2-liter suction flask which acts as a reservoir. This is equipped with a two-way stopcock for connection to suction or to the atmosphere. The receiving tube, calibrated at the 10-ml. mark, is suspended from glass hooks in the stopper of the flask to collect the eluate. The condenser, which acts intermittently as a steam jacket, is connected to a laboratory steam line, or to a 1-liter flask of boiling water equipped with a two-way stopcock.

Pass an aliquot of the filtered extract containing 15–50  $\mu\text{g.}$  of thiamine through the zeolite column at room temperature. Maintain a filtration rate of 3 or 4 drops per second with the aid of mild suction. Then pass steam

<sup>72</sup> Hochberg, Melnick, and Oser: *Cereal Chem.* **26**, 83, (1945).

<sup>73</sup> As much as 20 g. may be taken. Samples rich in protein should be hydrolyzed with 1 g. of pepsin at pH 1-2 after extraction.

<sup>74</sup> Prepare the adsorbent as directed in the thiochrome procedure above.

through the outside jacket, and pour 30 ml. of water on the column. Allow to heat for one-half minute, then draw through with full suction to wash and heat the zeolite adsorbate. Elute the thiamine immediately by passing 10 ml. of 25 per cent potassium chloride solution in 0.1 N hydrochloric acid down the wall of the hot condenser. Collect at the rate of approximately 1 drop per 2 seconds, drawing through the final few drops by suction. Wash the zeolite column with 200 ml. of distilled water under full suction and with the steam on. Cool the column by running the last 50 ml. of wash through with the steam turned off. The apparatus is then ready for the next extract.

Pass a standard solution containing 30  $\mu$ g. of thiamine in 50 ml. of acidulated water at pH 4.5 through the column in the same manner as the test extract.

**Colorimetric Procedure.** Transfer the eluate to a 100-ml. centrifuge tube. Add 10 ml. of alcohol-phenol reagent,<sup>75</sup> previously poured into the receiving tube as a wash, then 2 drops of a 1 per cent alcoholic solution of thymol blue. Bring all samples to this point before proceeding. Handling one tube at a time, add 2 N sodium hydroxide dropwise, with constant stirring, till the first distinct blue color is produced, then immediately add 25 ml. of freshly prepared thiamine reagent.<sup>76</sup> Allow to stand at least 2 hours, or preferably overnight, at room temperature. Add 5 to 15 ml. of xylene and shake vigorously for 3 minutes. Centrifuge. Transfer the xylene layer by means of a U-tipped pipet to a Nessler tube, a visual colorimeter cup, or the absorption cell of a photoelectric colorimeter (520  $m\mu$  filter), and evaluate versus the standard solution.

**CALCULATION.** The color intensity is linear in the range recommended. Calculate the thiamine content of the sample using the formula:

$$\frac{U}{S} \times 30 \times \frac{200}{G} = \mu\text{g. thiamine per g. of sample}$$

$U/S$  is the ratio of the concentration of red pigment in the unknown to that in the standard (the ratio of the photometric densities when a photoelectric colorimeter is employed);  $G$  is the weight of the sample in grams.

## BIOLOGICAL METHODS

The symptoms of thiamine deficiency which have been adapted to biological assay are polyneuritis and anorexia. Pigeons,<sup>77</sup> chicks,<sup>78</sup> and

<sup>75</sup> Dissolve 3.9 g. of phenol in 500 ml. of 95 per cent alcohol. Store in an amber glass bottle.

<sup>76</sup> Dissolve 0.635 g. of *p*-aminoacetophenone in 9 ml. of concentrated hydrochloric acid and dilute to 100 ml. with distilled water. Dissolve 22.5 g. of sodium nitrite in distilled water and dilute to 500 ml. Dissolve 20 g. of sodium hydroxide and 28.8 g. of sodium bicarbonate in distilled water and dilute to 1000 ml.

**Diazonium Salt Solution:** Pipet 5 ml. of *p*-aminoacetophenone solution into a 50-ml. cylinder surrounded with chopped ice and water and provided with a stirrer. Add 5 ml. of sodium nitrite solution slowly, and stir for 10 minutes. Add an additional 20 ml. of nitrite solution slowly with stirring and keep in the ice bath for 30 minutes longer. Store at a temperature below 5° C. and use the solution on the same day it is prepared.

**Thiamine Reagent:** Add 10 ml. of the diazonium salt solution to 137 ml. of sodium hydroxide-bicarbonate solution with vigorous stirring. Allow to stand till the initial pink coloration changes to pale yellow (5–20 minutes), then use immediately.

<sup>78</sup> Arnold and Elvehjem: *J. Nutrition*, **15**, 403 (1937).

rats<sup>79</sup> are employed in the methods based on cure or prevention of polyneuritis, which have the advantage of specificity but are not as adaptable to quantitative treatment as are growth methods. Curative methods are based on the duration of the cure of head retraction in birds or of paralytic convulsions in rats, resulting from feeding graded doses of the test material. The difficulty arises in determining precisely when the symptoms have advanced sufficiently to administer the test dose and when "cure" is effected, the question being one of hours rather than days, and subject to considerable personal judgment. The pigeon-curative method has strong defenders, particularly among English workers. Before the differentiation of vitamin B was established, most of the studies on the antineuritic properties of the vitamin B complex were conducted on pigeons, because rats rarely exhibit typical symptoms of polyneuritis even though they cease to grow when deprived of this complex. Polyneuritis can be produced in rats by maintaining a state of partial deficiency in order that the rats survive long enough for the symptoms to appear. A method based on the growth response of rats to graded doses of thiamine has been adopted by the Association of Official Agricultural Chemists.

In the complete absence of thiamine, weanling rats show a gain in weight for the first week or so, followed by a rapid decline and death in 25–40 days. If life is prolonged on a submaintenance allowance of thiamine, the characteristic picture of polyneuritis appears, including lack of appetite, torpidity, spastic movements of the head and legs, and, in more severe cases, head retraction and paralysis of the hind legs. Lack of muscular coordination and a tendency to hold the head to one side and walk in circles are frequently manifested. (See Fig. 276, p. 1135.)

After 4–7 weeks, evidences of polyneuritis are seen, including incoordination, spasticity, and rolling movements. Spinning the rat by its tail will usually evoke convulsive seizures. When these become distinctive and consistent, the test foods or extracts are fed or injected in sufficient dosage to effect cure, the quantitative criterion being the minimum dose which will prevent a return of the symptoms for at least five days. This method, as adapted by the U.S. Pharmacopeia, is described in full on p. 1148.

The rat-growth method of Sherman and Chase<sup>80</sup> has been the basis of many evaluations of the vitamin B<sub>1</sub> content of foods and, except for the composition of the basal diet, is substantially the biological assay method for thiamine tentatively adopted by the A.O.A.C. (see below).

Coprophagy must be prevented in assays for the B vitamins since bacterial synthesis in the intestinal tract may produce significant concentrations of vitamins. Thus rats may grow on a B-free diet, this condition being known as "refection."<sup>81</sup> Partial digestion (dextrinization or gelatinization) of the starch in the diet by boiling has been recommended to avoid refection.

**Rat-Growth Assay for Thiamine:**<sup>82</sup> *Principle.* Rats, depleted of their thiamine reserves by means of a vitamin B<sub>1</sub>-free basal diet, are fed graded supplements of thiamine in the form of the standard or test materials. The relative growth responses to the doses of assay material and of pure thiamine constitute the basis for evaluation.

*Procedure.* Healthy rats not exceeding 28 days of age and weighing between 40 and 50 g. are placed in individual cages with raised wire-mesh floors (not less than 8 × 8 mm. mesh). Water and basal diet are fed *ad libitum*.

BASAL THIAMINE-DEFICIENT DIETS

The rats are weighed at intervals not exceeding 3 days. After 10 (but before 30) days the rats are depleted, as evidenced by stationary or declining weight over any 5-day period. They are then assembled into groups of 8 or more, one group being maintained on the basal diet as the negative control, the remainder receiving either graded doses of U.S.P. thiamine hydrochloride (0.1 ml. = 3.0 μg. thiamine) fed directly into the mouth by means of a syringe with a blunt-edged 18-gauge needle, or measured doses of the assay material corresponding in expected thiamine content to the amounts of standard fed to the reference groups. The intervals between doses should be constant for both reference and assay groups; each dose is computed by multiplying the next lower dose by a constant factor (e.g., 1.5 or 2).

CALCULATION. During the 4-week assay period, weights are recorded at weekly intervals. The average net gains of the reference groups are plotted and the average gains of the assay groups interpolated on this curve in terms of thiamine content for each dose level of the assay material.

<sup>83</sup> Thiamine-free casein may be prepared as follows: Stir 400 g. of casein with 2 liters of 60 per cent (by weight) alcohol for ½ hour, let stand 5½ hours, filter with suction, and wash with 1 liter of 60 per cent alcohol. Repeat, letting stand 18 hours and adding a final wash with 1 liter of 90 per cent (by weight) alcohol. Spread on trays to dry in air. Vitamin-free casein is supplied by the Borden Co., Bainbridge, N. Y., and by General Biochemicals, Chagrin Falls, Ohio.

<sup>84</sup> See p. 1146.

<sup>85</sup> See U.S.P. salt mixture, p. 1262.

<sup>86</sup> In place of butterfat and codliver oil, 10 per cent hydrogenated vegetable oil may be used together with 2000 U.S.P. units of vitamin A and 200 units of vitamin D per 100 g. of basal diet added in the form of high-potency fish liver oil or concentrate.

<sup>87</sup> See footnote 93, p. 1150.

<sup>88</sup> See footnote 94, p. 1150.

If desired the data may be treated statistically according to the analysis of variance illustrated for vitamin A in Appendix VI.

Results are preferably expressed in gravimetric units—e.g., mg. of thiamine per 100 g. of assay material; the International or U.S. Pharmacopeial unit is the potency of 0.003 mg. (3  $\mu$ g.) of crystalline thiamine hydrochloride.

## ASSAYS FOR THIAMINE<sup>89</sup>

### Biological Method of the U.S. Pharmacopeia XIV.

The biological assay, comprising the recording of observations of rats throughout specified periods of their lives, while being maintained on specified dietary regimens, and the interpretation of such data, is as follows:

**PRELIMINARY PERIOD.** Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the thiamine hydrochloride intake may be restricted.

**DEPLETION PERIOD.** A rat shall be suitable for the depletion period when the age of the rat does not exceed 30 days, and if the body weight of the rat does not exceed 50 g. and if the animal manifests no evidence of injury or disease or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the thiamine hydrochloride test diet and water (U.S.P.) *ad libitum*, and during this period no other dietary supplement shall be available to the animal. Throughout the depletion period and until the assay shall have been completed, the rats shall be kept in cages provided with a wire cloth bottom, each mesh of which shall be not less than 8 mm.

**ASSAY PERIOD.** A rat shall be suitable for the assay period, provided that the depletion period shall not have exceeded 75 days, and provided that the rat shall manifest evidence of thiamine hydrochloride deficiency characterized by acute polyneuritis. Throughout the assay period each rat shall be kept in an individual cage and provided with the thiamine hydrochloride test diet, compounded from the same lots of ingredients, and water (U.S.P.) *ad libitum*. On the day beginning the assay period there shall be administered to each rat a single dose of the reference standard of such size that it will produce in individual animals a curative period of not less than 5 days and not more than 15 days. All of the rats used in any one assay shall receive the same quantity of the reference standard. Each rat shall then be observed for the cure of and recurrence of polyneuritis, and when polyneuritis reaches the same acute stage observed when the reference standard was administered, a single dose of the assay product shall be administered. The animals shall then be observed to determine if polyneuritis is cured, and, if so, observation shall be made of the duration of the period. Each assay shall include successive administration of the reference standard and assay product to not less than eight rats. The assay product may be administered orally or parenterally, but in any one assay the reference standard shall be administered in the same manner as the assay product, and the quantity of the assay product administered to each rat shall be the same.

**RECORDING OF DATA.** On the day beginning the depletion period and at intervals of not more than 7 days during the depletion period, a record shall be made of the body weight of each rat. On about the twenty-fifth day and each day thereafter for the remainder of the depletion period, each rat shall be observed for symptoms of polyneuritis. The following dates shall be recorded:

1. The day on which the reference standard is administered.

---

<sup>89</sup> Grateful acknowledgment for permission to reproduce these methods (U.S.P. XIV) is made to Dr. Lloyd C. Miller and the Board of Trustees of the U.S. Pharmacopeial Convention, Inc.

2. The day on which cure of polyneuritis is observed following the administration of the reference standard.
3. The day on which acute polyneuritis recurs and the assay product is fed.
4. The day on which cure of polyneuritis is observed following the administration of the assay product.
5. The day on which acute polyneuritis recurs after the administration of the assay product.

THIAMINE HYDROCHLORIDE OR VITAMIN B<sub>1</sub> POTENCY OF THE ASSAY PRODUCT. In determining the thiamine hydrochloride potency of the assay product, the duration of the curative period following the administration of the reference standard and the assay product shall be considered. The dose of the assay product administered contains an amount of the thiamine hydrochloride equal to or greater than that contained in the dose of the reference standard administered if that quantity promotes in the assay animals a total curative period (the sum of the number of days of the curative period of each of the animals) equal to or greater than the total curative period produced by administration of the reference standard.

DEFINITIONS. As used herein, unless the context otherwise indicates, the term *acute polyneuritis* means that stage of thiamine hydrochloride deficiency in which the animal regains control of the voluntary muscles, as evidenced by standing or walking, a few seconds after extreme muscular contraction, which has been induced by twirling the rat by its tail (the onset of acute polyneuritis is invariably accompanied by loss in body weight). The term *assay period* means the interval in the life of a rat between the last day of the depletion period and the final observation following the administration of the assay product; the term *assay product* means a product under examination for its thiamine hydrochloride potency; the term *curative period* is the interval of time between the administration of thiamine hydrochloride and the subsequent recurrence of acute polyneuritis after a complete disappearance of polyneuritis symptoms, and the duration of the curative period is expressed as the number of days in that interval; the term *cure of polyneuritis* means the complete disappearance of polyneuritic symptoms and is invariably accompanied by increase in body weight; the term *depletion period* means the interval in the life of a rat during which its food intake is only the thiamine hydrochloride test diet and water (U.S.P.); the term *preliminary period* means the interval in the life of a rat prior to the depletion period; the term *reference standard* means the U.S.P. Thiamine Hydrochloride Reference Standard;<sup>90</sup> the term *thiamine hydrochloride test diet* means a uniform mixture, which has not been compounded for more than 7 days, of the following food materials and in the proportions designated:

---

<sup>90</sup> *Suggestions for Using the U.S.P. Thiamine Hydrochloride Reference Standard.*

Before preparing a solution of the Reference Standard, dry it to constant weight in a desiccator over phosphorus pentoxide.

*Precautions to be Taken in the Preparation of Solutions.* Because of the hygroscopic nature of the completely desiccated U.S.P. Thiamine Hydrochloride Reference Standard, it is preferable to transfer the quantity required for a test to a small glass-stoppered weighing bottle, in which it can then be weighed on a microbalance, or an ordinary balance according to the number of tests for which it is to be used. Even without such precautions, however, exposure to air during weighing will not cause an increase in weight of more than about 0.6 per cent, if the operations are completed within 5 minutes.

Neutral and alkaline solutions of thiamine hydrochloride are unstable, and water-acid solutions are readily infected by molds, which inactivate the vitamin. Therefore, stock solutions should be prepared using 25 per cent alcohol and containing sufficient hydrochloric acid to make the solution approximately 0.002 N. A convenient strength for a stock solution is 0.5 mg. of thiamine hydrochloride to each ml. These solutions are stable if stored at about 4°.

Solutions of suitable strength for animal dosage (20 to 100 µg. per ml.) must be made at least twice weekly from the stock solution by dilution with water. Such dilutions must be kept at a low temperature and examined daily for mold.

Thiamine Hydrochloride or Vitamin B<sub>1</sub> Test Diet

|                                            |                |
|--------------------------------------------|----------------|
| Sucrose.....                               | 60.25 per cent |
| Casein <sup>91</sup> .....                 | 18 per cent    |
| Salt Mixture <sup>92</sup> .....           | 4 per cent     |
| Autoclaved Yeast <sup>93</sup> .....       | 5 per cent     |
| Autoclaved Peanuts <sup>94</sup> .....     | 10 per cent    |
| Purified Liver Extract <sup>95</sup> ..... | 0.75 per cent  |
| Cod Liver Oil.....                         | 2 per cent     |

The Liver Extract used in this *Test Diet* must contain, in each g., at least that amount of material from liver which, when given daily to patients with pernicious anemia, has produced a satisfactory hematopoietic response.

**Chemical (Thiochrome) Method of the U.S. Pharmacopeia.**

DOUBLE-NORMAL SODIUM ACETATE. Dissolve 275 g. of reagent sodium acetate in sufficient water to make 1000 ml.

BROMOCRESOL GREEN PH INDICATOR. See p. 39.

THYMOL BLUE PH INDICATOR. See p. 39.

ENZYME SOLUTION. Prepare on the day on which it is to be used a 10 per cent solution in water of an enzyme preparation potent in diastatic and phosphatatic activity.

BASE EXCHANGE SILICATE. Purify an artificially prepared silicate of the base-exchange type, in the form of a granular powder of 50- to 80-mesh size, in the following manner: Place a convenient quantity (100 to 500 g.) of the base exchange silicate in a suitable beaker, add sufficient hot 3 per cent acetic acid ( $\text{HC}_2\text{H}_3\text{O}_2$ ) to cover the material, and boil for 10 to 15 minutes, stirring frequently. Allow to settle, and decant the supernatant liquid. Repeat this washing three times. Then wash in a similar manner three times with a hot 25 per cent solution of potassium chloride (1 part by weight of KCl in 4 volumes of solution) and finally wash with boiling water until the last washing gives no reaction for chloride. Dry the material at approximately 100° and store in a well-closed container.

BASE EXCHANGE TUBE. The base exchange glass tube has an over-all length of 200 mm. A reservoir at the upper end is 50 mm. in length and 25 mm. in diameter. This converges into the adsorption tube which is 5 to 6 mm. in internal diameter and approximately 140 mm. long. At the lower end the tube is drawn into a capillary approximately 10 mm. long and of such diameter that when the tube is charged the rate of flow will be not more than 1 ml. per minute.

Prepare the tube for use by placing over the upper end of the capillary, with the aid of a glass rod, a pledget of fine glass wool. Add a water suspension of 1.0 to 2.0 g. of the purified base exchange silicate to the adsorption tube, taking care to wash

<sup>91</sup> The casein shall be free from demonstrable traces of thiamine hydrochloride. (See footnote 83, p. 1147.)

<sup>92</sup> The salt mixture shall be the salt mixture described on p. 1262, or a salt mixture having essentially the same proportions of the elements.

<sup>93</sup> Dried yeast which has been autoclaved in steam at 15 pounds pressure for 5 hours with the yeast spread in a layer not more than 6 mm. in depth and then dried at a temperature not exceeding 65°.

<sup>94</sup> Unroasted shelled No. 1 grade Virginia peanuts are crushed in a food chopper, autoclaved in steam at 15 pounds pressure for 5 hours with the ground peanuts spread in a layer not more than 12 mm. in depth, and then dried at a temperature not exceeding 65°. This preparation may be incorporated in the basal diet by grinding with the requisite quantity of sucrose.

<sup>95</sup> Dissolve 100 g. of Liver Extract in 1 liter of 0.6 per cent sodium bisulfite solution. Let stand 24 hours in a well-stoppered bottle; acidify with hydrochloric acid to a pH of 1.5. Concentrate by distillation under reduced pressure at a temperature not exceeding 50° to one-half the original volume. Dry on vitamin B<sub>1</sub>-free casein at a temperature not exceeding 65°.

down all of the silicate from the walls of the reservoir. To keep air out of the adsorption column, a layer of liquid must be kept above the surface of the silicate throughout the adsorption process and the tube may be prevented from draining by placing a rubber cap (filled with water to avoid inclusion of air) over the lower end of the capillary.

**NEUTRAL POTASSIUM CHLORIDE SOLUTION.** Dissolve 250 g. of reagent potassium chloride in sufficient water to make 1000 ml.

**ACID POTASSIUM CHLORIDE SOLUTION.** Add 8.5 ml. of reagent hydrochloric acid to 1000 ml. of the neutral potassium chloride solution.

**SODIUM HYDROXIDE SOLUTION, 15 PER CENT.** Dissolve 15 g. of sodium hydroxide in sufficient water to make 100 ml.

**POTASSIUM FERRICYANIDE SOLUTION, 1 PER CENT.** Dissolve 1 g. of reagent potassium ferricyanide in sufficient water to make 100 ml. This solution must be freshly prepared on the day it is used.

**OXIDIZING REAGENT.** Prepare the solution by mixing 4.0 ml. of the 1 per cent potassium ferricyanide solution with sufficient of the 15 per cent sodium hydroxide solution to make 100 ml. This solution should be used within 4 hours.

**QUININE SULFATE STOCK SOLUTION.** Quinine sulfate solution is used to govern the reproducibility of the fluorophotometer. A stock solution of quinine sulfate is prepared by dissolving 10 mg. of quinine sulfate in sufficient 0.1 N sulfuric acid to make 1000 ml. Preserve this solution in light-resistant containers.

**QUININE SULFATE STANDARD SOLUTION.** Dilute 1 volume of the quinine sulfate stock solution with 39 volumes of 0.1 N sulfuric acid. This solution fluoresces to approximately the same degree as the thiochrome obtained from 1  $\mu$ g. of thiamine hydrochloride. Preserve this solution in light-resistant containers.

**THIAMINE HYDROCHLORIDE STOCK SOLUTION.** Weigh accurately not less than 25 mg. of U.S.P. Thiamine Hydrochloride Reference Standard which has been kept in a desiccator over phosphorus pentoxide for at least 16 hours. Since the Reference Standard is hygroscopic, precautions must be taken to avoid absorption of moisture. Dissolve in 20 per cent alcohol adjusted to a pH of 3.5 to 4.3 with hydrochloric acid and make up to a volume of 1000 ml. Store in a cool place in a well-closed, light-resistant container.

**THIAMINE HYDROCHLORIDE STANDARD SOLUTION.** From a portion of the stock solution that has been warmed to room temperature, transfer to a 100-ml. volumetric flask an aliquot containing exactly 100  $\mu$ g. of thiamine hydrochloride, and dilute to 100 ml. with water adjusted to a pH of 3.5 to 4.3 with hydrochloric acid. Each ml. of this solution contains 1  $\mu$ g. of thiamine hydrochloride.

Dilutions of this solution are treated in the same manner as that used in the *Preparation of Assay Solution* with respect to acid digestion, enzyme treatment, adsorption, and elution from the base exchange silicate.

**PREPARATION OF ASSAY SOLUTION.** The amount of material taken for the assay should be such that the ratio of the volume of 0.1 N sulfuric acid used for the extraction to the quantity of sample is at least 15 to 1, and the content of thiamine equivalent to 30 to 100  $\mu$ g. of thiamine hydrochloride. Place the accurately weighed quantity of the material to be assayed in 65 ml. of 0.1 N sulfuric acid contained in a 100-ml. centrifuge tube and digest it on a steam bath, with frequent mixing, for 30 minutes, or heat in an autoclave at 121° to 123° for 15 minutes. The liquid must remain acid during the digestion. If it is not distinctly acid to the thymol blue pH indicator, add sufficient diluted sulfuric acid to make it acid. Cool, and adjust the pH to between 4 and 4.5 by the addition of 2 N sodium acetate solution, using bromocresol green pH indicator as an external indicator in conjunction with a spot plate. Add 5 ml. of the enzyme solution, mix, and incubate at 45° to 50° for 3 hours. Cool, centrifuge the mixture until the supernatant liquid is clear or practically so, and quantitatively transfer the supernatant liquid to a 100-ml. volumetric flask. Wash the residue by

centrifuging with 10 ml., then with 5 ml. of 0.1 N sulfuric acid. Add the washings to the supernatant liquid and dilute to 100 ml. with water.

Pass through the prepared base exchange tube an aliquot of the solution estimated to contain 5 to 10  $\mu$ g. of thiamine, wash the tube with three 5-ml. portions of boiling water, taking care to prevent the surface of the liquid from falling below the surface of the silicate.

Elute the thiamine from the *base exchange silicate* by passing successively through the tube small portions of hot *acid potassium chloride solution*. Collect the first 15 to 20 ml. of the liquid (*eluate*) in a glass-stoppered, 25-ml. volumetric flask, cool, and dilute to a volume of 25 ml. with acid potassium chloride solution. *This constitutes the assay solution.*

***Oxidation of Thiamine to Thiochrome and Measurement of Fluorescence.*** Determine the thiamine content of the oxidized assay solution by comparing the intensity of fluorescence of an extract of this solution exposed to ultraviolet rays ranging from 350  $m\mu$  to 400  $m\mu$  with that of oxidized Thiamine Hydrochloride Standard Solution. The intensity of the fluorescence is proportional to the quantity of thiamine present and may be measured with the aid of various instruments.

To oxidize thiamine to thiochrome, add to quantities of the assay solution and of the similarly treated Thiamine Hydrochloride Standard Solution containing from 0.10 to 2  $\mu$ g. of thiamine, sufficient acid potassium chloride solution to produce a volume of 5 ml. Then add, with mixing, 3 ml. of oxidizing solution. Within 2 minutes add 13 ml. of isobutyl alcohol and shake vigorously for at least 1½ minutes. Centrifuge the mixture at a low speed until a clear supernatant solution is obtained. Measure in a fluorometer the intensity of fluorescence of the isobutyl alcohol solution directly if clear, or, if cloudy, after shaking with 2 g. of anhydrous sodium sulfate. Compare with this the intensity of fluorescence produced after oxidation of the properly prepared Thiamine Hydrochloride Standard Solution. Quinine Sulfate Standard Solution is used to govern the reproducibility of the instrument. Correction must be made for fluorescence produced by substances other than thiamine by determining the intensity of fluorescence of Thiamine Hydrochloride Standard Solution, and assay solutions treated as described above, but with 15 per cent sodium hydroxide solution replacing the oxidizing reagent.

The *Thiochrome Method* is applicable to substances such as Thiamine Hydrochloride, and a number of other products, but cannot be relied upon when certain interfering substances are present; in the latter case, use the *Biological Method*, p. 1148.

## RIBOFLAVIN

Riboflavin owes its discovery as one of the components of the B vitamins to its heat-stability and its characteristic fluorescence. The growth-promoting effect of certain water-soluble yellow dyes extracted from foods was noted by several investigators early in 1933. The biological activity was proportional not only to the intensity of the yellow color, but also to the fluorescence of the extracts.<sup>96</sup> Kuhn, György, and Wagner-Jauregg<sup>97</sup> isolated crystalline riboflavin from several foods and demonstrated the

<sup>96</sup> Booher: *J. Biol. Chem.*, **102**, 39 (1933).

<sup>97</sup> Kuhn, György, and Wagner-Jauregg: *Ber.*, **66B**, 317, 576, 1034 (1933).

growth-promoting properties of the vitamin on rats. Riboflavin was synthesized shortly thereafter.<sup>98</sup>

The clinical syndrome of ariboflavinosis was first described in 1938 by Sebrell and Butler.<sup>99</sup> Ariboflavinosis occurs more frequently among infants and children<sup>100</sup> than among adults and since its prevention depends upon an adequate diet it occurs most often among low income groups.<sup>101</sup> It is one of the more common dietary deficiency diseases and is usually associated with lack of other vitamins, notably niacin. It is characterized by the occurrence of cheilosis and glossitis.

The naturally occurring flavins—lactoflavin, ovoflavin, hepatoflavin, and verdoflavin—isolated respectively from milk, eggs, liver, and grass, are all chemically identical with riboflavin.

**Physiological and Clinical Aspects of Riboflavin.** Vitamin B<sub>2</sub> deficiency affects primarily the ectodermal tissues, producing lesions of the skin, eye, and nervous system. One of the earliest symptoms is cheilosis, manifested at first by transverse fissures at the corners of the mouth, raw and scaly lips, and finally by many vertical, deep fissures. The tongue assumes a purplish or magenta tinge and glossitis (flattening of the papillae) is observed. A seborrheic dermatitis occurs at the body folds; e.g., at the *alae nasi*, and in the scrotal and vulvar regions. The ocular manifestations of riboflavin deficiency include dryness, burning and itching, photophobia and lacrimation, and vascular invasion particularly at the scleral junction of the cornea. Cataracts due to pigmentation and capillary invasion of the cornea are known to occur in animals on a riboflavin-deficient diet, but it is uncertain to what extent human cataracts result from dietary causes. Though these symptoms may not individually be specific, cheilosis, glossitis, seborrheic dermatitis, and corneal vascularization constitute a group of signs which separately or in combination are observed in ariboflavinosis. The symptomatology of clinical riboflavin deficiency is outlined in the syllabus on p. 1291.

Clinical tests of the riboflavin content of blood and urine have been employed for the diagnosis of riboflavin deficiency. Normal individuals have a blood level of 0.5  $\mu$ g. per ml. and when subsisting on an adequate diet excrete 500 to 800  $\mu$ g. per day in the urine. The excretion and blood levels show diurnal variations depending upon the dietary intake. A diagnostic procedure involves measurement of the urinary excretion for 4 hours following the intravenous injection of 1 mg. of riboflavin.<sup>102</sup> Blood riboflavin may be determined by the microbiological procedure, employing *Lactobacillus casei*, or by the fluorometric method. In addition to riboflavin, the latter measures uroflavin, a metabolite of the vitamin.

Riboflavin is required by all animals and many microorganisms. A deficiency of the vitamin in young animals results in inhibition of growth terminated by death. In rats, the syndrome includes early atrophy of the

testes, involution of the thymus, alopecia, cataract, and degeneration of the main peripheral nerve trunks. In fowls, riboflavin is essential for normal egg production and hatchability. Peripheral nerve degeneration in chicks is responsible for "curled toe paralysis." In monkeys, riboflavin deficiency results in anemia and leukopenia.

Riboflavin plays an important role in many enzyme systems. In 1932, Warburg and Christian isolated a yellow respiratory enzyme from yeast.<sup>103</sup> This enzyme was shown to consist of a combination of riboflavin phosphate and a protein. The riboflavin phosphate, a mononucleotide, could be separated from the protein (apoenzyme) by dialysis against a weak acid. Neither fraction alone possessed enzymic activity, but the two could be recombined in neutral solution to produce the original enzyme. The yellow enzyme of Warburg and Christian can participate in a series of enzyme reactions involved in the metabolism of carbohydrates. It is capable of transporting hydrogen from reduced coenzyme II, a niacin coenzyme which attacks hexosemonophosphate, for example, regenerating that enzyme of first attack. The reduced yellow enzyme may be reoxidized itself by molecular oxygen. This series of reactions, however, is extremely slow and is probably of no physiological significance. Two other enzymes, cytochrome C reductase<sup>104</sup> and L-amino acid oxidase,<sup>105</sup> contain riboflavin phosphate. The former transports hydrogen from reduced coenzyme II to cytochrome C at a rate which is sufficiently rapid to be physiologically important. This suggests that riboflavin functions in the oxidation-reduction metabolism of plant and animal tissues. L-Amino acid oxidase catalyzes the oxidation of L-amino acids and of  $\alpha$ -hydroxy acids.

**Riboflavin mononucleotide**

**Riboflavin-adenine dinucleotide**

Riboflavin also participates in enzyme reactions as a dinucleotide prosthetic group, consisting of riboflavin, two phosphoric acids, ribose, and adenine. This coenzyme is found in xanthine oxidase, diaphorase, D-amino acid oxidase, a synthetic enzyme of Warburg and Christian, fumaric hydrogenase, liver aldehyde oxidase, and the Haas enzyme. Xanthine oxidase<sup>106</sup> (Schardinger enzyme, aldehydrase) is found in liver and milk and catalyzes the oxidation of aliphatic and aromatic aldehydes, reduced coenzyme I (another niacin coenzyme) and of a number of purines (including xanthine and hypoxanthine). In the presence of air, the reduced enzyme transfers its hydrogen to oxygen, forming hydrogen peroxide which inhibits further action. The accumulation of hydrogen peroxide is prevented by the presence of catalase, an iron-porphyrin-protein enzyme which catalyzes the decomposition of hydrogen peroxide to water and oxygen. The hydrogens of xanthine oxidase, like those of numerous other reduced enzymes, can be accepted also by methylene blue and by other oxidizing dyes. Two different diaphorases<sup>107</sup> have been found in plants, animal tissues, and microorganisms. In the presence of suitable proteins, one of these oxidizes reduced coenzyme I and reduced coenzyme II. D-Amino acid oxidase<sup>108</sup> found in animal tissues, notably kidney and liver, converts D- $\alpha$ -amino acids to  $\alpha$ -keto acids. Different D-amino acids are acted upon at different rates by this enzyme. Fumaric hydrogenase, another enzyme which contains riboflavin dinucleotide, catalyzes the reduction of fumaric acid in the presence of certain reduced dyes<sup>109</sup> to

succinic acid. Aliphatic and aromatic aldehydes are oxidized by liver aldehyde oxidase,<sup>110</sup> a riboflavin dinucleotide enzyme found in the liver of mammals.

The riboflavin enzymes, called flavoproteins, may be dissociated more or less easily and the original enzyme reconstituted by recombining the mono- or dinucleotide with the original protein. The synthetic enzyme of Warburg and Christian<sup>111</sup> consists of the dinucleotide added to the protein of the old yellow respiratory enzyme. The new enzyme differs from the natural enzyme obtained from yeast only in that it contains the dinucleotide in place of the mononucleotide as its prosthetic group; it has the same properties as the old yellow respiratory enzyme. The Haas enzyme consists of the dinucleotide plus a protein from yeast and has the same activity as the old yellow enzyme.

Free riboflavin is phosphorylated in the intestines of higher animals, probably by an enzymatic reaction in which a secretion of the adrenals plays an important part. When iodoacetic acid (an inhibitor of many enzymatic reactions) is administered, or when the adrenals are removed, phosphorylation does not take place and the vitamin is not absorbed from the intestinal tract. Under these conditions, riboflavin is unable to support growth, whereas the phosphate is effective. Human blood cells are capable of synthesizing the dinucleotide from free riboflavin both *in vivo* and *in vitro*.<sup>112</sup>

Since flavoproteins are composed of both riboflavin nucleotides and specific proteins, disturbances in metabolism may result from diminished levels of either constituent. Deficiency of dietary riboflavin results in a decreased concentration of D-amino acid oxidase in liver and kidney<sup>113</sup> and of xanthine oxidase in liver.<sup>114</sup> Both of these conditions may be prevented or improved by feeding riboflavin. The D-amino acid oxidase activity of liver from animals on diets low in riboflavin may be restored by the *in vitro* addition of the nucleotide to the excised tissue.<sup>115</sup> On the other hand, rats on a low-protein diet do not retain dietary riboflavin in the liver, a condition which may be prevented by the administration of methionine. Likewise, liver slices from riboflavin-deficient rats are unable to inactivate estradiol; this ability is retained when methionine is fed. These observations illustrate the interrelationship of riboflavin with protein metabolism and with endocrine function.

Riboflavin is concerned with the regulatory function of the hormones involved in carbohydrate metabolism. The administration of thyroxine to rats causes the loss of liver glycogen unless riboflavin and thiamine are fed simultaneously. The administration of insulin is effective in depancreatized dogs only when these two vitamins are fed. Riboflavin has been employed successfully in the treatment of dark adaptation in certain cases where vitamin A was ineffective. The retina contains free riboflavin

which is converted by light to a compound which is involved in stimulation of the optic nerve.

Riboflavin and its two nucleotides are the only naturally occurring compounds which have vitamin B<sub>2</sub> activity. However, several synthetic compounds have been prepared having approximately one-half of the activity of riboflavin. These vitamers lack a methyl group in the six or seven position, or have this group substituted by an ethyl group. Removal of both methyl groups results in the formation of a highly toxic compound. Substitution of an alkyl group in the three position destroys the vitamin activity of riboflavin.

The minimum requirement of riboflavin necessary to maintain tissue stores in man has been estimated as approximately 0.5 mg. per 1000 calories.<sup>116</sup> The recommended dietary allowances of the Food and Nutrition Board of the National Research Council are about 0.6 to 0.7 mg. per 1000 calories as indicated in the table on p. 1108. These allowances are more liberal than minimal requirements in order to provide a margin of safety. Under normal conditions, with an adequate dietary supply of riboflavin, humans excrete approximately one-third of their intake. When larger amounts are ingested, approximately half is excreted in the urine. Very large doses of riboflavin have been fed to dogs and rats with no evidence of toxicity.

Of interest is the relation between riboflavin feeding and experimentally induced neoplasms. Ingestion by rats of 2-acetylaminofluorene, a carcinogen, has been shown to induce ariboflavinosis;<sup>117</sup> high intake of riboflavin (2 mg. per 100 g. diet) inhibited the appearance of choline-induced tumors.<sup>118</sup>

**Storage and Synthesis of Riboflavin.** Riboflavin is not stored to any considerable extent in animal organs, though higher concentrations are found in the liver and kidney than in other tissues. In plants the younger parts are richer than the older. Broccoli leaves contain twice as much riboflavin as the flower buds; the latter contain more than the stems. Ungerminated seeds, other than peas, contain little riboflavin but appreciable amounts are formed during germination.

Riboflavin is synthesized by most higher plants, by yeasts, and by some bacteria. Though higher animals are unable to synthesize the vitamin themselves, it is produced to a variable extent by microorganisms in the intestinal tract. In the rat this process is influenced by the nature of the carbohydrate in the diet. The ingestion of dextrin and corn starch favors synthesis, whereas sucrose is ineffective. In ruminants, the contribution of riboflavin by bacteria in the rumen is so great that a dietary source of riboflavin is not necessary.<sup>119</sup>

Riboflavin is synthesized commercially and the product is employed on a large scale in bread and flour enrichment and for pharmaceutical purposes. Natural concentrates prepared from whey, yeast, and the

anaerobic bacterial fermentation of distillers' slops are employed in animal feeds.

**Distribution of Riboflavin.**<sup>120</sup> Riboflavin is widely distributed in plant and animal tissues as free riboflavin, as the phosphate, or as the adenine-dinucleotide phosphate, the latter accounting for 70–90 per cent of the total riboflavin in tissues.<sup>121</sup> The free vitamin is found, for example, in milk, urine, and retina. Riboflavin nucleotides occur more or less firmly bound to proteins. Excellent dietary sources of riboflavin are heart, liver, kidney, muscle, eggs, milk, green leafy vegetables, yeast, and whole grain. The riboflavin content of the average American diet before and after large-scale enrichment of bread and flour was practiced was 1.4 and 1.6 mg. per day, respectively.

**Chemistry of Riboflavin.** Riboflavin is 6,7-dimethyl-9-(D-1'-ribityl) isoalloxazine. It crystallizes in orange-yellow needles which melt at 282° C. with decomposition. Riboflavin is insoluble in acetone, benzene, chloroform, and ether, and only slightly soluble in water (12 mg. per 100 ml. at room temperature), but very soluble in alkaline solution. Derivatives more soluble in water, such as the monosuccinate, borate, phosphate, and acetate, have been prepared for pharmaceutical use. The vitamin is adsorbed by fuller's earth in acid solution and by frankonit in neutral solution but not by talc, aluminum oxide, calcium carbonate, kaolin, or kieselguhr; it is eluted by 80 per cent acetone or by alkalies such as pyridine-methanol-water mixtures or ammonia water.

Riboflavin forms a yellow solution having a yellow-green fluorescence. It has a characteristic absorption spectrum in the ultraviolet and visible regions, with absorption maxima at 225, 269, 372, and 445 m $\mu$ . When exposed to ultraviolet radiation, it shows a fluorescence having a maximum at 565 m $\mu$  at pH 6. In acid or alkaline solutions (below pH 3 or above pH 9) the fluorescence of riboflavin increases considerably. Riboflavin is amphoteric, having an isoelectric point at pH 6. It is optically active;  $[\alpha]_D^{20} = -114^\circ$  in 0.1 N sodium hydroxide, this value decreasing in neutral or acid solution. Riboflavin is stable to heat in neutral and acid but not in alkaline solutions. It is also unstable to visible and ultraviolet radiation, especially at alkaline pH and at elevated temperatures. The riboflavin content of milk in clear bottles or of bread in transparent wrappings may drop significantly after only a few hours' exposure to sunlight. Alkaline irradiation of riboflavin produces lumiflavin (6,7,9-trimethylisoalloxazine), a fluorescent degradation product soluble in chloroform. In neutral or acid solution, lumichrome (6,7-dimethylalloxazine) is formed. Riboflavin is easily reduced by hydrogen in the presence of a catalyst, by zinc in acid, by sodium hydrosulfite, by hydrogen sulfide in alkaline solution, and by other reducing agents. Reduction is accompanied by a shifting of bonds in the isoalloxazine ring as shown on p. 1159. Leucoriboflavin, the reduction product, is a colorless non-fluorescent compound which is easily reoxidized by shaking with air in solution. The oxidation-reduction reaction is probably of great importance in the function of riboflavin nucleotide in cellular respiration.

<sup>120</sup> See Appendix III.

<sup>121</sup> Bessey, Lowry, and Love: *J. Biol. Chem.*, **180**, 755 (1949).

Riboflavin may be converted to its mononucleotide, riboflavin phosphate, by treatment with phosphorus oxychloride, or by suspending it in a phosphate buffer with intestinal epithelial powder.

**Determination of Riboflavin.** Chemical determinations of riboflavin are based upon colorimetric<sup>122</sup> and fluorometric<sup>123</sup> procedures. In the analysis of food materials, colored and fluorescent compounds often interfere not only with the colorimetric determination of riboflavin but also with the fluorometric procedure in which the activating and fluorescent light are quenched. Some interfering pigments may be destroyed in the chemical test by oxidation with potassium permanganate or by reduction with stannous chloride. Fluorescence measurement before and after reduction of riboflavin by treatment with sodium hydrosulfite has been employed to correct for the fluorescence produced by interfering substances. Correction may be made for the quenching effect of foreign pigments or other factors by the internal standard procedure. One method for the chemical determination of riboflavin<sup>124</sup> involves the conversion of the vitamin by irradiation in alkaline solution to lumiflavin. The latter is extracted from acid solution by chloroform and then determined colorimetrically or fluorometrically.

The microbiological determination of riboflavin depending upon the growth stimulation of *Lactobacillus casei* is more generally applicable to the determination of the vitamin in foods than the chemical methods. The microbiological procedure is sensitive and specific, and has been adopted as an official method by the U.S. Pharmacopeia. It has been found that the growth of *Lactobacillus casei* in the presence of riboflavin is stimulated by suspended particles such as fat and starch. It is therefore essential to conduct the test on crystal-clear extracts. These are some-

<sup>122</sup> Warburg and Christian: *Biochem. Z.*, **257**, 492 (1933).

<sup>123</sup> Hodson and Norris: *J. Biol. Chem.*, **131**, 621 (1939); Scott, Hill, Norris, and Heuser: *J. Biol. Chem.*, **165**, 65 (1946).

<sup>124</sup> Kuhn, Wagner-Jauregg, and Kaltschmitt: *Ber.*, **67**, 1452 (1934).

times difficult to obtain when starchy samples are tested. Digestion with "Mylase" or "Taka-Diastase" is often helpful.

**Modified Microbiological Method of Snell and Strong:**<sup>125</sup> **Principle.** Riboflavin is determined by measurement of the growth stimulation of *Lactobacillus casei*. The acid produced by the microorganism is determined by titration with sodium hydroxide.

**Procedure: Preparation of Sample.** Conduct all operations in dim light. Weigh out a sample containing approximately 200  $\mu$ g. riboflavin and heat in an autoclave with 400 ml. 0.1 N hydrochloric acid for 30 minutes at 15 pounds pressure. Cool and adjust to pH 4.5 with 1 N sodium hydroxide. Dilute to 1000 ml. and filter through a fine filter paper which does not adsorb riboflavin. Adjust a 100-ml. aliquot of the clear filtrate to pH 6.8 with 1 N sodium hydroxide solution and dilute to 200 ml. Filter again if the solution is not clear.

Prepare the following solutions:

**Yeast Extract Solution.** Heat a suspension of 500 g. fresh, starch-free baker's yeast in 5 liters of distilled water for 2 hours in flowing steam; then autoclave for 40 minutes at 15 pounds pressure. Allow the suspension to settle, filter, and evaporate the filtrate to 125 ml. under reduced pressure below 50° C.

**Yeast Supplement Solution.** Add 125 ml. of an aqueous solution containing 38 g. lead subacetate to 125 ml. of yeast extract solution. Filter and adjust the filtrate to pH 10 with ammonia. Filter and adjust the pH to 6.5 with glacial acetic acid. Treat the solution with hydrogen sulfide, filter off the lead sulfide, and dilute the filtrate to 250 ml. with water. Preserve under toluene in a refrigerator.

**Photolyzed Peptone Solution.** Dissolve 40 g. peptone in 250 ml. of distilled water, and 20 g. sodium hydroxide in 250 ml. distilled water. Mix the solutions and irradiate 6 to 10 hours in a crystallizing dish (diameter 24 cm.) 1 foot from a 100-watt bulb fitted with a reflector; then allow the mixture to stand for the remainder of a 24-hour period, keeping the temperature below 25° C. during the entire treatment. Adjust to pH 7 with glacial acetic acid, add 7 g. anhydrous sodium acetate, and dilute to 800 ml. Store under toluene in a refrigerator.

**Cystine Solution.** Dissolve 1 g. L-cystine in 20 ml. 10 per cent hydrochloric acid and dilute to 1000 ml. with distilled water. Store under toluene in a refrigerator not below 10° C.

**Salt Solution A.** Dissolve 25 g. monobasic potassium phosphate and 25 g. dibasic potassium phosphate in distilled water and dilute to 250 ml.

**Salt Solution B.** Dissolve 10 g. magnesium sulfate, 0.5 g. sodium chloride, 0.5 g. ferrous sulfate, and 0.5 g. manganese sulfate in distilled water, and dilute to 250 ml.

---

<sup>125</sup> Snell and Strong: *Ind. Eng. Chem., Anal. Ed.*, **11**, 346 (1939). See also U.S. Pharmacopeia XIV.

**Reference Standard Solution.** Dissolve 50 mg. U.S.P. riboflavin reference standard in 500 ml. distilled water containing 1 ml. glacial acetic acid. Preserve this stock solution under toluene in an amber bottle in the refrigerator. For each set of assays, dilute 1 ml. of this solution to 1000 ml. with distilled water. This solution contains 0.1  $\mu\text{g}$ . riboflavin per ml.

**Basal Medium Stock Solution.** Dissolve 15 g. anhydrous dextrose in a mixture of 50 ml. photolyzed peptone solution, 50 ml. cystine solution, 5 ml. yeast supplement solution, 2.5 ml. salt solution A, and 2.5 ml. salt solution B. Adjust to pH 6.8 with 1 N sodium hydroxide and dilute to 250 ml.

**Preparation of the Stock Culture.** Dilute 10 ml. yeast extract solution to 100 ml. with distilled water, and add 1 g. anhydrous dextrose and 1.5 g. agar. Heat on a steam bath to dissolve the agar. Add approximately 10 ml. portions of the hot solution to test tubes, plug with nonabsorbent cotton and sterilize in an autoclave at 15 pounds pressure for 20 minutes. Allow to cool in an upright position. Prepare several stab cultures of *Lactobacillus casei* (American Type Culture Collection No. 7469) and incubate for 16 to 24 hours at any constant temperature between 30° and 37° C. Finally store in a refrigerator. Prepare a fresh stab every week, and do not use for inoculum if more than two weeks old.

**Preparation of the Inoculum.** To each of two tubes containing 5 ml. of the basal medium stock solution, add 5 ml. distilled water containing 1  $\mu\text{g}$ . riboflavin. Autoclave at 15 pounds pressure for 20 minutes and cool. To one of the tubes make a transfer of cells from the stock culture of *Lactobacillus casei* and incubate for 16 to 24 hours at any constant temperature between 30° and 37°. Transfer 1 drop of this culture to the second tube and incubate again for 16 to 24 hours. Centrifuge the culture under aseptic conditions and decant the supernatant liquid. Suspend the cells in 10 ml. sterile isotonic solution of sodium chloride.

**Assay.** In duplicate tubes, 16 by 150 mm. in size, place respectively 0.5, 1.0, 1.5, and 2.0 ml. of the extract of the test material. To each add 5 ml. of the basal medium stock solution and sufficient distilled water to bring the volume in each tube to 10 ml. Prepare a similar set of duplicate tubes containing respectively 0.00, 0.05, 0.10, 0.15, 0.20, 0.30, and 0.50  $\mu\text{g}$ . standard riboflavin. Mix the solutions thoroughly, plug the tubes with nonabsorbent cotton, and autoclave at 15 pounds pressure for 20 minutes. Cool aseptically, add 1 drop of inoculum to each tube, and incubate for 72 hours at any constant temperature between 30° and 37° C. Keep all the tubes in darkness or semidarkness during their preparation and incubation, and protect against contamination by foreign microorganisms. Transfer the contents of each tube to a small Erlenmeyer flask, using a fixed volume of distilled water for rinsing. Titrate with 0.1 N sodium hydroxide using bromothymol blue as the indicator.

**CALCULATION.** On ordinary graph paper, plot the average titrations in ml. of 0.1 N sodium hydroxide against  $\mu\text{g}$ . of riboflavin in the series of standard tubes. From this standard curve, estimate the riboflavin content of each ml. of the test solution in each duplicate set of tubes. Calculate the riboflavin content of the test material from the average values obtained from not less than three sets of these tubes which do not vary by more than  $\pm 10$  per cent from the average.

**Comment.** The microbiological method for the determination of riboflavin employing *Lactobacillus casei* is highly sensitive and shows a good

degree of specificity for the vitamin. If desired, turbidity in place of acidimetric titration may be used to measure response. For measurement of turbidity follow the directions given in the Microbiological Assay for Vitamin B<sub>12</sub>, p. 1210, beginning with the fifth paragraph under the heading *Procedure* and substituting riboflavin for cyanocobalamin. For this procedure it may be necessary to reduce the level of riboflavin used in the standard and sample tubes.

**Fluorometric Method of Arnold:**<sup>126</sup> **Principle.** The fluorometric procedure for the determination of riboflavin depends upon the extraction of the vitamin with dilute acid, filtration, treatment of the filtrate with permanganate and hydrogen peroxide to destroy interfering pigments, and measurement of the fluorescence. The vitamin content of the extract is evaluated by means of an internal standard.

**Procedure.** Suspend a finely ground sample containing approximately 5 µg. riboflavin in 75 ml. 0.1 N sulfuric acid. Heat in an autoclave for 15 minutes at 15 pounds pressure, or in a boiling water bath for 45 minutes with intermittent shaking. Cool the suspension and adjust the pH to 4.3 with 2.5 M sodium acetate. Dilute to 100 ml., shake well, and filter through Whatman No. 1 or No. 40 filter paper. Discard the first 15 ml. filtrate. Treat 60 ml. of the filtrate with 2 ml. 4 per cent potassium permanganate solution. After 3 minutes, discharge the permanganate color with freshly prepared 3 per cent hydrogen peroxide solution. Break the froth with a few drops of acetone, and dilute to 65 ml. with distilled water. Mix and filter. Pipet out two 15-ml. portions of the filtrate. To one, add 1 ml. distilled water and measure the fluorescence (*A*) (see p. 1163). To the other, add 1 ml. riboflavin standard solution containing 1 µg. of the vitamin, and measure the fluorescence (*B*). Obtain the blank (*C*) after adding exactly 20 mg. of sodium hydrosulfite<sup>127</sup> to *A* or *B*.

CALCULATION. Obtain the riboflavin content of the sample using the formula,

$$\frac{A - C}{B - A} \times \frac{1}{15} \times \frac{65}{60} \times \frac{100}{G} = \mu\text{g. riboflavin per g. of sample}$$

where *G* is the weight of the sample taken and *A*, *B*, and *C* are as indicated above.

**Comment.** The fluorometric method may be employed for the determination of the riboflavin content of yeast, white flour, bread, milk powder, and similar products. However, for samples which yield highly pigmented extracts, or for materials containing less than 1 µg. of riboflavin per g. of solids, the microbiological procedure is preferred.

**Determination of Riboflavin in Urine (Fluorometric Method of Najjar):**<sup>128</sup> **Principle.** The riboflavin is extracted with acetic acid-pyridine-butanol mixture after interfering urinary pigments are oxidized with permanganate. The concentration of riboflavin in the extract is measured fluorometrically.

**Procedure.** Collect a 24-hour urine sample in a brown glass bottle containing 20 ml. of 10 per cent sulfuric acid. Since riboflavin is destroyed by light, conduct all of the following operations in semidarkness. Measure the volume.

<sup>126</sup> Arnold: *Cereal Chem.*, 22, 455 (1945).

<sup>127</sup> Sodium hydrosulfite (highest purity) should be stored so as to avoid undue exposure to light or air.

<sup>128</sup> Najjar: *J. Biol. Chem.*, 141, 355 (1941).

Transfer an aliquot containing approximately 5  $\mu\text{g}$  riboflavin to a 100-ml. centrifuge cup, and add sufficient water to make the volume 10 ml. Add 2 ml. glacial acetic acid and 4 ml. colorless pyridine and mix. For each ml. of urine, add 2 drops 4 per cent  $\text{KMnO}_4$ . After exactly 1 minute, decolorize the excess permanganate with a few drops of freshly prepared 3 per cent hydrogen peroxide solution. Add 10 g. anhydrous sodium sulfate, then 20 ml. *n*-butanol. Shake vigorously for 5 minutes. Centrifuge.

Determine the fluorescence of the supernatant solution, that of a standard containing 5  $\mu\text{g}$ . riboflavin, and of a water blank, the latter two likewise carried through the entire procedure.

For these measurements, a Pfaltz and Bauer fluorophotometer may be employed. The source of light should be a mercury vapor lamp equipped with a dark blue filter (Jena, No. BG12) and a yellow filter (Jena No. GG3). An orange filter (Jena, No. OG1) should be placed between the fluorescent solution and the photocell. Set the diaphragm so that the galvanometer reads 50 when the extract of the 5  $\mu\text{g}$ . standard is in the instrument.

At the concentrations recommended in this procedure, the fluorescence of a riboflavin solution is directly proportional to its concentration. With most instruments, the galvanometer deflection is proportional to the fluorescence. Establish the linearity of the instrument employed by measuring the fluorescence of standard aqueous solutions of riboflavin as follows:

Dissolve 50.0 mg. riboflavin in 1000 ml. of hot water in the dark. Cool. Prepare aqueous dilutions containing 0.00, 0.05, 0.10, 0.15, 0.20, 0.25, 0.30, and 0.40  $\mu\text{g}$ . riboflavin per ml. Set the instrument at 100 with the most concentrated standard and measure the fluorescence of the other solutions. Plot the galvanometer readings against concentration of the vitamin on ordinary graph paper. Check the setting of the instrument before each reading.

CALCULATION. If the relation is linear, calculate the riboflavin content of the 24-hour sample by means of the following formula:

$$\frac{U - C}{50 - C} \times 5 \times \frac{V}{A} = \mu\text{g. riboflavin per 24-hour sample}$$

where  $U$  is the galvanometer reading of the unknown,  $C$  is that of the reagent blank,  $V$  is the volume of the 24-hour sample in ml., and  $A$  that of the aliquot taken for test.

If the curve obtained above is not linear, standard solutions containing 0, 2, 4, 6, and 8  $\mu\text{g}$ . riboflavin must be carried through the entire procedure and the concentration of riboflavin in the unknown determined from a standard curve. This value, multiplied by  $\frac{V}{A}$ , gives the amount of riboflavin in the 24-hour urine sample.

**Comment.** The fluorometric method for the determination of riboflavin in urine, as described above, measures in addition uroflavin, a fluorescent metabolite of the vitamin. For diagnostic purposes, however, the total fluorescence following the ingestion of a test dose of the vitamin is a good index of the nutritional state with respect to riboflavin.

## BIOLOGICAL ASSAY OF RIBOFLAVIN

The essential feature in the biological assay for riboflavin is to select a basal ration which includes all of the required factors of the vitamin B complex with the sole exception of riboflavin. In the past the practice has been to supplement a basal ration otherwise free from all sources of the vitamin B complex with alcoholic extracts of wheat germ or of rice polish-

ings (so-called tiki-tiki). However, such diets were undoubtedly deficient in more respects than riboflavin alone. Since crystalline preparations of each of the known B vitamins are now available, it is possible to supplement an otherwise adequate diet of purified components with all of the factors of the B complex except the one under assay.

There is at present no officially recognized procedure for the biological assay of riboflavin. Procedures employing both the rat and the chick have been described. The curative rat assay is more widely employed in the evaluation of foods or pharmaceutical products for human use. The customary procedure is to place rats on the riboflavin-free basal diet at weaning, making observations of weight changes at semiweekly intervals. Cessation of growth is one of the earliest symptoms of riboflavin depletion, and if the deprivation is complete, it is usually followed by decline in weight and death without the appearance of characteristic symptomatology. If the deficiency is prolonged (as may occur if the basal diet is not completely devoid of riboflavin) the symptoms of ariboflavinosis appear. These include bilaterally symmetrical patches of baldness around the nose, neck, back, and abdomen, and corneal vascularization, and if the deficiency is particularly prolonged, cataracts are observed. It is interesting to point out that riboflavin-deficient rats are particularly susceptible to pediculosis. The occurrence of alopecia is noted in deficiencies of other factors of the B complex—e.g., biotin. Whether this phenomenon has a common origin in deficiencies of various members of this group of vitamins is not known.

After three to four weeks on the riboflavin-free diet, the weight of the rat reaches a plateau or decline and at this point the material to be assayed is fed as a supplement to the basal ration. Comparable groups of animals receive graded dosages of crystalline riboflavin at levels which result in a graded dose-response curve. For example, doses of 1, 2, 4, 8, and 16  $\mu\text{g}$ . of crystalline riboflavin may be fed daily. Together with a resumption of growth, restoration of the body hair occurs over the denuded areas. Potency may be estimated by comparison of the log dose vs. growth response data for the test material with those for the standard (*cf.* calculation in vitamin A growth assay, Appendix VI).

### NIACIN (NICOTINIC ACID)

The most common acute deficiency disease in this country is pellagra. Before the discovery of its relationship to niacin, this disease was responsible for thousands of deaths annually in the South. Pellagra occurs in endemic and epidemic form in many other countries including the Soviet Union, Egypt, Italy, Spain, and the Balkan countries. Epidemic pellagra follows any serious interruption of food supply or intake, especially after war, famine, disease, or economic depression.

Pellagra has been known for many centuries and was described as early as 1735 by Casal of Spain. That the disease was of dietary origin was not recognized until 1912 when Goldberger, Waring, and Willets<sup>129</sup> demonstrated that pellagra could be prevented by an adequate diet. At about

---

<sup>129</sup> Goldberger, Waring, and Willets: *U.S. Pub. Health Repts.*, **30**, 3117 (1915).

the same time, nicotinic acid, a compound synthesized as early as 1867,<sup>130</sup> was isolated by Funk while attempting to purify the antiberiberi vitamin. He failed to recognize the relationship between nicotinic acid and pellagra but noted its beneficial effects when fed along with "vitamine B."<sup>131</sup> Deficiency syndromes analogous to human pellagra were demonstrated in dogs<sup>132</sup> in 1917 and in albino rats<sup>133</sup> in 1926. It was soon recognized that those foods which were effective for the cure of canine blacktongue were also effective for the cure of pellagra.<sup>134</sup> Following the discovery in 1937 of the importance of the amide of nicotinic acid (niacinamide) in the nutrition of certain unicellular organisms,<sup>135</sup> the therapeutic effects of nicotinic acid in the treatment of blacktongue<sup>136</sup> and of niacinamide in pellagra<sup>137</sup> were demonstrated.

**Physiological and Clinical Aspects of Niacin.** In niacin deficiency, the demonstrable tissue lesions are preceded by functional disturbances which are characteristic of deficiencies of a number of the B vitamins. These include weakness, anorexia, indigestion, diarrhea, and mental and emotional disturbances. Though pellagra is generally complicated by deficiencies of other B vitamins, certain lesions of the skin, the digestive tract, and the nervous system (the "three D's"—dermatitis, diarrhea, dementia) have been attributed specifically to deficiency of niacin. The skin lesion is an erythema, generally bilaterally symmetrical, which affects the back of the hands, the knees, elbows, dorsum of the feet, and ankles. Exposure to the sun increases the severity of the lesions. In chronic pellagra the affected areas become permanently pigmented and either atrophied or roughened and thickened. Epithelial lesions are also noted in the digestive tract, particularly on the tongue (glossitis) and in the rectum. The organic nerve lesions of pellagra include myelin degeneration of the spinal column fibers and degeneration of the axis cylinders of pyramidal cells of the cortex. Mild mental disturbances are common in pellagra, and acute delirium and dementia occur in severe cases.

Though anemia is not generally recognized as a symptom of pellagra, it is frequently accompanied by a macrocytic anemia. Since this condition responds to pteroylglutamic (folic) acid, its occurrence in pellagra may be due to the multiple nature of the clinically observed condition. Dogs with blacktongue also show anemia which responds to the administration of niacin.<sup>138</sup>

Dramatic cures of pellagra occur upon the administration of niacinamide. Therapeutic doses of 50 to 500 mg. of niacinamide per day cause the disappearance of glossitis in 24 hours and of lesions of the tongue and

lips in three to five days. Since uncomplicated niacin deficiency is comparatively rare, other members of the vitamin B complex are usually also administered in treating the disease.

Niacinamide is an essential constituent of diphosphopyridine and triphosphopyridine nucleotides (DPN and TPN, also known as coenzymes I and II, or codehydrogenases I and II), which participate in a large number of physiologically important oxidation reactions. These coenzymes occur in practically all cells and have been synthesized from niacin and niacinamide *in vitro* by nucleated cells. The structures of coenzyme I and of its reduction product, reduced coenzyme I, are shown below:

The structure of reduced coenzyme I is based upon the evidence presented by Pullman *et al.*<sup>138a</sup> that reduction involves saturation of the carbon atom para to the nitrogen in the pyridine ring, rather than ortho to it, as had been previously thought. Note furthermore that reduction involves the addition of only one hydrogen atom to a molecule of coenzyme; the second hydrogen furnishes an electron to the quaternary N and becomes a hydrogen ion. Hence the stoichiometry of the reaction is as follows:

TPN differs from DPN in that it contains an extra phosphoric acid group probably linked to the 2' position of the ribose moiety of adenosine. These coenzymes, in the presence of specific proteins, catalyze physiological oxidation reactions. Among the 35 different known reactions in which DPN participates are the oxidation of alcohol to acetaldehyde, of glucose to gluconic acid, of malic acid to oxalacetic acid, of lactic acid to pyruvic acid, and of glycerophosphate to phosphoglyceraldehyde. Among the enzyme reactions catalyzed by TPN are the conversion of Robison's ester (glucose-6-monophosphate) to phosphohexonic acid and of glutamic

<sup>138a</sup> Pullman, San Pietro, and Colowick: *J. Biol. Chem.*, **206**, 129 (1954).

acid to iminoglutamic acid. These enzymatic reactions are all reversible, and the reduced coenzymes may combine with their apoenzymes to catalyze physiological reductions. In practice there is a dynamic equilibrium which depends on the relative concentrations of the reduced and oxidized forms of the substrates and coenzymes and on other conditions. *In vitro* experiments indicate that reduced coenzymes I and II may be reoxidized by flavoprotein enzymes, and that coenzyme II may be converted to I by a phosphatase.<sup>139</sup> Both coenzymes are inactivated by enzymatic destruction when cells of brain, liver, kidney, or muscle are ruptured. In contrast to the riboflavin coenzymes, which are present in flavoproteins in simple numerical proportion to their apoenzymes, the niacinamide coenzymes are found in great excess and are bound only loosely to the protein moieties. The niacinamide prosthetic groups have been designated mobile coenzymes. DPN can be hydrolyzed by dilute alkali, the cleavage occurring between the niacinamide and ribose moieties. Similar splitting can be induced by enzymes (designated DPN nucleosidases) found in brain tissue<sup>140</sup> and in *Neurospora*.<sup>141</sup>

That dietary niacin is important in the maintenance of physiological enzyme systems is indicated by the positive correlation between the intake of the vitamin and the concentration of the coenzymes in the muscles.<sup>142</sup> Niacin is essential to the physiology of animals, plants, and microorganisms. All plants and some microorganisms synthesize the vitamin. Others—e.g., *C. diphtheriae*, lactic acid bacteria, and *B. dysenteriae*—require an external source, and still others—e.g., *B. influenzae*—require an external source of the coenzymes. Though the mold *Neurospora* does not ordinarily require niacin, a mutant strain produced by irradiation requires an external supply of the vitamin. Whereas niacin is essential to all animals, certain species, e.g., the rat and the horse, do not require dietary sources because their intestinal flora synthesize enough to meet metabolic needs. A dietary supply is required by the cotton rat, dog, pig, rabbit, chick, monkey, and man. However, even in these species, significant contributions are made by intestinal microorganisms. Urinary excretion studies<sup>143</sup> show that human subjects on a constant diet excrete lower concentrations of N<sup>1</sup>-methylnicotinamide (the principal metabolite of niacin and niacinamide found in human urine) after dosage with sulfaguanidine and succinylsulfathiazole which destroy intestinal bacteria. Microorganisms have been isolated from the human cecum<sup>144</sup> which synthesize niacin *in vitro*.

The amount of niacin required by animals from external sources depends upon the nature of the diet, particularly with regard to protein and carbohydrate. Endemic pellagra occurs almost exclusively in localities where corn is employed as a staple cereal. Populations which consume

<sup>141</sup> Kaplan, Colowick, and Nason: *J. Biol. Chem.*, **191**, 473 (1951).

<sup>142</sup> Anderson, Teply, and Elvehjem: *Arch. Biochem.*, **3**, 357 (1944).

<sup>143</sup> Ellinger, Coulson, and Benesch: *Nature*, **154**, 270 (1944); Ellinger, Benesch, and Kay: *Lancet*, **1**, 432 (1945).

<sup>144</sup> Benesch: *Lancet*, **1**, 718 (1945).

large quantities of rice rarely show pellagra even though their dietary intake of niacin is no more than 5 mg. per day, whereas maize-eaters develop pellagra despite much higher intakes.<sup>145</sup> Rats, which ordinarily synthesize their own niacin, show a typical niacin deficiency syndrome when fed a corn diet.<sup>146</sup> This may be prevented by adding either tryptophan or more protein. On an otherwise adequate diet, young growing pigs show little sign of niacin deficiency, though the amount of the vitamin ingested is small. A decrease in the protein of the ration, however, produces symptoms of niacin deficiency which may be prevented by administration of more of the vitamin.<sup>147</sup>

Since niacin deficiency in white rats on a corn diet is prevented by the administration of tryptophan, it appears that the lack of this amino acid, which is present in only low concentrations in corn, is responsible for the apparent increased requirement of many species for niacin. This effect may possibly be attributed to changes in the intestinal flora resulting in the loss of microorganisms which require tryptophan from which they are capable of synthesizing niacin. Tryptophan serves as a precursor for the biosynthesis of niacin not only by these microorganisms but in animal tissues as well. Hence pellagra must be viewed as a dual deficiency of both tryptophan and niacin. The possible existence of a pellagrigenic antivitamin (see Chapter 36) in corn has received consideration.

The effect of corn on the growth of white rats depends upon the nature of the carbohydrate ingested. When the latter is sucrose, considerable inhibition of growth occurs. However, when sucrose is replaced by glucose and dextrin, or partially replaced by lactose, the inhibition of growth does not occur.<sup>148</sup> Further evidence that the increased requirement for niacin is associated with the nature of dietary carbohydrate and with a diminished intake of tryptophan is provided by observations on white rats subsisting on a diet containing wheat gluten and gelatin, and deficient only in niacin and tryptophan. With sucrose as the source of carbohydrate, very poor growth resulted. The administration of tryptophan or niacin, or the substitution of glucose and dextrin for sucrose, restored normal growth.

The principal metabolite excreted in the urine of man, rats, dogs, and cats following the ingestion of niacin or niacinamide is N<sup>1</sup>-methylnicotinamide. Some nicotinamide but only small amounts of nicotinic acid are also excreted. However, rabbits and guinea pigs excrete principally nicotinic acid and practically no N<sup>1</sup>-methylnicotinamide.<sup>149</sup> The latter compound, after alkaline hydrolysis, reacts like niacin with cyanogen bromide and aniline, and because of its physical and chemical similarity to trigonelline (the betaine of N-methylniacin) was at first believed to be that compound.<sup>150</sup> N<sup>1</sup>-methylnicotinamide has the following structure:

<sup>145</sup> Aykroyd and Swaminathan: *Indian J. Med. Research*, **27**, 667 (1940).

<sup>149</sup> Ellinger and Abdel Kader: *Biochem. J.*, **44**, 627 (1949).

<sup>150</sup> Melnick and Field: *J. Biol. Chem.*, **134**, 1 (1940); Melnick, Robinson, and Field: *Ibid.*, **136**, 145 (1940); Field, Melnick, Robinson, and Wilkinson: *J. Clin. Invest.*, **20**, 379 (1941).

Pellagrins were observed to excrete only small quantities of this metabolite. Early tests for the diagnosis of niacin deficiency were based upon the colorimetric determination of urinary "trigonelline" after the ingestion of a test dose of the vitamin. It was subsequently discovered<sup>151</sup> that administration of niacin or niacinamide was followed by excretion of a metabolite which was readily converted to a highly fluorescent substance by alkalization and subsequent extraction with butanol. The urine of niacin-deficient subjects contained only small amounts of this compound, even after dosage with the vitamin. The metabolite was identified as N<sup>1</sup>-methylnicotinamide<sup>152</sup> and found to be identical with the compound measured colorimetrically after alkaline hydrolysis which had been erroneously designated "trigonelline." Humans in a normal state of nutrition excrete approximately 20 per cent of their intake of niacinamide in the form of the N<sup>1</sup>-methyl compound on a molar basis and approximately half of this amount when ingesting niacin.<sup>153</sup> The conversion of the latter to N<sup>1</sup>-methylnicotinamide requires both an amidation and a methylation, whereas niacinamide requires only the latter step. *In vitro* studies<sup>154</sup> show that rat liver (but not kidney or muscle) is capable of converting niacinamide, but not niacin, to N<sup>1</sup>-methylnicotinamide, the degree of conversion being increased by the addition of methionine.

The possibility that niacin or its amide acts physiologically in the form of N<sup>1</sup>-methylnicotinamide has been investigated with conflicting results. Some observers have found that the compound is capable of curing black-tongue,<sup>155</sup> but this has been disputed by others.<sup>156</sup> In man, N<sup>1</sup>-methylnicotinamide has been found to improve the dermatitis and glossitis of pellagra but simultaneously to aggravate the psychomotor symptoms.<sup>157</sup> The latter however, could be alleviated by the administration of thiamine and riboflavin. In view of these findings, the metabolic role of N<sup>1</sup>-methylnicotinamide remains to be established.

Certain derivatives of niacin and niacinamide are biologically active in higher animals when administered orally. These include various esters, and the ureide and diethylamide of niacin. These compounds are probably

<sup>157</sup> Vance: *Bull. Johns Hopkins Hosp.*, **77**, 393 (1945).

hydrolyzed in the gastrointestinal tract to niacin and niacinamide. Trigonelline, the betaine of N-methylniacin, is biologically inactive. It occurs naturally in a number of foods, especially legumes, coffee, and tobacco. A synthetic analog of niacin, pyridine-3-sulfonic acid, has been found to inhibit the growth of microorganisms requiring niacin or its amide.<sup>158</sup> 3-Acetylpyridine does not inhibit microbial growth but induces niacin deficiency in mice, a species which normally does not require a dietary supply of niacin.<sup>159</sup> This compound, because of its chemical similarity to niacin, probably acts by competition with the vitamin in physiological enzyme systems (see Chapter 36).

Wheat bran and other natural materials contain a compound which, upon heating with strong acid or alkali, behaves like niacin toward *Lactobacillus arabinosus*.<sup>160</sup> This compound is extracted from natural materials by heating with water or dilute acid, but must be subsequently hydrolyzed with strong acid or with alkali before it can stimulate the microorganism. Concentrates of the unhydrolyzed material have been prepared and found to be inactive when fed to chicks. After hydrolysis, the compound meets the niacin requirements of both the chick and the dog. Nikethamide ("Coramine"), niacin-diethylamide, exhibits similar behavior<sup>161</sup> in that it is inactive for *L. arabinosus* but is active after heating with alkali. Nikethamide is biologically active in higher animals.

Large doses of niacin dilate the superficial blood vessels. The administration of 50 mg. or more orally or of 10 mg. intravenously to humans not deficient in the vitamin produces flushing, itching, and burning of the skin, especially in areas subjected to pressure. Individuals vary greatly in their sensitivity to this reaction. The effect is observed only with the free acid and not with niacinamide, so that the latter is preferred for therapeutic purposes. The flushing reaction may be prevented by simultaneous administration of glycine which provides amino groups for conversion of the free vitamin to its amide.

Large doses of niacin or niacinamide are toxic to the rat because of the depletion of the methyl donor, methionine.<sup>162</sup> Niacinamide is more toxic than the free acid, since more N<sup>1</sup>-methylnicotinamide is excreted when the amide is fed. The toxicity is seen only in animals which excrete N<sup>1</sup>-methylnicotinamide after dosage with the vitamin. Large doses of niacinamide are not toxic to young rabbits and guinea pigs, which do not excrete the methylated derivative. The toxicity of large doses of the vitamin in rats may be prevented by feeding methionine, or choline plus homocystine (see p. 1030).

For further discussion of the clinical aspects of niacin, see the American Medical Association syllabus, p. 1291.

**Storage and Synthesis of Niacin.** No significant amount of niacin or its amide is stored passively in animal tissue. Higher concentrations are

<sup>158</sup> McIlvain: *Brit. J. Exptl. Path.*, **21**, 136 (1940).

<sup>159</sup> Woolley: *J. Biol. Chem.*, **157**, 455 (1945).

found in the liver, muscle, and kidney for the performance of metabolic functions. A decrease in the niacin intake of man is followed by a diminished concentration of the niacin coenzymes in the striated muscles, but has little effect on the coenzyme content of the erythrocytes.

Biosynthesis of niacin by plants and microorganisms, the importance of the contribution by intestinal flora in the nutrition of animals, and the effect of other dietary factors have been discussed above.

A number of practical syntheses for niacin and niacinamide are available for commercial use. The simplest of these include the nitric acid oxidation of nicotine obtained from tobacco or the oxidation of  $\beta$ -picoline or quinoline with potassium permanganate or in the vapor phase with air and metallic oxide catalysts. Niacinamide may be prepared from the free acid by heating with ammonia, from esters by treatment with alcoholic ammonia, or from 3-cyanopyridine by acid or alkaline hydrolysis in the presence of hydrogen peroxide and subsequent treatment with a quaternary ammonium resin.<sup>163</sup>

**Distribution of Niacin.**<sup>164</sup> In natural materials, niacin occurs predominantly as the amide, the form in which it is active biologically in enzyme systems. Good sources of the vitamin are liver, adrenal glands, fish, meats, whole wheat or rye, and enriched flour. The vitamin occurs in relatively high concentration as coenzyme I in yeast, red blood cells, and heart muscle. Fruits are poor sources of the vitamin, nuts are somewhat richer, and vegetables are variable, potatoes and legumes being generally higher than leafy varieties. Cow's milk may contain from about 1 mg. to as much as 5 mg. per quart, whereas human milk contains relatively less. Tea, coffee, and beer are good sources of niacin.

**Chemistry of Niacin.** Niacin (pyridine-3-carboxylic acid) is a white crystalline solid which melts at 236° C. and may be sublimed without destruction. The vitamin is stable to boiling in neutral, acid, or alkaline solution. The vitamin has an absorption maximum in the ultraviolet region at 385 m $\mu$ .

**Niacin (Nicotinic Acid)**

**Niacinamide**

Niacinamide crystallizes in light needles from benzene and melts at 129° C. It may be distilled at 150 to 160° at  $5 \times 10^{-4}$  mm. Niacinamide is more soluble in organic solvents than the free acid and, unlike the latter, may be extracted from water with ether. The amide has a characteristic absorption curve in the ultraviolet region with maxima at 210, 220, and 260 m $\mu$ . Niacinamide is readily hydrolyzed to free niacin by heating with acid or alkali.

Niacin and niacinamide react with cyanogen bromide in the presence of

<sup>163</sup> Galat: *J. Am. Chem. Soc.*, **70**, 3945 (1948).

<sup>164</sup> See Appendix III.

a primary or secondary amine to produce a compound having a yellow-green color. Colors are also formed with trigonelline, nicotinuric acid, and nicotine, as well as certain other pyridine compounds. This reaction is employed in the chemical determination of niacin. Since the amide produces only half the color of the free acid, it must first be hydrolyzed for the colorimetric test.

Coenzymes I and II (DPN and TPN) are colorless, water-soluble compounds, insoluble in organic solvents. Coenzyme II, however, is soluble in methanol-hydrochloric acid mixtures. Both coenzymes are relatively stable in acid solution but are readily decomposed by alkali. Coenzyme I has an absorption maximum at 260  $m\mu$ . It is nonfluorescent, optically active,  $[\alpha]_{546 m\mu} = -70^\circ$ , and is not precipitated by lead acetate, but does produce an insoluble cuprous salt. Reduced coenzyme I has an absorption maximum at 340  $m\mu$  and fluoresces upon ultraviolet irradiation. This compound is stable in alkali but is destroyed by acid in which it reverts to the oxidized form which is non-fluorescent. Coenzyme II has an absorption maximum at 360  $m\mu$ . Its optical rotation  $[\alpha]_{546 m\mu} = -29.4^\circ$ . Its cuprous salt is soluble but the coenzyme is precipitated by lead acetate.

**Determination of Niacin.** Accurate chemical and microbiological methods for the determination of niacin in natural materials are available. The chemical procedures involve reaction of the vitamin with cyanogen bromide in the presence of an amine. Extracts are prepared for chemical or microbiological assay by acid or alkaline hydrolysis, both to facilitate extraction and to hydrolyze niacinamide and a niacin precursor found in natural materials. In the chemical procedure, hydrolysis with acid results in the formation of furfural from the degradation of pentoses, which interferes with colorimetric reaction. This compound is separated from the niacin by adsorption of the vitamin on a hydrated aluminum silicate which does not adsorb the furfural. The niacin is subsequently eluted from the adsorbate by washing with alkali.

Because niacin and niacinamide have somewhat different physiological effects, it is sometimes desirable to determine their relative concentrations in mixtures. This may be accomplished chemically by time-reaction measurements conducted on the hydrolyzed and unhydrolyzed extracts.<sup>165</sup> The assay is based on the differences in the rate of formation of the yellow-green pigment with cyanogen bromide and aniline.

The microbiological determination of niacin is based upon the growth stimulation of *Lactobacillus arabinosus*. This organism responds equally to niacin and its amide. These compounds, however, may be differentiated microbiologically by destruction of the amide with bromine and potassium hydroxide (Hoffman degradation), converting it to  $\beta$ -amino-pyridine, which is microbiologically inert.<sup>166</sup> Differential microbiological assays may also be conducted to distinguish between the several metabolites of the vitamin, including niacin, its amide, nicotinuric acid, and N<sup>1</sup>-methyl-nicotinamide. Two microorganisms are employed, *Lactobacillus arabino-*

<sup>165</sup> Lamb: *Ind. Eng. Chem., Anal. Ed.*, **15**, 352 (1943); Melnick and Oser: *ibid.*, **15**, 355 (1943).

<sup>166</sup> Atkin, Schultz, Williams, and Frey: *J. Am. Chem. Soc.*, **65**, 992 (1943).

*sus*, which utilizes niacin, niacinamide, and nicotinuric acid, and *Leuconostoc mesenteroides*, for which only niacin is active.<sup>167</sup> Hydrolysis with 0.6 N sulfuric acid at 15 pounds pressure for one hour is also employed to convert the amide completely to free niacin without affecting nicotinuric acid. The microbiological assays are conducted in conjunction with the fluorometric test which measures only N<sup>1</sup>-methylnicotinamide. Differential assays such as those described above show that the major part (about 90 per cent) of the niacin metabolites excreted after the ingestion of the vitamin appears as N<sup>1</sup>-methylnicotinamide. Small amounts of niacin and niacinamide also occur in urine and somewhat larger amounts of the latter after the administration of large doses of the free acid. Human urine contains little if any nicotinuric acid except after large doses of free nicotinic acid.

The biochemical diagnosis of niacin deficiency is based upon the measurement of urinary excretion of N<sup>1</sup>-methylnicotinamide.<sup>168</sup> A satisfactory clinical test involves measurement of the 6-hour urinary excretion of N<sup>1</sup>-methylnicotinamide following the oral administration of 300 mg. niacinamide.<sup>169</sup>

Earlier clinical tests for the diagnosis of pellagra, based upon measurement of urinary "porphyrins," are not reliable since the color reaction has been found to be due to urochrome rather than to porphyrin and depends on the presence of other compounds in the urine.

**Modified Colorimetric Method of the Research Corporation:**<sup>170</sup> **Principle.** The method involves strong acid hydrolysis to convert derivatives to nicotinic acid, adsorption of the vitamin on Lloyd's reagent, clarification of the eluate with lead hydroxide, and reaction of nicotinic acid with cyanogen bromide and aniline to produce a yellow pigment which is measured photometrically.

**Procedure: Preparation of the Sample.** Hydrolyze a sample of tissue or food containing 100–500 µg. of niacin by heating in a boiling water bath with 75 ml. 4 N hydrochloric acid for 30–40 minutes. Cool and dilute to 100 ml. Transfer 25 ml. of the suspension to a narrow (18-mm. diameter) centrifuge tube calibrated at the 26.5-ml. mark. Adjust the pH to 0.5–1.0 with 18 N sodium hydroxide using 0.1 per cent methyl violet as an outside indicator.<sup>171</sup> Cool, add 2.5 g. Lloyd's reagent,<sup>172</sup> and shake 1 minute. Centrifuge and discard the supernatant liquid. Wash the residue twice with 10 ml. 0.2 N sulfuric acid, each time centrifuging and discarding the supernatant. Add 0.5 N sodium hydroxide to the 26.5-ml. mark and break up the precipitate with a stirring rod. Immerse the tube in a boiling water bath for 5 minutes, stirring the contents occasionally. Cool and centrifuge. Transfer the supernatant to another tube, add 1.6 g. finely divided lead nitrate, and shake vigorously for 1 minute. If the solution is still alkaline, add more lead nitrate until acid.

<sup>167</sup> Johnson: *J. Biol. Chem.*, **159**, 277 (1945).

<sup>168</sup> Huff and Perlzweig: *J. Biol. Chem.*, **150**, 395 (1943).

<sup>169</sup> Goldsmith: *Arch. Internal Med.*, **73**, 410 (1944).

<sup>170</sup> Melnick: *Cereal Chem.*, **19**, 553 (1942).

<sup>171</sup> Use one drop of sample to one drop of indicator on a spot plate. Match with the blue color given by one drop of 0.2 N sulfuric acid.

<sup>172</sup> A hydrated aluminum silicate obtained from Eli Lilly and Co., Indianapolis, Ind. When suspended in water, 2.5 g. occupies a volume of 1.5 ml.

Centrifuge and pour the clear supernatant into another tube. Neutralize with tertiary potassium phosphate and 20 per cent phosphoric acid.

Colorimetric measurements are made in a photoelectric photometer. Two center settings are necessary, one for evaluating the residual color in the test solution, the other for the color developed in the chemical reaction. Set the photometer at 100 per cent transmittance with 3 ml. water and 7 ml. alcoholic buffer.<sup>173</sup> With this setting read a solution of 3 ml. of the test extract plus 7 ml. of alcoholic buffer (*A*). Now set the photometer at 100 per cent transmittance with the reagent blank: 3 ml. water, plus 6 ml. cyanogen bromide solution<sup>174</sup> plus 1 ml. aniline solution.<sup>175</sup> Remove the tube and record the center setting. To 3 ml. of the test extract, add 6 ml. cyanogen bromide, and 10 minutes later 1 ml. aniline; read the solution 5 minutes later using the center setting obtained with reagent blank (*B*). Similarly read a solution containing 3 ml. of test extract, 10  $\mu$ g. of nicotinic acid in 0.1 ml. of an alcoholic solution, 6 ml. of cyanogen bromide, and 1 ml. of aniline (*C*).

CALCULATION. Convert galvanometer readings, *G*, to photometric density, *P.D.*, as follows:

$$P.D. = 2 - \log G$$

Then:

$$\frac{B - A}{1.01C - B} \times 10 \times \text{dilution factor} = \mu\text{g. nicotinic acid per g. sample}$$

**Comment.** Values obtained by the colorimetric method for nicotinic acid agree well with those obtained by microbiological assay of acid or alkaline extracts. Exhaustive aqueous extraction, without preliminary hydrolysis, removes all the nicotinic acid from cereal products but yields lower microbiological and chemical values. A nicotinic acid derivative other than nicotinamide is broken down by the hydrolytic procedure (see p. 1172).

**Determination of *N*<sup>1</sup>-Methylnicotinamide in Urine (Fluorometric Method of Hochberg, Melnick, and Oser):**<sup>176</sup> **Principle.** The method involves adsorption of a small urine aliquot at pH 4.5 on a column of synthetic zeolite, elution with potassium chloride solution, alkalization, extraction of the resulting compound with *n*-butanol, and measurement of the fluorescence.

**Procedure: Preparation of Sample.** Collect a 24-hour urine sample in an amber bottle containing 20 ml. 10 per cent sulfuric acid. Measure the volume. Dilute a 6-minute aliquot<sup>177</sup> with acetate buffer<sup>178</sup> to 50 ml., and pass the solution through the special adsorption column shown in Fig. 278, following the directions given for the colorimetric determination of thiamine. Elute the *N*<sup>1</sup>-methylnicotinamide with 15 ml. of a neutral 25 per cent solution of potassium chloride, passed down the wall of the hot condenser. Regenerate the

<sup>173</sup> Mix 980 ml. water, 15 ml. 15 per cent sodium hydroxide, 4 ml. 85 per cent phosphoric acid, and 167 ml. absolute ethyl alcohol.

<sup>174</sup> In a well-ventilated hood dissolve 20 g. cyanogen bromide crystals in 500 ml. cold water. Do not allow the crystals to come in contact with the skin since they produce serious burns.

<sup>175</sup> Four per cent redistilled aniline in absolute alcohol.

<sup>176</sup> Hochberg, Melnick, and Oser: *J. Biol. Chem.*, **158**, 265 (1945).

<sup>177</sup> Larger aliquots should not be taken, since incomplete absorption on the zeolite may result.

<sup>178</sup> Dissolve 7.5 g. sodium acetate in 1000 ml. of distilled water containing 1.0 ml. concentrated sulfuric acid. The pH is 4.5.

column by washing with water (see p. 1145). Pass a standard solution containing 50  $\mu$ g. of N<sup>1</sup>-methylnicotinamide chloride<sup>179</sup> in 50 ml. acetate buffer through the column in the same manner as the diluted urine samples.

**Fluorometric Measurement.** Mix the eluate and pipet a 5-ml. aliquot into each of two 30-ml. separatory funnels. To one, the blank, add 1 ml. of water followed by 16.5 ml. *n*-butanol. To the other, the test, add 16.5 ml. butanol, then 1 ml. 15 per cent sodium hydroxide. Stopper the vessels immediately and shake vigorously for 3 minutes. Centrifuge for 0.5 minute and discard the aqueous layer. Clarify the butanol by shaking with approximately 1 g. anhydrous sodium sulfate. Allow the butanol extracts to stand in the dark for 15 minutes during which the fluorescence reaches a maximum, then read in a fluorometer with appropriate light filters. Use a solution of quinine sulfate containing 0.2  $\mu$ g. per ml. in 0.1 N sulfuric acid to check the setting of the instrument.

**CALCULATION.** Calculate the 24-hour urinary excretion of N<sup>1</sup>-methylnicotinamide chloride, expressed in terms of niacinamide, using the formula,

$$50 \times \frac{G_u}{G_s} \times \frac{60}{M} \times 0.707 = \mu\text{g. niacinamide per 24 hr.}$$

*G<sub>u</sub>* and *G<sub>s</sub>* are the galvanometer deflections of the unknown and the standard, both corrected for their respective blanks. *M* is the period represented by the urinary aliquot, expressed in minutes, and 0.707 is the factor for conversion of N<sup>1</sup>-methylnicotinamide chloride to niacinamide.

**Comment.** N<sup>1</sup>-Methylnicotinamide is the principal derivative of niacinamide found in human urine. Average basal excretion values approximate 25–30 per cent of the dietary intake, with wide individual variations. The metabolite is excreted rapidly following ingestion of the vitamin, approximately 20 per cent appearing in the urine within 24 hours following dosage with 50–200 mg. niacinamide.

### ASSAY FOR NIACIN OR NIACINAMIDE

#### Microbiological Method of the U.S. Pharmacopeia XIV.<sup>180</sup>

**TEST SOLUTION OF THE MATERIAL TO BE ASSAYED.** Place the prescribed amount of

FIG. 278. Apparatus for the adsorption and elution of N<sup>1</sup>-methylnicotinamide in urine.

<sup>179</sup> The compound may be prepared by the method of Karrer, Schwazenbach, Benz, and Solmssen: *Helv. Chim. Acta*, **19**, 826 (1936); or it may be purchased from W. A. Taylor and Company, 7300 York Road, Baltimore, Md.

<sup>180</sup> Grateful acknowledgement for permission to reproduce this method is made to Dr. Lloyd C. Miller and the Board of Trustees of the U.S. Pharmacopeial Convention, Inc.

the material to be assayed in a flask of suitable size, and proceed by one of the methods given below.<sup>181</sup>

(a) *For dry or semi-dry materials that contain no appreciable amount of basic substances.* Add a volume of 1 N sulfuric acid equal in ml. to not less than ten times the dry weight of the material in g., but the resulting solution shall contain not more than 5.0 mg. of nicotinic acid per ml. If the material is not readily soluble, comminute it so that it may be evenly dispersed in the liquid, then agitate vigorously and wash down the sides of the flask with 1 N sulfuric acid.

Heat the mixture in an autoclave at 121° to 123° for 30 minutes and cool. If lumping occurs, agitate the mixture until the particles are evenly dispersed. Adjust the mixture to a pH of 6.8 with sodium hydroxide solution, dilute with water to make a final measured volume that contains approximately 0.1 µg. of nicotinic acid in each ml., and filter if the solution is not clear.

(b) *For dry or semi-dry materials that contain appreciable amounts of basic substances.* Add sufficient sulfuric acid solution to bring the pH of the mixture to between 5.0 and 6.0. Add such an amount of water that the total volume of liquid shall be equal in ml. to not less than ten times the dry weight of the sample in g., but the resulting solution shall contain not more than 5.0 mg. of nicotinic acid in each ml. Then add the equivalent of 10 ml. of 10 N sulfuric acid for each 100 ml. of liquid and proceed as directed under (a), beginning with the second sentence.

(c) *For liquid materials.* Adjust the material to a pH of 5.0 to 6.0 with either sulfuric acid solution or sodium hydroxide solution, and proceed as directed under (b), beginning with the second sentence.

**STANDARD NICOTINIC ACID STOCK SOLUTION I.** Dissolve 50 mg. of U.S.P. Nicotinic Acid Reference Standard, previously dried and stored in the dark in a desiccator over phosphorus pentoxide, in sufficient alcohol to make 500 ml. Store in a refrigerator. Each 1.0 ml. represents 100 µg. of U.S.P. Nicotinic Acid Reference Standard.

**STANDARD NICOTINIC ACID STOCK SOLUTION II.** To 100 ml. of stock solution I, add sufficient water to make 1000 ml. Store under toluene in a refrigerator. Each 1.0 ml. represents 10 µg. of U.S.P. Nicotinic Acid Reference Standard.

**STANDARD NICOTINIC ACID SOLUTION.** Dilute 10 ml. of stock solution II with sufficient water to make 1000 ml. Each 1.0 ml. represents 0.1 µg. of U.S.P. Nicotinic Acid Reference Standard. Prepare fresh standard solution for each assay.

#### BASAL MEDIUM STOCK SOLUTION

|                                                                              |        |
|------------------------------------------------------------------------------|--------|
| Acid-hydrolyzed Casein Solution.....                                         | 25 ml. |
| Cystine-Tryptophan Solution.....                                             | 25 ml. |
| Dextrose, Anhydrous.....                                                     | 10 g.  |
| Sodium Acetate, Anhydrous.....                                               | 5 g.   |
| Adenine-Guanine-Uracil Solution.....                                         | 5 ml.  |
| Riboflavin-Thiamine-Biotin Solution.....                                     | 5 ml.  |
| <i>p</i> -Aminobenzoic Acid-Calcium Pantothenate-Pyridoxine<br>Solution..... | 5 ml.  |
| Salt Solution A.....                                                         | 5 ml.  |
| Salt Solution B.....                                                         | 5 ml.  |

Dissolve the anhydrous dextrose and sodium acetate in the solutions previously mixed, and adjust to a pH of 6.8 with sodium hydroxide T.S. [Test Solution]. Finally add water to make 250 ml.

**ACID-HYDROLYZED CASEIN SOLUTION.** Mix 100 g. of vitamin-free casein with 500 ml. of constant-boiling hydrochloric acid (approximately 20 per cent HCl), and reflux

<sup>181</sup> The concentrations of the sulfuric acid and sodium hydroxide solutions used are not stated in each instance because these concentrations may be varied depending upon the amount of material taken for assay, volume of test solution, and buffering effect of material.

the mixture for 24 hours. Remove the hydrochloric acid from the mixture by distillation under reduced pressure until a thick paste remains. Redissolve the resulting paste in water, adjust the solution to a pH of 3.5 ( $\pm 0.1$ ) with sodium hydroxide T.S., and add water to make 1000 ml. Add 20 g. of activated charcoal, stir for 1 hour, and filter. Repeat the treatment with activated charcoal if the filtrate does not appear straw colored to colorless. Store under toluene in a refrigerator. Filter the solution if a precipitate forms upon storage.

**CYSTINE-TRYPTOPHAN SOLUTION.** Suspend 4.0 g. of L-cystine and 1.0 g. of L-tryptophan (or 2.0 g. of D,L-tryptophan) in 700 to 800 ml. of water, heat to 70° to 80° and add 20 per cent hydrochloric acid, dropwise, with stirring, until the solids are dissolved. Cool, and add water to make 1000 ml. Store under toluene in a refrigerator at a temperature not below 10°.

**ADENINE-GUANINE-URACIL SOLUTION.** Dissolve 0.1 g. each of adenine sulfate, guanine hydrochloride, and uracil, with the aid of heat, in 5.0 ml. of 20 per cent hydrochloric acid, cool, and add water to make 100 ml. Store under toluene in a refrigerator.

**RIBOFLAVIN-THIAMINE HYDROCHLORIDE-BIOTIN SOLUTION.** Prepare a solution containing, in each ml., 20  $\mu$ g. of riboflavin, 10  $\mu$ g. of thiamine hydrochloride, and 0.04  $\mu$ g. of biotin, by dissolving crystalline riboflavin, crystalline thiamine hydrochloride, and crystalline biotin (free acid) in 0.02 N acetic acid. Store, protected from light, under toluene in a refrigerator.

**p-AMINOBENZOIC ACID-CALCIUM PANTOTHENATE-PYRIDOXINE HYDROCHLORIDE SOLUTION.** Prepare a solution in neutral 25 per cent alcohol to contain 10  $\mu$ g. of p-aminobenzoic acid, 20  $\mu$ g. of calcium pantothenate, and 40  $\mu$ g. of pyridoxine hydrochloride in each ml. Store in a refrigerator.

**SALT SOLUTION A.** Dissolve 25 g. of monobasic potassium phosphate and 25 g. of dibasic potassium phosphate in water to make 500 ml. Add 5 drops of hydrochloric acid and store under toluene.

**SALT SOLUTION B.** Dissolve 10 g. of magnesium sulfate, 0.5 g. of sodium chloride, 0.5 g. of ferrous sulfate, and 0.5 g. of manganese sulfate in water to make 500 ml. Add 5 drops of hydrochloric acid and store under toluene.

**STOCK CULTURE OF LACTOBACILLUS ARABINOSUS 17-5.** Dissolve 2.0 g. of water-soluble yeast extract in 100 ml. of water, add 0.5 g. of anhydrous dextrose, 0.5 g. of anhydrous sodium acetate, and 1.5 g. of agar, and heat the mixture, with stirring, on a steam bath, until the agar dissolves. Add approximately 10-ml. portions of the hot solution to test tubes, plug the tubes with cotton, sterilize in an autoclave at 121° to 123°, and allow the tubes to cool in an upright position. Prepare stab cultures in 3 or more of the tubes, using a pure culture of *Lactobacillus arabinosus* 17-5,<sup>182</sup> incubating for 16 to 24 hours at any selected temperature between 30° and 37° but held constant to within  $\pm 0.5^\circ$ , and finally store in a refrigerator. Prepare a fresh stab of the stock culture every week and do not use for inoculum if the culture is more than 1 week old.

**CULTURE MEDIUM.** To each of a series of test tubes containing 5.0 ml. of the basal medium stock solution, add 5.0 ml. of water containing 1.0  $\mu$ g. of nicotinic acid. Plug the tubes with cotton, sterilize in an autoclave at 121° to 123°, and cool.

**INOCULUM.** Make a transfer of cells from the stock culture of *Lactobacillus arabinosus* 17-5 to a sterile tube containing 10 ml. of culture medium. Incubate this culture for 16 to 24 hours at any selected temperature between 30° and 37° but held constant to within  $\pm 0.5^\circ$ . The cell suspension so obtained is the inoculum.

**Assay Procedure.** Prepare standard nicotinic acid tubes as follows: To duplicate test tubes, add 0.0 ml., 0.5 ml., 1.0 ml., 1.5 ml., 2.0 ml., 2.5 ml., 3.0 ml., 3.5 ml., 4.0 ml., 4.5 ml., and 5.0 ml., respectively, of the standard

<sup>182</sup> Pure cultures of *Lactobacillus arabinosus* 17-5 may be obtained from the American Type Culture Collection, 2029 M Street, N. W., Washington 6, D. C., as number 8014.

nicotinic acid solution. To each tube add 5.0 ml. of basal medium stock solution and water to make 10 ml.

Prepare tubes containing the material to be assayed as follows: To duplicate test tubes add, respectively, 1.0 ml., 2.0 ml., 3.0 ml., and 4.0 ml. of the test solution of the material to be assayed. To each tube add 5.0 ml. of basal medium stock solution and water to make 10 ml. After mixing, plug the tubes with cotton or cover with caps, and sterilize in an autoclave at  $121^{\circ}$  to  $123^{\circ}$ .<sup>183</sup> Cool, aseptically inoculate each tube with 1 drop of inoculum, and incubate for 72 hours at any selected temperature between  $30^{\circ}$  and  $37^{\circ}$ , but held constant to within  $\pm 0.5^{\circ}$ . Contamination of the assay tubes with any foreign organism invalidates the assay.

Titrate the contents of each tube with 0.1 N sodium hydroxide, using bromothymol blue T.S. as the indicator, or to a pH of 6.8 measured electrometrically.

CALCULATION. Prepare a standard curve of the nicotinic acid standard titrations by plotting the average of the titration values expressed in ml. of 0.1 N sodium hydroxide for each level of the nicotinic acid standard solution used, against  $\mu\text{g.}$  of nicotinic acid contained in the respective tubes. From this standard curve, determine by interpolation the nicotinic acid content of the test solution in each tube. Discard any values of more than 0.40 or less than 0.05  $\mu\text{g.}$  of nicotinic acid in each tube. Calculate the nicotinic acid content in each ml. of the test solution for each of the tubes. The nicotinic acid content of the test material is calculated from the average of the values obtained from not less than 6 of these tubes that do not vary by more than  $\pm 10$  per cent from the average. If the titration values of less than 6 of these tubes containing the test solution are within the range of the titration values of the nicotinic acid standard tubes containing 0.05 to 0.40  $\mu\text{g.}$  of nicotinic acid, the data are insufficient to permit calculation of nicotinic acid content of the test material. Titration values exceeding 1.0 ml. for the tubes of the standard nicotinic acid solution series containing 0.0 ml. of the solution indicate the presence of an excessive amount of nicotinic acid in the basal medium stock solution and invalidate the assay.

## PYRIDOXINE AND RELATED COMPOUNDS (VITAMIN B<sub>6</sub>)

Goldberger and Lillie in 1926 reported the development of a characteristic dermatitis, called acrodynia, in rats fed a diet deficient in what they regarded as the pellagra-preventive (P-P) factor. In 1934, recognizing the multiple nature of the vitamin B complex, P. György<sup>184</sup> designated the missing factor vitamin B<sub>6</sub>, the rat pellagra-preventive factor, the deficiency being characterized by edema and denuding of the paws and the areas around the nose and mouth, and thickening of the ears. Lack of this vitamin was also shown to induce microcytic hypochromic anemia and neurologic lesions in dogs and pigs. Vitamin B<sub>6</sub> attracted so much attention that within one year, 1938, it was isolated independently by five groups—Lepkovsky; Keresztesy and Stevens; P. György; Kuhn and Wendt; and Itiba and Miti. In the following year, the chemical structure was elucidated and the compound was synthesized independently by Keresztesy, Stevens, Harris, Stiller, and Folkers in the United States and by Kuhn, Westphal, Wendt, and Westphal in Germany. The vitamin was named pyridoxine by the American investigators and adermin by the Germans.

<sup>183</sup> Overheating of the assay tubes during sterilization may produce unsatisfactory results.

<sup>184</sup> György: *Nature*, **133**, 498 (1934).

It should be noted that the term vitamin B<sub>6</sub> includes not only pyridoxine but pyridoxal and pyridoxamine as well, all three compounds being found in nature.

This is the reason for the anomalous results obtained in microbiological<sup>185</sup> and chemical assays<sup>186</sup> for vitamin B<sub>6</sub> which led to the discovery of the aldehyde and amine derivatives, pyridoxal and pyridoxamine. These derivatives have biological activity equal to that of pyridoxine for rats and somewhat less for chicks, but their utilization by microorganisms varies considerably. All three compounds are equally active for *Saccharomyces carlsbergensis*, while pyridoxal and pyridoxamine are less active than pyridoxine for *Saccharomyces cerevisiae*; on the other hand the aldehyde and amine are relatively more active for *L. helveticus* or *S. fecalis* R, and only pyridoxal has activity for *L. casei*. Evidence suggests the existence of members of the vitamin B<sub>6</sub> complex as yet unknown.<sup>187</sup> It is probable that these are known forms bound in such a way that they are not released by conventional methods of hydrolysis.

**Physiological and Clinical Aspects of Pyridoxine.** Deficiency of vitamin B<sub>6</sub> in rats causes acrodynia (see Fig. 279), edema, inhibition of growth, and nerve degeneration. The vitamin is essential for the chick, rat, dog, and pig, and for numerous microorganisms. The significance of the vitamin is claimed to be related in part to the metabolism of unsaturated fatty acids. The dermatitis observed in vitamin B<sub>6</sub> deficiency closely resembles that noted in cases of fatty acid deficiency. Some observers have reported that the addition of certain unsaturated fatty acids to a diet deficient in vitamin B<sub>6</sub> protects against the appearance of the deficiency syndrome of the vitamin.

The role of pyridoxine in amino acid metabolism is illustrated by the increased severity of symptoms upon the addition to a pyridoxine-poor diet of supplemental levels of cystine, methionine, tryptophan, glycine, or serine. Pyridoxine-deficient infants<sup>188</sup> or rats<sup>189</sup> lose their normal capacity to form niacin and N<sup>1</sup>-methylnicotinamide from tryptophan. However the dependence of the tryptophan conversion on pyridoxine is questioned by some investigators.<sup>190</sup> Vitamin B<sub>6</sub> deficiency in rats and swine is characterized by the appearance in the urine of xanthurenic acid, a metabolite of tryptophan. All three known members of the vitamin B<sub>6</sub> group—pyridoxine, pyridoxal, and pyridoxamine—are converted by organisms capable of utilizing them into amino acid decarboxylases.<sup>191</sup> Pyridoxal phosphate functions as a coenzyme which, when combined with the apoenzyme (the protein moiety of the enzyme), such as is present in *Streptococcus fecalis* R grown in a medium deficient in vitamin B<sub>6</sub>, catalyzes

<sup>185</sup> Snell: *J. Biol. Chem.*, **157**, 491 (1945).

<sup>190</sup> Sarett: *J. Biol. Chem.*, **182**, 691 (1950).

Heimberg, Rosen, Leder, and Perlzweig: *Arch. Biochem.*, **28**, 225 (1950).

<sup>191</sup> Gunsalus and Bellamy: *J. Biol. Chem.*, **155**, 357 (1944); Bellamy, Umbreit, and Gunsalus: *J. Biol. Chem.*, **160**, 461 (1945); O'Kane and Gunsalus: *J. Biol. Chem.*, **170**, 425, 433 (1947).

decarboxylation reactions. Amino acids reported to require pyridoxal phosphate as a coenzyme for decarboxylation include tyrosine, lysine, arginine, ornithine, glutamic acid, and dioxyphenylalanine ("dopa") the end products being, respectively, tyramine, cadaverine, agmatine, putrescine,  $\gamma$ -aminobutyric acid, and 3,4-dihydroxyphenylethylamine.

FIG. 279. Pyridoxine-deficient rat.  
Note edema and dermatitis of paws and nose.

The high specificity of decarboxylation reactions permits their use for analytical purposes. Glutamic acid decarboxylase is present in the brain tissue of rats, and in vitamin B<sub>6</sub>-deficiency it is the pyridoxal phosphate coenzyme that is depleted rather than the apoenzyme.<sup>192</sup>

The same coenzyme, pyridoxal phosphate, has been demonstrated to function in transamination reactions<sup>193</sup> of which the following is an

<sup>192</sup> For studies of this glutamic acid decarboxylase, see papers by Awapara, *et al.*; Udenfriend; and Roberts, *et al.* in *J. Biol. Chem.*, 1950-51.

<sup>193</sup> Lichstein, Gunsalus, and Umbreit: *J. Biol. Chem.*, **161**, 311 (1945).

example. Such reactions are suggested as the explanation of the growth response of rats to keto and hydroxy analogs of certain amino acids.<sup>194</sup> Evidence also indicates that vitamin B<sub>6</sub> participates in enzyme systems involved in the synthesis of amino acids by microorganisms.

The fact that pyridoxine derivatives play a part in such a variety of amino acid reactions would seem to justify the belief that vitamin B<sub>6</sub> is required in the nutrition of man, as it is for rodents, fowl, and other species. While no clear-cut deficiency syndrome is seen clinically which is comparable to thiamine or niacin deficiency, vitamin B<sub>6</sub> deficiency has been produced experimentally in man.<sup>195</sup> The daily human requirement of vitamin B<sub>6</sub>, estimated chiefly on the basis of animal experiments, is 2 mg. The vitamin B<sub>6</sub> compounds are excreted mainly as 4-pyridoxic acid.

Pyridoxine has been used clinically in acne and other dermatologic disorders, but its value has yet to be conclusively demonstrated. Parkinson's disease, muscular dystrophy, and especially nausea and vomiting of pregnancy are among the conditions which have been treated with pyridoxine, but the results are too indefinite to justify associating these conditions with vitamin deficiencies. Clinical vitamin deficiencies, particularly of the B group, generally are of a multiple nature. Pellagrins who responded only partially to the administration of thiamine, riboflavin, and niacin showed considerable improvement after intravenous administration of pyridoxine.

**Storage and Synthesis of Vitamin B<sub>6</sub>.** Vitamin B<sub>6</sub> is present in most animal tissues, with high concentrations in the liver. It is synthesized by bacteria in the rumen of sheep and cattle.

**Distribution of Vitamin B<sub>6</sub>.**<sup>196</sup> In natural materials vitamin B<sub>6</sub> occurs principally bound to proteins. Rich sources are yeast and rice polishings. Seeds and cereals are good sources, especially the germ. In rice bran the vitamin is present to a small extent in the free form, but a major portion is a bound complex of pyridoxine, readily hydrolyzable by heating with strong acids. Pyridoxine was isolated from rice polishings in 1932 by Ohdake before its identity as a vitamin was known. In yeast and liver, it is present chiefly as bound pyridoxamine, though small concentrations of pyridoxine and pyridoxal are also found.

<sup>196</sup> See Appendix IV.

**Chemistry of Vitamin B<sub>6</sub>.** Pyridoxine hydrochloride is a white, odorless, slightly bitter, crystalline solid, melting at 207° C. with slight decomposition. It is optically inactive and very soluble in water, slightly soluble in 95 per cent alcohol and in acetone, and insoluble in ether. The free base is also a colorless, crystalline solid, melting at 160° C. It is soluble in water, acetone, and alcohol, and slightly soluble in ether and chloroform. The aqueous solution of pyridoxine hydrochloride has a pH of approximately 3. It is adsorbed from acid solution on zeolite, charcoal, or fuller's earth, and may be eluted from zeolite with 10 per cent potassium chloride or from fuller's earth with a weak alkali. The structures of pyridoxine (2-methyl-3-hydroxy-4,5bis(hydroxymethyl)pyridine), pyridoxal, and pyridoxamine are:

Pyridoxine

Pyridoxal

Pyridoxamine

Pyridoxine, pyridoxamine, and pyridoxal can be separated by paper chromatography and distinguished by their relative positions on the strip. For this purpose a "bioautographic" procedure developed in the senior authors' laboratory<sup>197</sup> is used. The developed strip is laid flat on an agar plate containing a B<sub>6</sub>-deficient medium and lightly seeded with *Saccharomyces carlsbergensis*, an organism capable of utilizing any of these forms of the vitamin. After incubation, the loci of B<sub>6</sub>-factors on the strip are recognized by the zones of yeast growth.

Early chemical and microbiological studies of vitamin B<sub>6</sub> were complicated by the presence of the several forms, and by the facility of transformation of one compound to another. Conditions favoring amination or partial oxidation of pyridoxine result in the formation of some of the amine or aldehyde. This is attended by considerable change in the capacity for growth stimulation of certain microorganisms.

The three known forms of vitamin B<sub>6</sub> possess characteristic absorption curves in the ultraviolet region of the spectrum. These curves show no absorption maximum common to all three compounds. However, the total concentration of vitamin B<sub>6</sub> present in a solution relatively free of interfering substances may be determined by measurement at 325 mμ and pH 6.75. Under these conditions, the  $E_{1\text{ cm}}^{1\%}$  value for each of the compounds is 440.<sup>186</sup>

Pyridoxine, pyridoxal, and pyridoxamine are destroyed by exposure to light. Destruction is most rapid in the ultraviolet region of the spectrum in neutral or alkaline solution. Though all three compounds are comparatively stable to light in 0.1 N acid, pyridoxamine is slightly sensitive. The photolysis of vitamin B<sub>6</sub> is not affected by the presence of air. All three forms of the vitamin are stable to heating at 100° C. with 5 N sulfuric or hydrochloric acid; only pyridoxal is unstable to heat in alkaline solutions. All three compounds are stable to mild oxidizing agents like

## DETERMINATION OF VITAMIN B<sub>6</sub>

Cc1cc(CO)c(CO)c(O)c1 + ClN=C1C=CC(=O)C=C1Cl >> COc1cc(CO)c(O)c(Cc2cc(Cl)c(Cl)c(=O)n2)c1 + Cl

Pyridoxine + 2,6-Dichloroquinone chloroimide → Blue dye + HCl

Microbiological methods for the determination of vitamin B<sub>6</sub> are based on the growth stimulation of yeast or bacteria. These are complicated by the variable responses of the microorganisms to the different forms of the vitamin. All three forms have equal activity on a molar basis for *Saccharomyces carlsbergensis*. For *Saccharomyces cerevisiae*, however, the amine has 40 per cent, and the aldehyde 46 per cent, of the activity of pyridoxine. Though pyridoxine itself is inactive for *Lactobacillus casei* and *Streptococcus fecalis* R, pyridoxal is active and pyridoxamine inactive for the former, whereas pyridoxamine is active and pyridoxal 36 per cent as active as pyridoxamine for the latter. Assuming that vitamin B<sub>6</sub> complex contains no other members than pyridoxine, pyridoxal, and pyridoxamine, differential assays may be conducted on natural materials or on mixtures of the three synthetic forms, employing several microorganisms. Such assays are difficult, however, because of the ease of conversion from one form to any other. Pyridoxal when autoclaved with hydrolyzed casein produces some pyridoxamine, resulting in increased activity for *S. fecalis*. The reverse of this transamination reaction occurs when pyri-

doxamine is autoclaved with  $\alpha$ -ketoglutaric acid. Such treatment results in increased activity for *L. casei* and decreased activity for *S. fecalis*. Autoclaving pyridoxine with cystine, glycine, ammonia, or thioglycolic acid or treating with hydrogen peroxide results in the formation of "pseudopyridoxine" (probably pyridoxal and pyridoxamine), having increased biological activity for lactic acid organisms. Attempts have been made to prevent these transamination or partial oxidation reactions by sterilizing the hydrolyzed samples and the microbiological media separately, and then combining them aseptically. Such procedures, however, may not give a true picture of the concentrations of the various forms originally present in the test materials, since the undesirable conversions may occur during the sterilization of the samples themselves. When animal tissues are autoclaved with pyridoxine, the activity for certain lactic acid bacteria may increase several thousandfold. Moreover, the differential assays are based on the assumption that pyridoxine, pyridoxal, and pyridoxamine are the only existing forms of vitamin B<sub>6</sub>.

Certain anomalous results obtained in the assay of natural materials for vitamin B<sub>6</sub> have been interpreted to indicate the presence of forms of the vitamin as yet unknown. The bound pyridoxine in rice bran concentrates is completely liberated by autoclaving with 2 N sulfuric acid, so that analysis of such hydrolyzates with *Saccharomyces carlsbergensis* gives values agreeing with those of the rat assay. Hydrolysis of yeast and liver samples by the same treatment, however, gives low values by the microbiological procedure. When the sample is hydrolyzed by heating with comparatively weak acid, 0.055 N sulfuric, the values agree with those found in the rat assay. The low results are not attributable to destruction of the known forms of vitamin B<sub>6</sub> by the strong acid treatment, since pyridoxine, pyridoxal, or pyridoxamine may be heated in the presence of yeast and liver without measurable destruction.

Since all members of the vitamin B<sub>6</sub> complex, both known and unknown, have equal activity for *Saccharomyces carlsbergensis* and for the rat, reliable microbiological assays of natural materials may be made employing this microorganism. As described above, the concentration of sulfuric acid required for the hydrolytic liberation of bound forms of the vitamin varies with the type of product under assay. Hence careful attention must be given to this preliminary step. To destroy thiamine which, under certain conditions, may interfere with the pyridoxine assay, it has been suggested that the sample be hydrolyzed with N sodium hydroxide under pressure.<sup>198</sup>

Biological procedures have been described for the estimation of vitamin B<sub>6</sub> based on the growth of rats and on the cure of specific rat dermatitis. Of these, the methods of Dimick and Schreffler<sup>199</sup> and of Sarma, Snell, and Elvehjem<sup>200</sup> have been widely used. The latter authors have also reported a chick-growth assay.

The principal urinary excretion product resulting from the ingestion of pyridoxine by man is pyridoxic acid (2-methyl-3-hydroxy-4-carboxy-5-

<sup>198</sup> Morris, Herwig, and Jones: *Analyst*, 74, 37 (1949).

<sup>199</sup> Dimick and Schreffler: *J. Nutrition*, 17, 23 (1939).

<sup>200</sup> Sarma, Snell, and Elvehjem: *J. Biol. Chem.*, 165, 55 (1946).

hydroxymethyl pyridine). This compound is converted by heating with strong acid to a highly fluorescent lactone which can be determined by simple fluorometric means.<sup>201</sup> This reaction is useful in metabolic studies of vitamin B<sub>6</sub>.

**Determination of the Vitamin B<sub>6</sub> Complex (Microbiological Method of Atkin, Schultz, Williams, and Frey):**<sup>202</sup> **Principle.** The growth stimulation of a strain of the yeast *Saccharomyces carlsbergensis* by vitamin B<sub>6</sub> is employed for the microbiological assay of the vitamin.

**Procedure: Preparation of Yeast Inoculum.** Prepare a fresh slant of Culture 4228 (American Type Culture Collection), a strain of *Saccharomyces carlsbergensis*, on "Difco" malt agar and incubate for 24 hours at 30° C. Remove a quantity of fresh growth with a sterile wire loop and suspend in 10 ml. sterile 0.9 per cent saline in a colorimeter tube. With the aid of a densitometer<sup>203</sup> or photoelectric colorimeter, adjust the concentration to an equivalent of 1 mg. moist yeast per ml. by adding sterile saline. Dilute 5 ml. of the adjusted suspension with 45 ml. saline in a sterile Erlenmeyer flask.

**Preparation of the Sample.** Suspend a portion of the sample containing between 2 and 4 µg. vitamin B<sub>6</sub> in 180 ml. 0.055 N sulfuric acid.<sup>204</sup> Autoclave at 15 pounds pressure for 1.5 hours, cool, neutralize to pH 5.2, and dilute to 200 ml. Centrifuge if turbid and assay the clear supernatant extract.

**Preparation of Basal Medium.** Mix 100 ml. sugar and salts solution,<sup>205</sup> 20 ml. potassium citrate buffer, 20 ml. casein hydrolyzate, 10 ml. thiamine solution, 10 ml. inositol solution, 4 ml. biotin solution, 5 ml. calcium pantothenate solution, and 10 ml. niacin solution. Dilute to 200 ml.

**Microbiological Assay.** Place 5 ml. basal medium in each of a series of 18-mm. pyrex test tubes. In successive tubes pipet respectively 0.25, 0.50, 1.00, 2.00, 3.00, and 4.00 ml. of extract. With each assay series also include a reference series consisting of tubes containing 0, 5, 10, 15, 20, 30, and 40 millimicrograms pyridoxine hydrochloride. Adjust the total volume in each tube to 9 ml. Plug the tubes and steam for 10 minutes and cool. Under aseptic

<sup>201</sup> Huff and Perlzweig: *J. Biol. Chem.*, **155**, 345 (1944).

<sup>202</sup> Atkin, Schultz, Williams, and Frey: *Ind. Eng. Chem., Anal. Ed.*, **15**, 141 (1943). The addition of niacin to the basal medium was proposed by Hopkins and Pennington: *Biochem. J.*, **41**, 110 (1947).

<sup>203</sup> Calibrate the densitometer with a suspension of moist baker's yeast.

<sup>204</sup> Some materials, wheat, and wheat products require more acid. For such samples use 2.0 N sulfuric acid.

<sup>205</sup> *Sugar and Salts Solution.* Dissolve 200 g. C.P. dextrose (anhydrous), 2.2 g. monopotassium phosphate, 1.7 g. potassium chloride, 0.5 g. calcium chloride dihydrate, 0.5 g. magnesium sulfate, 0.01 g. ferric chloride, and 0.01 g. manganese sulfate in distilled water and dilute to 1000 ml.

*Potassium Citrate Buffer.* Dissolve 100 g. potassium citrate monohydrate and 20 g. citric acid monohydrate in distilled water and dilute to 1 liter.

*Casein Hydrolyzate Solution.* Neutralize 80 ml. "vitamin-free" casein hydrolyzate (10 per cent solution, obtainable from General Biochemicals, Inc., Chagrin Falls, O.) to pH 4-6 and dilute to 100 ml.

*Thiamine Solution.* 10 µg. per ml.

*Inositol Solution.* 1 mg. per ml.

*Biotin Solution.* 0.8 µg. per ml.

*Calcium Pantothenate Solution.* 200 µg. per ml.

*Niacin Solution.* 0.1 mg. per ml.

conditions introduce into each tube 1 ml. of the yeast inoculum. Place the tubes in a mechanical shaker for 16–18 hours at 30° C. Immediately thereafter estimate the yeast growth turbidimetrically in a densitometer or photo-electric colorimeter with a 660 or 720 m $\mu$  filter.<sup>206</sup>

CALCULATION. Plot the results of the reference series in per cent absorption against m $\mu$ g. of pyridoxine hydrochloride. Estimate the values for the unknowns from the graph. Calculate the pyridoxine content of the sample for each tube. Average all values which agree within 10 per cent of their mean.

**Interpretation.** The vitamin B<sub>6</sub> group consists of pyridoxine, pyridoxal, pyridoxamine, and one or more unidentified labile factors. All members of the complex show comparable activity for *Saccharomyces carlsbergensis* (Culture 4228) and the rat. Hence this procedure measures biological vitamin B<sub>6</sub> activity rather than the concentration of pyridoxine or any single derivative.

## PANTOTHENIC ACID

Bios, a growth stimulant essential for yeast, was described in 1901 by Wildiers.<sup>207</sup> Numerous attempts were made to elucidate the nature of this factor (or, as later discovered, factors), but not until 1933 was a crystalline product isolated by R. J. Williams and his co-workers,<sup>208</sup> who called it *pantothenic acid* (and later suggested *pantothen*) to indicate its universal distribution. In the meantime, other groups of workers were interested in an extract prepared from liver, variously designated “filtrate factor,” “chick antidermatitis factor,” or Factor II, which was found to be necessary to restore growth and prevent a severe dermatitis in chicks receiving a diet of heated grains. The introduction of microbiological assays using lactic acid bacteria stimulated progress along these lines which were merged in 1939. Jukes,<sup>209</sup> testing potent concentrates of Williams’ yeast-growth factor on chicks, showed it to be identical with the “filtrate factor,” and Woolley, Waisman, and Elvehjem<sup>210</sup> showed that it was a derivative of  $\beta$ -alanine which Williams had reported to be a cleavage product of pantothenic acid.

The crystallization of pantothenic acid, its structure, and finally its synthesis were reported in 1940 by the Merck group of investigators.<sup>211</sup> Pantothenic acid is available commercially as the calcium and sodium salts.

**Physiological and Clinical Aspects of Pantothenic Acid.** The wide distribution of pantothenic acid in animal and plant tissues gave

---

<sup>206</sup> In almost every case pigments, when present in the test extracts, absorb light maximally in the visible spectrum at about 400 to 450 m $\mu$ , but not to any extent in the range 660 to 720 m $\mu$ . Thus with the use of a proper filter no interference results from the increasing pigmentation of the solution with increasing quantities of test extract. In any case it is recommended that a separate tube containing 4.00 ml. test extract plus 1 ml. of water (no inoculum) be included in the series. Readings of this solution allow proportional corrections of the photometric densities of the serial tubes for absorption due to interfering pigments.

indication that it plays a fundamental role in metabolism. The nature of its function has become clear since the discovery by Lipmann and associates<sup>212</sup> of coenzyme A, of which pantothenic acid is a molecular component. It is now believed that coenzyme A is the functional form of pantothenic acid in plant and animal tissues and in microorganisms.

Pantothenic acid is required by the chick, rat, pig, dog, and other vertebrates. Deficiency symptoms are quite varied in different species. In the chick, the syndrome includes keratitis, dermatitis, fatty liver, lesions of the spinal cord, and involution of the thymus; the vitamin is necessary for reproduction in hens but not for egg production. In rats, insufficient intake of dietary pantothenic acid results in necrotic lesions of the adrenal cortex and other related symptoms. Regulation of salt and water balance are functions of the adrenal cortex. Pantothenic acid deficiency results in increased appetite for salt, and a low-salt diet promotes the graying of hair which results from pantothenic acid deficiency. Deprivation of water produces "bloody whiskers" (i.e., porphyrin staining) in rats, a condition also brought about by pantothenic acid deficiency.

Achromotrichia or graying of hair in black rats ("rusting" in white rats) on diets lacking pantothenic acid, and similar phenomena in dogs and foxes, probably are due to a complex deficiency, since pantothenic acid itself is less effective than extracts containing mixtures of B-complex factors. Pantothenic acid has not been established to be of specific value in restoring the color to human gray hair.

The "spectacled eye" condition in rats, associated with a deficiency of inositol or biotin, may develop in the absence of sufficient pantothenic acid. Pantothenic acid is required in the metabolism of all bacteria. Those which do not require an external supply synthesize it themselves. Dietary deficiency of this factor may result in secondary vitamin deficiencies due to diminished synthesis by intestinal flora.

The physiologically active form of pantothenic acid in the animal organism appears to be coenzyme A. This coenzyme (abbreviated CoA) participates in a wide variety of reactions involving the transfer of acetate or two-carbon units. Its acetyl derivative (acetyl CoA)

is considered to be synonymous with "active acetate" and has been described as the "pivot on which acetyl transfer mechanisms turn."<sup>213</sup> However, it is necessary to point out that many of these metabolic transformations are quite complex and involve the mediation of numerous enzymes and coenzymes. CoA participates in the acetylation of amines; examples are sulfanilamide, glycine, etc. In these reactions the carbonyl group of the acetyl radical is involved:

<sup>212</sup> Lipmann, Kaplan, Novelli, Tuttle, and Guirard: *J. Biol. Chem.*, **167**, 869 (1947); **186**, 235 (1950).

<sup>213</sup> Welch and Nichol: *Ann. Rev. Biochem.*, **21**, 633 (1952).

In contrast with this mechanism, the methyl group is involved in CoA condensation reactions such as the formation of citric from oxalacetic acid:

a reaction mediated by a condensing enzyme.<sup>214</sup>

It is believed that all substances (e.g., acetaldehyde, acetate) entering the tricarboxylic acid cycle as two-carbon fragments generate acetyl CoA.<sup>215</sup> This may be illustrated by the following reactions for acetate and pyruvate:

The foregoing indicates, in part at least, the vital role played by the pantothenic acid coenzyme in carbohydrate metabolism. Acetyl transfer also occurs in the metabolism of fatty acids and  $\beta$ -keto fatty acids. *In vitro* studies on butyrate oxidation<sup>216</sup> have suggested that for every two carbons of a fatty acid chain one mole of acetyl CoA is generated; in a secondary reaction acetyl phosphate is formed releasing CoA for further degradation of the chain. It has furthermore been demonstrated that two moles of acetyl phosphate can be condensed to form acetoacetate. What relation these facts have to the biosynthesis of fatty acid is not yet established, since labeled acetoacetic acid is not incorporated into fatty acid in rat liver preparations, although labeled cholesterol is formed.

The role of two-carbon fragments in intermediary metabolism is under active investigation, and reference should be made to Chapter 33 and to the current literature (see Bibliography, p. 1293). Much of the work in this field is based on *in vitro* studies of microorganisms, tissue slices, and extracts thereof, and its significance for the living animal awaits further study.

The bound forms of pantothenic acid in natural materials are available to higher animals but not to microorganisms. For the latter, it must first be released by suitable hydrolytic procedures. Certain synthetic forms of bound pantothenate have been investigated. Ethyl monoacetylpantothenate is active for the rat and chick, and ethyl pantothenate for the rat. However, neither of these forms shows activity for microorganisms unless they are previously hydrolyzed by procedures similar to those employed for the release of bound pantothenate in natural materials.

Certain structurally related compounds behave as antivitamins toward pantothenic acid. Pantoyltaurine (the sulfonic analog), pantoyl-

<sup>214</sup> Ochoa, Stern, and Schneider: *J. Biol. Chem.*, **193**, 691 (1951).

<sup>215</sup> Ochoa and Stern: *Ann. Rev. Biochem.*, **21**, 547 (1952).

<sup>216</sup> Barker, in *Phosphorus Metabolism*, Baltimore, Johns Hopkins University Press, 1951.

tauramine, and homopantoyltaurine inhibit the growth of bacteria which require an external source of the vitamin. These antivitamins probably operate by competing in some enzyme systems. One observer has found that the administration of pantoyltaurine to mice produces symptoms similar to those of pantothenic acid deficiency. This observation could not be confirmed by other investigators. For a further discussion of anti-vitamins, see Chapter 36.

Possibly because of intestinal synthesis, pantothenic acid deficiency has not been observed in man and hence its importance in human nutrition has not been clarified. The daily requirement, as estimated from the analysis of good diets and from urinary excretion data is approximately 5–10 mg. per 2500 calories. Pantothenic acid is present in normal human blood or plasma to the extent of 20 to 40  $\mu$ g. per 100 ml.

The physiological effect of pantothenic acid is highly specific for that molecule. Replacement of the  $\beta$ -alanine portion with  $\alpha$ -alanine, or with other amino acids having structures similar to  $\beta$ -alanine, produces inactive compounds. The optical antipode of the natural L-isomer is also inactive. The  $\beta$ -alanine portion alone is sufficient for some yeasts and diphtheria bacilli, and is partly available for rats, but not for chicks. These organisms probably utilize the  $\beta$ -alanine for the synthesis of pantothenic acid. Certain hemolytic bacteria require only the dihydroxydimethylbutyryl portion of the molecule. Hydroxypantothenic acid has a biological activity varying from 2 to 25 per cent of that of pantothenic acid, depending upon the organism employed and the conditions of assay.

**Storage and Synthesis of Pantothenic Acid.** Pantothenic acid from external sources is not required by sheep and cattle, since the vitamin is synthesized by microorganisms in the rumen of these animals. It may be synthesized by certain molds, bacteria, and yeast, when grown in media devoid of pantothenic acid. Some yeasts require an external supply of  $\beta$ -alanine. Pantothenic acid is produced by green plants after they have developed sufficiently to perform their photosynthetic functions.

**Distribution of Pantothenic Acid.** Pantothenic acid is present in all living tissues. Excellent sources are liver, kidney, rice bran, molasses, egg yolk, peanuts, and peas. Appreciable concentrations are also found in sweet potatoes, oats, wheat, rye, barley, and broccoli. Pantothenic acid occurs in natural materials both free and combined, though a major fraction of the vitamin in animal sources is bound. While it has not been definitely established that all forms of conjugated pantothenic acid released by an enzymatic digestion procedure are equally available for animal species, rat-growth studies indicate this to be so for coenzyme A and *L. bulgaricus* factor. In certain foods or extracts (liver powder, yeast, wheat-bran and rice-bran extracts) where rat assays were reported to be considerably higher than microbiological assays, the discrepancies may have been due to unidentified dietary factors or incomplete enzymatic release of pantothenic acid prior to microbiological assay.

**Chemistry of Pantothenic Acid.** Pantothenic acid (D-N-( $\alpha,\gamma$ -dihydroxy- $\beta,\beta$ -dimethylbutyryl)- $\beta$ -alanine) is a condensation product of  $\beta$ -alanine and a hydroxyl- and methyl-substituted butyric acid. It is a pale yellow, unstable, viscous oil.

The natural or vitamin-active form of pantothenic acid is the dextro-rotatory isomer, specific rotation  $[\alpha]_D^{25} = +37.5^\circ$ . Synthetic pantothenic acid is produced commercially as the calcium or sodium salts, in either dextrorotatory or racemic form, the latter having half the potency of the former. The dextrorotatory alcohol corresponding to pantothenic acid, pantothenyl alcohol, is vitamin-active and is also available commercially.

PANTOTHENIC ACID CONTENT OF FOODS  
(AFTER NEILANDS AND STRONG\*)

| <i>Food</i>     | <i>Pantothenic Acid</i><br><i>mg. per 100 g.</i> |

\* Neilands and Strong: *Arch. Biochem.*, **19**, 287 (1948). Based on microbiological assay after digestion with liver enzyme and phosphatase.

It is claimed to be more stable than the acid at pH below 6. Pantothenic acid is adsorbed by "Norit" at pH 3.5 or by aluminum oxide previously activated with hydrochloric acid but not by fuller's earth. It may be eluted from "Norit" with ammonia or pyridine and methanol. Pantothenic acid is soluble in water, ethyl acetate, dioxane, and glacial acetic

acid, and is slightly soluble in ether and amyl alcohol, and insoluble in chloroform and benzene. It is unstable to heat in the dry state or in acid or alkaline medium. In the pH range 5 to 7 it may be autoclaved at 15 pounds pressure for one-half hour without loss.

The butyrolactone moiety of pantothenic acid is known as pantolactone and the corresponding acid is pantoic acid,  $\text{HOCH}_2\text{C}(\text{CH}_3)_2\text{CHOH}\cdot\text{COOH}$ . A naturally occurring growth factor for certain microorganisms (*Lactobacillus bulgaris* factor or LBF) has been identified as a  $\beta$ -mercaptoethylamine derivative of pantothenic acid and given the name pantetheine.

The corresponding disulfide, pantethine, exists presumably in equilibrium with the reduced form. The following diagram illustrates the relationship between these compounds in terms of the various moieties in the molecule of acetyl coenzyme A.

## DETERMINATION OF PANTOTHENIC ACID

No satisfactory chemical method is available for the determination of pantothenic acid in natural products, although several procedures have been described for pharmaceutical preparations. One<sup>217</sup> is based on the hydrolytic release of the  $\beta$ -alanine moiety, followed by colorimetric estimation as the alkaline 2,4-dinitrophenylhydrazone. Interfering B vitamins may be removed chromatographically, but ascorbic acid still presents a problem.

Another procedure<sup>218</sup> is based on a reaction between the pantoyl lactone moiety and hydroxylamine in alkaline solution and the development of a purple color upon acidification and addition of ferric chloride. In contrast to the previous method, this may be applied to the estimation of pantothenyl alcohol, known commercially as "Panthenol." However interference due to ascorbic acid, pantoic acid, and the lactone must be eliminated by adsorption on a basic resin XE-75.<sup>219</sup>

**Determination of Pantothenic Acid (Microbiological).** The absolute requirement of a number of microorganisms for free pantothenic acid was primarily responsible for the original discovery of this vitamin. Many determinations of the pantothenic acid content of natural materials have been published. By far the majority of these have been microbiological procedures although a considerable amount of work has also been reported based on the use of chicks,<sup>220</sup> rats, and other species as test animals. The repeated observation that animal assays in general gave higher values than the microbial tests, together with several early reports on the release of additional increments of pantothenic acid activity by autolysis of tissues or treatment with specific enzyme preparations, led to the recognition of "bound forms" of the vitamin which occurred in many natural materials. However, the release of activity from these hypothetical conjugates was neither striking nor consistent.

The discovery that coenzyme A was in reality a pantothenate-containing prosthetic group of enzymes responsible for transacetylation in living cells proved to be the key to the problem of bound or conjugated forms of the vitamin which had been shown to be unavailable to microorganisms such as *L. arabinosus*. A specially prepared enzyme obtained from pigeon or chicken liver was found capable of inactivating coenzyme A with the

<sup>220</sup> Jukes: *J. Biol. Chem.*, **117**, 11 (1937); *J. Nutrition*, **21**, 193 (1941).

concurrent liberation of free pantothenate. At the same time, an alkaline phosphatase from intestine was shown to split CoA in another manner with the liberation of phosphate.<sup>221</sup>

By combining in a single treatment both an intestinal phosphatase and the CoA-splitting enzyme from pigeon liver, Neilands and Strong<sup>222</sup> showed that some natural materials contained as much as four times the amount of pantothenate which could be demonstrated by simple direct assay. They also showed that other nonspecific phosphatases were relatively ineffective in liberating the vitamin. On the basis of this work, it is evident that a large part of the data previously accumulated on the distribution of pantothenate in foods and tissues is in error and needs reinvestigation. Some of the new values reported are given in the table, p. 1190.

**Determination of Pantothenic Acid: Modified Microbiological Method of Skeggs and Wright.**<sup>223</sup> Pantothenic acid is determined by measurement of the growth stimulation of *Lactobacillus arabinosus* 17-5 by titration of the lactic acid formed or by turbidimetric determination of the cell population. The bound vitamin is first liberated by digestion with alkaline phosphatase and chicken liver enzyme.

**Procedure: Preparation of liver enzyme.**<sup>224</sup> Liver from freshly killed chicken or pigeon is chilled, minced, and homogenized with 20 volumes of ice-cold acetone in a Waring blender. The acetone-insoluble material is filtered and washed with acetone and ether and dried quickly in a current of dry air. The resulting liver powder<sup>225</sup> may be preserved in small, well-sealed vials under refrigeration for a considerable period. For use, the acetone powder is rubbed in a chilled mortar to a smooth paste with 10 times its weight of cold 0.02 M sodium bicarbonate solution. The suspension is centrifuged below 5° C. for 30 minutes at 3,000 r.p.m., and the reddish-brown supernatant liquid is preserved by freezing and holding below -20° C.

This solution possesses good activity on coenzyme A but has the disadvantage of containing considerable amounts of pantothenic acid in a free form. Its use in the assay of materials of low pantothenate content presents the problem of an excessive blank. The amount of free vitamin may be substantially reduced by treatment of the solution with an anion-exchange resin.<sup>226</sup> The following procedure is recommended.

Prepare the resin for use by washing twice with 10 volumes of N HCl and centrifuging. The acid-treated resin is then washed 8 to 10 times with 10 volumes of water until the pH of the wash is about 5. The resin is left in a slurry of a consistency which can be pipetted with a 10 ml. serological pipet. To 1 volume of resin slurry is added a few drops of M tris-(hydroxymethyl)-aminomethane buffer, pH 8.3, to bring the pH to 8.0, and 1 volume of ice-cold liver enzyme solution is added and the suspension stirred for 3 to 5 minutes in an ice bath. The suspension is centrifuged at 5,000 r.p.m. The enzyme solu-

<sup>221</sup> Lipmann, Kaplan, Novelli, Tuttle, and Guirard: *J. Biol. Chem.*, **167**, 869 (1947); Novelli, *et al.*: *J. Biol. Chem.*, **177**, 97 (1949); **192**, 181 (1951).

<sup>222</sup> Neilands and Strong: *Arch. Biochem.*, **19**, 287 (1948).

<sup>223</sup> Skeggs and Wright: *J. Biol. Chem.*, **156**, 21 (1944). A similar method has been adopted by the Association of Official Agricultural Chemists, *J. Assoc. Official Agr. Chemists*, **35**, 103 (1952).

<sup>224</sup> Novelli and Schmetz: *J. Biol. Chem.*, **192**, 181 (1951).

<sup>225</sup> The prepared acetone powder may be obtained from Armour and Co., Chicago, Ill.

<sup>226</sup> Dowex-1, 200-400 mesh, obtainable from the Dow Chemical Co., Midland, Michigan.

tion is again treated with another volume of anion resin slurry and centrifuged. This process usually reduces the free pantothenate content of the solution to less than one-tenth its original value. Preserve the preparation at  $-20^{\circ}\text{C}$ . until ready for use.

*Preparation of Intestinal Phosphatase.* This preparation can be obtained by following the procedure of Schmidt and Thannhauser<sup>227</sup> but is more conveniently obtainable from commercial sources.<sup>228</sup> A 2 per cent solution of this material usually contains about 100 Schmidt-Thannhauser units per ml. and is quite low in free pantothenic acid activity.

*Liberation of Bound Pantothenate.* To a sample containing 5 to 15  $\mu\text{g}$ . bound pantothenate are added 0.1 ml. intestinal phosphatase, 0.2 ml. liver enzyme, 0.1 ml. M tris(hydroxymethyl)aminomethane buffer, pH 8.3, and the whole is made to a total volume of 1 ml. Suitable blank and control tubes should also be set up to allow a correction for any free pantothenate activity in the enzyme preparations. The tubes are incubated at  $37^{\circ}\text{C}$ . for 3 hours and then immersed in a boiling water bath to stop enzyme reactions. The samples are then diluted to bring them into the range of the usual standard curve employed in the pantothenic acid assay of Skeggs and Wright described below.

*Preparation of Medium.* Prepare the basal medium having the composition shown in the table below. Five liters may be prepared as a stock solution at one time provided the glucose and synthetic vitamins are omitted. This solution keeps indefinitely at room temperature under benzene even without sterilization. Prepare a stock vitamin solution containing 4 mg. each of thiamine, riboflavin, and niacin, 8 mg. pyridoxine hydrochloride, 0.4 mg. *p*-aminobenzoic acid and 10  $\mu\text{g}$ . biotin per 100 ml. Store the vitamin supplement in a dark bottle in the refrigerator and renew monthly. Prepare a solution containing 100  $\mu\text{g}$ . per ml. of calcium pantothenate.

*Culture.* Carry stab cultures<sup>229</sup> of *Lactobacillus arabinosus* 17-5 by monthly transfer in a medium containing 1 per cent yeast extract, 1 per cent glucose, and 1.5 per cent agar. After transfer, incubate the culture at  $33^{\circ}\text{C}$ . for 24 to 48 hours, then store in the refrigerator. Prepare the inoculum for the assay tubes by transferring from the stock culture to a sterile tube containing 10 ml. of the basal medium to which 0.2  $\mu\text{g}$ . calcium pantothenate has been added. Incubate for 24 hours at  $33^{\circ}\text{C}$ ., centrifuge, and discard the supernatant liquid. Resuspend the cells in 10 ml. physiological saline, centrifuge, and discard the supernatant. Resuspend the cells in sufficient physiological saline to produce a very light suspension.

*Assay.* Into a series of test tubes, pipet the following volumes: 0.00, 0.25, 0.50, 0.75, 1.00, 1.25, 1.50, 1.75, and 5.00 ml. Similarly prepare a standard series of tubes from a dilution of the standard solution of calcium pantothenate containing 0.1  $\mu\text{g}$ . per ml. Dilute the aliquots in both the standard and unknown series with distilled water so that each tube contains a total volume of 5 ml. To each tube add 5 ml. of the double strength medium, cover with cotton plugs or metal caps and heat in an autoclave at 15 pounds pres-

Equally satisfactory results may be obtained by measurement of the population of the microorganisms turbidimetrically after 18 hours of incubation at 33° C. A photoelectric colorimeter is employed for this purpose. The instrument is set at 100 per cent transmittancy with the solution from the assay tube containing no added pantothenic acid.

CALCULATION. Prepare a standard reference curve, employing the data obtained in the standard series by plotting on ordinary graph paper, μg. of calcium pantothenate as the abscissae and ml. of 0.1 N sodium hydroxide, or photometric density, as the ordinates. From this reference curve, estimate the “calcium pantothenate” content of each tube in the unknown series. Divide this value by the volume of the extract, originally placed in each tube, in order to obtain the concentration per ml. of extract. Determine the average of at least four values which differ from each other by no more than 10 per cent. Calculate the pantothenic acid content of sample using the formula:

$$C \times \frac{D}{G} \times 0.92 = \mu\text{g. pantothenic acid per g. of sample}$$

where *C* is the concentration of calcium pantothenate per ml. of extract, *D* is the final volume to which the extract was diluted, *G* is the weight of the sample taken for analysis, and 0.92 is the factor for converting calcium pantothenate to pantothenic acid.

**Comment.** The microbiological determination of pantothenic acid in these enzymic digests, employing *Lactobacillus arabinosus* 17-5, gives values which are in agreement with microbiological procedures employing other microorganisms as well as with the biological chick assay.

<sup>230</sup> Hydrochloric acid-hydrolyzed, “Norit”-treated, vitamin-free casein is employed. A 10 per cent solution of casein hydrolyzate suitable for this medium may be obtained from General Biochemicals, Inc., Chagrin Falls, Ohio.

## PTEROYLGLUTAMIC ACID (FOLIC ACID)

In early investigations, this vitamin was described under various names including vitamin M, factor U, yeast Norit eluate factor, vitamin B<sub>9</sub>, and *L. casei* factor. The multiplicity of the nomenclature was occasioned by the fact that various conjugates of pteroylglutamic acid exist in natural materials. These conjugates vary in their physical and chemical properties, and in their biological potencies.

**Physiological and Clinical Aspects of Pteroylglutamic Acid.** This vitamin is a growth factor for various bacteria. Its deficiency in chicks leads to slow growth, poor feathering, and macrocytic anemia. In rats a deficiency of pteroylglutamic acid may be produced by adding sulfonamides to purified diets. Anemia, leukopenia and agranulocytosis are produced and may be cured by administering pteroylglutamic acid. Monkeys on a purified diet develop a syndrome characterized by leukopenia, anemia, necrosis of the gums, loss of appetite, diarrhea, and eventual death. The syndrome responds either to pteroylglutamic acid or to pteroyltriglutamic acid or to citrovorum factor.

Pteroylglutamic acid produces a clinical response in the megaloblastic anemias. It is used in the treatment of sprue, nutritional megaloblastic anemia, and the megaloblastic anemias of pregnancy and infancy. The blood picture in these diseases is marked by a low erythrocyte count, reduced hemoglobin, high color and volume indices of the erythrocytes, and lowered leukocytic and platelet counts. Accompanying this is "megaloblastic arrest" in the bone marrow so that an increase of nucleated red cells, including more than 2 per cent megaloblasts, is seen in films prepared from fluid aspirated from sternal bone marrow. Pernicious anemia is included in the megaloblastic group, but the disease is accompanied by neurological changes which respond only to vitamin B<sub>12</sub>. In sprue, the administration of pteroylglutamic acid either parentally or orally results first in the disappearance of the symptoms of glossitis. A reticulocyte peak is commonly reached in six to nine days. Increases occur in erythrocyte count, per cent hemoglobin, white cell count, and number of platelets in a manner similar to that described above for pernicious anemia. There is an improvement in the sense of well-being, an increase in appetite, a subsidence of diarrhea, and a gain in body weight. The bone marrow picture shows a disappearance of the more primitive red blood cells and a return of the differential white cell count to normal proportions.

Nutritional anemia and the macrocytic anemias of pregnancy and infancy show hemopoietic responses similar to those described for pernicious anemia and sprue.

Pteroylglutamic acid appears to be specific in the treatment of the megaloblastic anemia of pregnancy. Typical findings were described in a case by Day and co-workers,<sup>231</sup> and are illustrated in Fig. 280. The patient, a parturient woman, had a hemoglobin of 6.5 g. per cent and a red cell count of 1.7 million. The administration of liver extract and vitamin B<sub>12</sub> did not relieve the anemia and appeared to aggravate the associated symptoms which included glossitis and diarrhea. The changes following

---

<sup>231</sup> Day, Hall, and Pease: *Proc. Staff Meetings Mayo Clinic*, 24, 119 (1949).

administration of pteroylglutamic acid were accompanied by hunger, recession of edema, and disappearance of the other signs and symptoms, including return of the hemopoietic system to normal. The increased dietary need for pteroylglutamic acid in pregnancy is also manifested in "lactation leukopenia"<sup>232</sup> in rats. The rats show blood changes due to a deficiency of pteroylglutamic acid in diets which suffice for maintenance but do not meet the extra demand occasioned by lactation.

FIG. 280. ABSENCE OF HEMATOPOIETIC RESPONSE TO LIVER EXTRACT AND TO VITAMIN B<sub>12</sub>, FOLLOWED BY PROMPT RESPONSE TO PTEROYLGLUTAMIC ACID.

Courtesy, Drs. Day, Hall, and Pease.

**Relation of Pteroylglutamic Acid to Vitamin B<sub>12</sub>.** These two anti-anemic substances show some unique clinical interrelationships. The blood and bone marrow changes in pernicious anemia respond to either pteroylglutamic acid or vitamin B<sub>12</sub> even though no dietary deficiencies of pteroylglutamic acid may exist. The uptake of pteroylglutamic acid from the digestive tract of patients with pernicious anemia appears to be normal, but these patients cannot utilize vitamin B<sub>12</sub> adequately owing to a functional deficiency of "intrinsic factor." The megaloblastic anemia of infancy responds uniformly to pteroylglutamic acid but does not respond consistently to vitamin B<sub>12</sub>. These clinical phenomena find some interesting analogies in biochemistry; for example, both pteroylglutamic acid and vitamin B<sub>12</sub> are concerned in biological reactions involving the formation of methionine from homocystine.<sup>233</sup>

**Distribution of Pteroylglutamic Acid.** Pteroylglutamic acid and its close relative, the citrovorum factor, are widely distributed in biological

<sup>232</sup> Nelson and Evans: *J. Nutrition*, **38**, 11 (1949).

<sup>233</sup> Bennett: *Science*, **110**, 589 (1949).

materials, often as polyglutamic acid conjugates. Good dietary sources include green leaves, asparagus, liver, yeast, cowpeas, and soybeans. The distribution of “folic acid activity” in foods has been exhaustively studied by microbiological and chick assays.<sup>234</sup> The name “folic acid” was originally defined in terms of a factor in spinach showing biological activity for *Streptococcus fecalis*. This factor was probably a mixture of pteroylglutamic acid and “citrovorum factor” which are interchangeable with respect to their biological activity for *S. fecalis* and are both present in spinach and many other natural materials.

\* Condensed from *Agricultural Handbook No. 29*, U.S. Dept. of Agriculture.

**Chemistry of Pteroylglutamic Acid.** The structure and synthesis of pteroylglutamic acid were described in 1946.<sup>235</sup> The molecule consists of a pteridyl group connected in methylene linkage through *p*-aminobenzoic acid to L(+)-glutamic acid and the structural formula is as follows:

<sup>234</sup> *Folic Acid Content of Foods (Agricultural Handbook No. 29)*, Washington, D. C., U.S. Government Printing Office, September 1951.

<sup>235</sup> Angier, *et al.*, *Science*, **102**, 227 (1945); **103**, 667 (1946).

The pteridyl group is chemically related to xanthopterin, a yellow pigment which is present in certain natural materials including urine and the wings of butterflies.

Pteroylglutamic acid is a substance of low toxicity as measured by toxicological tests with mice, rats, guinea pigs, rabbits, cats, and dogs. The LD<sub>50</sub> for mice and rats is about 0.5 g. per kg. body weight when injected intravenously.

A second form of vitamin, "fermentation *L. casei* factor," isolated from an aerobic fermentation of an organism of the genus *Corynebacterium*,

FIG. 281. SYNTHETIC PTEROYLGLUTAMIC ACID CRYSTALS, VIEWED THROUGH CROSSED POLARIZERS.

Photographed by Dr. A. F. Kirkpatrick, Stamford Laboratories, American Cyanamid Co. Courtesy, Dr. T. H. Jukes.

has been identified as pteroyldi- $\gamma$ -glutamylglutamic acid. Upon partial degradation with alkali, it yields DL-pteroylglutamic acid. "Fermentation *L. casei* factor" is relatively inactive as a growth factor for *S. fecalis* R by comparison with pteroylglutamic acid. However, on a molar basis, it appears to be just as active as pteroylglutamic acid for *L. casei*, for chicks, for rats, and for monkeys. When the *p*-aminobenzoyl-glutamic-acid radical in the pteroylglutamic acid molecule is replaced by *p*-aminobenzoic acid, the resultant substance is termed "pteroic acid." This substance is active for *S. fecalis* R but not for *L. casei* or for animals.

Other members of the pteroylglutamic acid family of vitamins are pteroylhexa- $\gamma$ -glutamylglutamic acid (previously known as the vitamin B<sub>6</sub> conjugate); N-formyl pteroic acid (rhizopterin or *S. lactis* R factor)

which is inactive for animals; and folinic acid (citrovorum factor, or leucovorin), discussed in the next section. The differences in biological potency among the various natural forms of pteroylglutamic acid raises a question concerning the significance of microbiological assays in which the preliminary digestion procedures liberate maximum amounts of the parent compound.

Pteroylglutamic acid is a yellow, tasteless substance which is only slightly soluble in water; about 0.01 mg. per ml. dissolves at room temperature. It is destroyed rapidly by boiling with dilute hydrochloric acid. Its sodium salt is fairly soluble. Light has a destructive action on the solution. Pteroylglutamic acid has an absorption spectrum which shows characteristic maxima in the ultraviolet range.<sup>236</sup> The substance crystallizes from water in the form of thin lenticular crystals (Fig. 281) which exhibit birefringence and parallel extinction.

DETERMINATION OF PTEROYLGLUTAMIC ACID

**Microbiological Assay.**<sup>237</sup> The assay is carried out with either *Lactobacillus casei* (ATCC #7469) or *Streptococcus fecalis* (ATCC #8043).

PTEROYLGLUTAMIC ACID STANDARD SOLUTION.

(a) *Preparation.* Wash 20 mg. of pteroylglutamic acid with water into a 100-ml. volumetric flask. Add 2 ml. 0.1 N NaOH. Shake until material is in solution. Add 5 ml. of 1.0 M sodium phosphate buffer, pH 7.0, and 25 ml. absolute ethanol, and make up to 100 ml. with water.

<sup>237</sup> Flynn, Williams, O'Dell, and Hogan: *Anal. Chem.*, **23**, 180 (1951).

<sup>238</sup> For assay with *Streptococcus fecalis*, omit sodium acetate and KH<sub>2</sub>PO<sub>4</sub>. Add 27.5 g. sodium citrate (dihydrate) and change amount of K<sub>2</sub>HPO<sub>4</sub> to 3.10 g.

<sup>239</sup> Obtained from Atlas Powder Company, Wilmington, Del.

(b) *Dilutions*. Dilute to 0.001  $\mu\text{g.}$  per ml. for assay with *L. casei*; to 0.005  $\mu\text{g.}$  per ml. for assay with *S. fecalis*.

(c) *Assay Levels of Diluted Standard Solutions*. 0.1, 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0, 3.0, 5.0 ml. for *L. casei*; 0.1, 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0, 3.0 ml. for *S. fecalis*.

The preparation of the various constituents of the medium is as follows:

VITAMIN-FREE, ACID-HYDROLYZED CASEIN.<sup>240</sup> Labco "vitamin-free" casein (300 g.) is refluxed at least 12 hours with 3 liters 20 per cent HCl. It is evaporated under vacuum to a thick syrup, then diluted to 3 liters with distilled water. This concentration procedure is repeated twice. The final concentrate is diluted to 1 liter. The pH is adjusted to 2.5 with KOH. The mixture is stirred with 30 g. activated carbon (Darco G 60) for 15 minutes, then filtered with the aid of "Filter-cel." The pH is adjusted to 6.8 with KOH after the volume of solution is brought to 3 liters, and the charcoal treatment and filtration are repeated. One ml. of the solution contains the equivalent of 100 mg. original casein.

ADENINE AND GUANINE. These are dissolved together in a small amount of 1.0 N HCl with heat and diluted to 1 mg. per ml.

XANTHINE AND URACIL. These are dissolved in dilute  $\text{NH}_4\text{OH}$  and diluted to 1 mg. per ml.

TRYPTOPHAN. Dissolve in a small amount of 1.0 N HCl and dilute to 10 mg. per ml.

ASPARAGINE. One g. asparagine is dissolved in 100 ml. water.

VITAMINS. Four mg. thiamine hydrochloride, 10 mg. riboflavin, 8 mg. calcium pantothenate, 8 mg. nicotinic acid, 40 mg. pyridoxine hydrochloride, 10 mg. *p*-aminobenzoic acid, and 200  $\mu\text{g.}$  biotin are dissolved in 100 ml. distilled water and stored in the cold room under toluene. One ml. of this solution is added per 100 ml. double-strength medium.

**Preparation of sample solutions.** Each sample for assay is blended with 150 ml. 0.05 M phosphate buffer pH 7.2 per g. of sample (dry basis). Caprylic alcohol is added to prevent foaming, and the mixture is autoclaved 15 minutes at 15 pounds. It is then cooled and incubated with desiccated chicken pancreas (Difco) using 20 mg. of dry pancreas per g. dry weight of sample under toluene for 24 hours at 37° C. After incubation the samples are autoclaved 5 minutes at 15 pounds, cooled and filtered. The samples together with the standard pteroylglutamic acid dilutions are pipetted into 18 × 150 mm. test tubes and brought to a volume of 5 ml. with water; 5 ml. of double-strength basal medium is added per tube; the tubes are capped with metal or glass caps and then are sterilized for 15 minutes at 15 pounds pressure. After cooling to room temperature the tubes are inoculated as described below.

**Preparation of the Inoculum.** The inoculum medium for *S. fecalis* contains in addition to the basal medium, 0.5  $\mu\text{g.}$  of pteroylglutamic acid, 200 ml. tomato juice, 5 g. Bacto tryptone, 0.5 g. Wilson's liver fraction L<sup>241</sup> and water to 1,000 ml. The inoculum medium for *L. casei* contains in addition to the basal medium, 0.5  $\mu\text{g.}$  pteroylglutamic acid, 0.5 g. Wilson's liver fraction L and water to 1,000 ml. The inoculum is incubated for 20–24 hours. The cells are centrifuged, the supernatant liquid is discarded, and the cells are resuspended in 0.9 per cent saline. One drop of this suspension is added to 10 ml. sterile 0.9 per cent saline and one drop of this cell suspension is added per tube. Microbiological assays with either organism may be incubated at 37° C. for the desired length of time. The growth response with *S. fecalis* may be determined after 16–20 hours' incubation by use of a photoelectric tur-

<sup>240</sup> Kitay, McNutt, and Snell: *J. Bact.*, 59, 727 (1950).

<sup>241</sup> Other crude liver extracts may be used.

bidimeter or after 72 hours' incubation by titration of the acid formed with 0.1 N NaOH. The growth response with *L. casei* may be determined turbidimetrically after 40 hours' incubation, or after 72 hours' incubation by titration of the acid formed with 0.1 N NaOH. From these data a curve can be plotted relating growth to pteroylglutamic acid concentration, and from this response curve the potency of the unknown samples can be calculated.

### CITROVORUM FACTOR (CF)

The occurrence of a growth factor for *Leuconostoc citrovorum* 8081 in certain natural materials including liver extract and yeast was reported in 1948.<sup>242</sup> The organism was shown to respond either to thymidine or to an unidentified "citrovorum factor" which was related to pteroylglutamic acid as indicated by the fact that a delayed and submaximal response was produced in the organism by massive doses of pteroylglutamic acid. It was shown that natural materials containing CF would reverse the inhibitory effect of 4-aminopteroylglutamic acid (aminopterin) for *Leuconostoc citrovorum* and that the administration of large doses of pteroylglutamic acid to animals produced many-fold increases in urinary CF. The factor was eventually synthesized by the formylation and reduction of pteroylglutamic acid.

FIG. 282. CALCIUM LEUCOVORIN.

Courtesy, Dr. T. H. Jukes, American Cyanamid Co.

#### Chemistry of Citrovorum Factor (Leucovorin, Folinic Acid)

It was shown that 5-formyl-5, 6, 7, 8-tetrahydropteroylglutamic acid had the biological properties of the naturally occurring CF. The compound was synthesized from pteroylglutamic acid by hydrogenation in formic acid, alkaline treatment, and isolation of the active material.<sup>243</sup> A photomicrograph of crystals of the calcium salt of leucovorin is shown in Fig. 282.

Leucovorin produces responses in the megaloblastic anemias similar to those obtained with pteroylglutamic acid. It blocks the toxic effects of 4-aminopteroylglutamic acid and other "folic acid antagonists."

### DETERMINATION OF CITROVORUM FACTOR

**Microbiological Assay.** The microbiological assay for the citrovorum factor is carried out with *Leuconostoc citrovorum* (ATCC #8081) following the procedures proposed by Sauberlich.<sup>244</sup>

#### CITROVORUM FACTOR (LEUCOVORIN, FOLINIC ACID) STANDARD SOLUTION.

(a) *Preparation.* A water solution containing 100  $\mu$ g. DL-5-formyl-5, 6, 7, 8-tetra-

| MnSO <sub>4</sub> ·H <sub>2</sub> O  | 0.01                                             |                                 |                                                  |

Combine ingredients, adjust to pH 6.8 and make up to 500 ml. with water.

The preparation of the various constituents of the medium is as follows:

VITAMIN-FREE, ACID-HYDROLYZED CASEIN.<sup>245</sup> Labco “vitamin-free” casein (300 g.) is refluxed at least 12 hours with 3 liters 20 per cent HCl. It is evaporated under vacuum to a thick syrup, then diluted to 3 liters with distilled water. This concentration procedure is repeated twice. The final concentrate is diluted to 1 liter. The pH is adjusted to 2.5 with KOH. The mixture is stirred with 30 g. of activated carbon (Darco G 60) for 15 minutes, then filtered with the aid of “Filter-cel.” The pH is adjusted to 6.8 with KOH after the volume of solution is brought to 3 liters, and the charcoal treatment and filtration are repeated. One ml. of the solution contains the equivalent of 100 mg. of original casein.

ADENINE AND GUANINE. These are dissolved together in a small amount of 1.0 N HCl with heat and diluted to 1 mg. per ml.

XANTHINE AND URACIL. These are dissolved in dilute NH<sub>4</sub>OH and diluted to 1 mg. per ml.

TRYPTOPHAN. Dissolve in a small amount of 1.0 N HCl and dilute to 10 mg. per ml.

ASPARAGINE. One g. of asparagine is dissolved in 100 ml. of water.

VITAMINS. Ten mg. thiamine hydrochloride, 20 mg. pyridoxine hydrochloride, 6 mg. pyridoxamine hydrochloride, 6 mg. pyridoxal, 10 mg. calcium pantothenate, 10 mg. riboflavin, 20 mg. nicotinic acid, and 0.02 mg. biotin are dissolved in 100 ml. distilled water and stored in the cold room under toluene. One ml. of this solution is added per 100 ml. of double-strength medium.

<sup>245</sup> Kitay, McNutt, and Snell: *J. Bact.*, **59**, 727 (1950).

**Preparation of sample solutions.** Each sample for assay is blended with 150 ml. 0.05 M phosphate buffer (pH 7.2) per g. of sample (dry basis). Caprylic alcohol is added to prevent foaming, and the mixture is autoclaved 15 minutes at 15 pounds. It is then cooled and incubated with desiccated chicken pancreas (Difco) using 20 mg. dry pancreas per g. dry weight of sample under toluene for 24 hours at 37° C. After incubation the samples are autoclaved 5 minutes at 15 pounds, cooled, and filtered. The samples, together with the standard citrovorum factor dilutions, are pipetted into 12 × 100 mm. test tubes and brought to a volume of 1 ml. with water; 1 ml. double-strength basal medium is added per tube. The tubes are capped with metal or glass caps and then are sterilized for 15 minutes at 15 pounds pressure. After cooling to room temperature, the tubes are inoculated as described below.

**Preparation of the Inoculum.** An inoculum is prepared by growing the organism at 37° C. for 24 hours on the basal medium plus 10 mg. Wilson's liver fraction L<sup>246</sup> per tube. The cells are centrifuged, the supernatant liquid is discarded, and the cells are resuspended in 0.9 per cent saline. One drop of this suspension is added to 10 ml. sterile 0.9 per cent saline, and one drop of this cell suspension is added per tube. The assay tubes are incubated at 37° C. for 20–24 hours. The growth response is measured by recording the optical density of the cultures with the photoelectric turbidimeter. From these data a curve can be plotted relating growth to citrovorum factor, and from this response curve the potency of the unknown samples can be calculated.

## BIOTIN

A striking example of how the isolation of an active principle in pure form can lead to coordination of a vast amount of seemingly unrelated observations may be seen in the story of biotin. Kögl and Tönnis<sup>247</sup> in 1936 reported the isolation from egg yolk of a yeast-growth factor (bios II) in the form of its methyl ester. They assigned the name *biotin* to the free acid. Recognition by West and Wilson<sup>248</sup> of the probable identity of this factor with coenzyme R, a growth and respiratory stimulant for the legume nodule organism *Rhizobium*, was followed by the demonstration by György, Melville, Burk, and du Vigneaud<sup>249</sup> of the identity of biotin with both coenzyme R and vitamin H. The latter had been previously reported to protect against a form of dermatitis induced by feeding raw egg white. The identification of biotin also illustrates the contribution to the advance in nutritional science made possible by the application of microbiological methods. The structure of biotin was established by du Vigneaud and associates.

In terms of the minimum protective dosage, biotin is one of the most potent physiological substances known, less than 0.03  $\mu$ g. per day being sufficient for the rat. The role of biotin in nutrition is not clearly understood, but various investigations suggest that it may function as a coenzyme in certain enzymatic reactions associated with decarboxylation and carbon dioxide fixation. The high concentration of biotin in embry-

<sup>249</sup> György, Melville, Burk, and du Vigneaud: *Science*, **91**, 243 (1940).

onic and tumor tissue has attracted considerable interest in the possible clinical significance of this vitamin.

**Physiological Properties of Biotin.** Biotin has been shown to be an essential nutrient for various lower organisms (including yeast, molds, bacteria, and fungi), for the rat, chick, turkey, monkey, rabbit, dog, and guinea pig, and for man. Deficiencies of this vitamin are difficult to produce experimentally because it may be synthesized by intestinal flora in higher animals. Deficiency symptoms may be induced, however, by feeding materials which either combine with the biotin to form non-absorbable complexes (such as avidin of egg white, see below) or by feeding sulfa drugs which interfere with bacterial synthesis of the vitamin in the intestines.

In 1927 Boas discovered that the inclusion of large amounts of raw (but not of cooked) egg white in the diet of rats resulted in loss of hair, loss of weight, dermatitis, and death. It was also found that certain foods could cure or prevent these symptoms. Raw egg white contains a distinctive protein, later designated as *avidin*, capable of combining stoichiometrically with biotin, thus preventing its absorption from the digestive tract or its utilization by yeast. Symptoms of a biotin deficiency may be induced even in man by feeding a sufficient amount of raw egg white. Crystallized avidin (mol. wt. 70,000) has 15,000 times the biotin-combining power of raw egg white. Though the biotin-avidin complex is not absorbed from the gastrointestinal tract, the compound is biologically active when administered parenterally.

Biotin deficiency in animals is associated with the development of dermatitis, loss of fur, disturbances of the nervous system, and death. Biotin appears to be required for normal gestation and lactation in the rat and mouse as well as for normal development of the chick embryo. A marked increase in the biotin content of the blood of sexually immature chicks was observed following the administration of estrogen; subsequent administration of progesterone caused no change in blood biotin but produced a rise in the avidin content of the oviduct. These observations suggest a role of avidin and biotin in reproduction. The "spectacled eye" condition in rats (due to loss of hair around the eyes) may be associated with biotin deficiency. In the chick the deficiency symptoms dermatitis and perosis are similar to those of pantothenic acid deficiency. That vitamin interrelationships are involved in intestinal synthesis is illustrated by the observation that a pantothenic acid deficiency produced in rats on a diet containing succinylsulfathiazole could be relieved by administering folic acid and biotin.<sup>250</sup>

That biotin may play a part in the synthesis of oleic acid is suggested by studies with certain lactobacilli.<sup>251</sup> For example, *L. arabinosus* can multiply in the absence of biotin provided oleate and aspartate are present. Aspartic acid has a pronounced sparing action on the requirement of microorganisms for biotin. If just sufficient biotin is present to

<sup>251</sup> Potter and Elvehjem: *J. Biol. Chem.*, **172**, 531 (1948); Williams and Fieger: *J. Biol. Chem.*, **170**, 399 (1947); Williams, Broquist, and Snell: *J. Biol. Chem.*, **170**, 619 (1947); Broquist and Snell: *J. Biol. Chem.*, **188**, 431 (1951).

permit synthesis of oleic acid, aspartic acid can be replaced by oxalacetic acid. The microbial growth-stimulating effect of oleic acid is also manifested by certain detergents, e.g., Tween 80 (the polyoxyethylene derivative of sorbitan oleate). The significance of these observations in mammalian nutrition has not been established.

The protective effect of liver or yeast concentrates against butter yellow (dimethylaminoazobenzene) hepatoma in rats has been found to be unrelated to their content of biotin. In fact pure biotin was reported to increase the incidence of tumors in susceptible mice.<sup>252</sup> Egg white affords some protection against tumors in rats, but this is independent of the biotin-avidin relationship.<sup>253</sup> Addition of biotin to a diet containing butter yellow, but otherwise protective against tumor development, accelerated carcinogenesis; however, when the diet was conducive to tumor development, this effect was not observed.<sup>254</sup>

Most microorganisms require biotin in the form of the free acid, though the methyl ester is biologically active for yeast and partially so for *Lactobacillus casei*. The diaminocarboxylic acid obtained from biotin by the hydrolysis of the urea portion of the molecule possesses 10 per cent of the activity of the original vitamin. Oxidation to the sulfoxide does not affect the activity of biotin, whereas conversion to the sulfone causes considerable inhibition of the growth stimulation of yeast. Parenteral administration of biotin is three to five times more effective than oral administration in the treatment of deficiency symptoms.

The presence in urine of a substance having biotin potency for yeast which is not inhibited by avidin has been reported. The existence of other similar substances has been demonstrated, but in no instance have they been shown to be chemically similar to or related to biotin. Interference by such substances in the microbiological assay for biotin may be avoided by utilizing the ability of avidin to combine specifically with biotin.

**Storage and Synthesis of Biotin.** Biotin may be stored in the liver and kidneys, although newborn infants have no such reserves. It is probable that infants obtain some of their biotin from bacterial synthesis in the gastrointestinal tract. That such synthesis furnishes a considerable proportion of the biotin requirements of higher organisms is indicated by the fact that humans have been known to excrete via stools and urine three to six times as much biotin as they ingest. Rats do not require an external supply of biotin and excrete more than they consume. The vitamin is synthesized to a considerable extent in the rumen of the calf and cow. In the case of the rat the oral administration of sulfaguanidine or succinylsulfathiazole produces symptoms of biotin deficiency which are curable by administration of biotin.

**Distribution of Biotin.**<sup>255</sup> Biotin is present in most animal tissues but in higher concentration in liver, kidneys, egg yolk, yeast, pancreas, and

Biol. Chem.*, **178**, 533 (1949).

milk. It is also found in vegetables, grains, nuts, feeds, pollens, and molasses. Biotin occurs naturally in combined forms, among which is a complex isolated from yeast and designated *biocytin*.<sup>256</sup> It is  $\epsilon$ -N-biotinyl-L-lysine. Biocytin has the activity of biotin for *L. casei* but not for *L. arabinosus*. Biotin exists in the free state in fruits and grasses, partly bound in nuts, vegetables, and grains, and mostly in combined form in yeast and liver. For assay with microorganisms it may be liberated by autolysis, acid hydrolysis, or enzymatic digestion.

### Chemistry of Biotin.

$\beta$ -Biotin ( $\text{C}_{10}\text{H}_{16}\text{O}_3\text{N}_2\text{S}$ )

*cis*-Hexahydro-2-oxo-1-H-thieno(3,4)imidazole-4-valeric acid

The structural formula shown is that of  $\beta$ -biotin, isolated from liver or milk.  $\alpha$ -Biotin, from egg yolk, differs only in respect to the side chain which, instead of *n*-valeric acid, is

The biotins are crystalline compounds soluble in water and alcohol and insoluble in chloroform, ether, and petroleum ether. The  $\alpha$ - and  $\beta$ -biotins melt at 220° and 231° C., respectively. They have specific rotations  $[\alpha]_D^{25}$  of +51° and +91°, respectively, and an isoelectric point at pH 3–3.5. Biotin has an ultraviolet absorption maximum at 234 m $\mu$  with a specific extinction coefficient of 42.5. It has a molecular weight of 244.3. The stability of biotin toward heat in the presence of acid or alkali has not yet been established. It has been reported that biotin in natural materials resists autoclaving with strong mineral acids (4–6 N HCl for two hours at 120° C.), a procedure used for the liberation of the vitamin in natural materials for microbiological assay. Some authors, however, have reported a loss of biotin by this hydrolytic procedure. In natural materials the vitamin is destroyed by heating with strong alkali, and is even less stable to this treatment in pure solutions. Both free and combined biotin are inactivated by oxidizing agents. Though esterification impairs the biological activity of biotin for microorganisms, acylation or alkylation do not affect it. Synthetic  $\beta$ -biotin is produced commercially.

In oxybiotin the sulfur atom is replaced by oxygen. Oxybiotin possesses biological properties similar to biotin but in considerably less degree. It has about one-fourth the growth-promoting activity of biotin for *L. helveticus* and *S. cerevisiae* and half the activity for *L. arabinosus*; it is one-third as active in curing biotin deficiency in chicks and even less effective against egg-white injury in the rat.

<sup>256</sup> Wright, et al.: *J. Am. Chem. Soc.*, 72, 1048 (1950).

Dethiobiotin, the natural precursor of biotin, is believed to be derived in part from pimelic acid ( $\text{COOH} \cdot (\text{CH}_2)_5 \cdot \text{COOH}$ ). It can be made by reducing biotin with Raney nickel, a reaction which leaves the furan ring intact.

Dethiobiotin is as active as biotin for yeast, *E. coli*, and various molds, but not for several species of lactobacilli, and has very little of the activity of biotin against egg-white injury in the rat.

### DETERMINATION OF BIOTIN

Biotin may be determined microbiologically by measurement of its effect upon the growth of microorganisms. The method of Snell, Eakin, and Williams<sup>257</sup> involves measurement of the growth stimulation of *Saccharomyces cerevisiae*. The procedure is similar to that described on p. 1185. The extremely high physiological potency of biotin is illustrated by the fact that it stimulates yeast growth when present in a concentration as low as one part in  $5 \times 10^{11}$  parts of medium. Biotin may also be determined by its growth stimulation of other microorganisms including *Lactobacillus arabinosus* and *Lactobacillus casei*. A rat assay such as was used in studies of the anti-egg-white-injury factor (vitamin H) may also be employed, though it requires large groups of animals and is not as satisfactory as the microbiological determination. One mg. of biotin methyl ester is equivalent to 27,000 units of vitamin H, the unit being the minimum daily dose required to cure the egg-white dermatosis in rats in 30 days. One great difficulty in the rat assay is that of producing biotin deficiencies, since rats obtain a considerable portion of their biotin from products of bacterial synthesis in their intestines. The assay for biotin using chicks is somewhat more satisfactory because they require greater amounts from dietary sources so that the deficiency is easily produced. Of the various assay methods, the microbiological procedure is generally preferred. See p. 1131.

### VITAMIN B<sub>12</sub> (COBALAMIN)

Vitamin B<sub>12</sub>, the anti-pernicious-anemia factor of concentrated liver extracts and the major vitamin in sources of the "animal protein factor," was isolated in 1948 and found to be a cobalt coordination compound or "chelate." A second form, which was isolated in 1949, proved to be biolog-

<sup>257</sup> Snell, Eakin, and Williams: *Univ. Texas Pub. No. 4137*, 18 (1941).

ically interchangeable with the first. Later, these forms were identified as cyano ( $B_{12}$ ) and hydroxo ( $B_{12a} = B_{12b}$ <sup>258</sup>) forms of the organometallic molecule containing cobalt. The known role of cobalt in the nutrition of ruminants could now be explained by the presence of this element in the molecule of these "cobalamins" which are synthesized by microorganisms in the rumen. The identity of cobalamin with the "extrinsic factor" of pernicious anemia was demonstrated, and the production of cobalamin by industrial fermentation made a new source of the substance available in medicine and animal nutrition.

The term "vitamin  $B_{12}$ " refers chemically to *cyanocobalamin* but is commonly used to designate the cobalamin group with respect to their biological effect. For example, the vitamin  $B_{12}$  content of liver extract is commonly expressed in terms of a measurement of cyanocobalamin plus hydroxocobalamin.

**Physiological and Clinical Aspects of Cobalamin.** This vitamin is a growth factor for certain lactic acid bacteria and for the algal flagellate *Euglena gracilis*. The deficiency in young rats and chicks is seen when diets low in the vitamin are fed during the maternal period and is accentuated by raising the level of protein in such diets or by the addition of thyroid hormone to the diets fed to young animals. The deficiency in young rats is marked by a high mortality which is most prominent during the suckling period and is associated with leukopenia and uremia. The hatchability of the eggs of hens on deficient diets falls to low levels, and there is slow growth and a high mortality in newly hatched chicks.

Pernicious anemia is the best-known example of the result of vitamin  $B_{12}$  deficiency. In this disease, which is peculiar to the human species, the patient by some degenerative process is deprived of an "intrinsic factor" which is present in normal gastric juice. This "intrinsic factor" is needed for the uptake of vitamin  $B_{12}$  ("extrinsic factor") from the digestive tract. The disease is marked by a macrocytic anemia, by leukopenia, by megaloblastic changes in the bone marrow, and usually by subacute combined degeneration of the spinal cord. The signs and symptoms are reversed by administration of cobalamin. As little as 1 or 2  $\mu\text{g.}$  daily will produce a therapeutic response when injected, as will 5  $\mu\text{g.}$  daily by mouth when given with intrinsic factor or a single dose of 3000  $\mu\text{g.}$  orally without intrinsic factor. Pteroylglutamic acid will restore the blood and bone marrow pictures to normal in doses of a few milligrams daily when given either orally or by injection but this treatment fails to stem the progress of, or to alleviate, the neural changes which respond only to cobalamin. If, however, these changes are not of recent origin, they are refractory to even large doses of cobalamin.

Vitamin  $B_{12}$  deficiency in pigs is marked by slow growth and is accompanied by nervousness and irritability, but not by macrocytic anemia. A wasting disease in ruminants known to be endemic in many areas was identified in 1935 as being due to a deficiency of inorganic cobalt in the soil, with a consequent lack of this element in the forage. The disease in

---

<sup>258</sup> These designations were assigned by different groups of investigators before the identity of the compound was established.

sheep has been described as accompanied by listlessness, anemia, loss of appetite, and weakness progressing to a fatal termination. The disease can be prevented or arrested by cobalt salts when they are administered orally, but not when injected. Vitamin B<sub>12</sub> is effective when either fed or injected, and it is thought that cobalt deficiency in the diet of ruminants leads to a failure in the fermentation process by which vitamin B<sub>12</sub> is normally produced by the rumen microflora.

A source of the "labile methyl" group such as choline, betaine, or dimethylthetin will enable rats to grow on a "labile-methyl-free" purified diet, containing homocystine and succinylsulfathiazole, without adding vitamin B<sub>12</sub> or pteroylglutamic acid. However, the rats will grow at a rate of 0.8 to 1.0 g. daily without a dietary source of "labile methyl" if both vitamin B<sub>12</sub> and pteroylglutamic acid are added to the diet.<sup>259</sup> This relates these two substances to biological reactions involving precursors such as serine and glycine as sources of "formate," supplying a single-carbon fragment for the methylation of homocystine to form methionine. It was found by Shive<sup>260</sup> that the inhibitory effect of sulfanilamide on the growth of *E. coli* was overcome either by vitamin B<sub>12</sub> at a level of 0.3 µg. per liter of culture medium or by methionine at a level of 90 mg., but not by homocystine. A function of vitamin B<sub>12</sub> in the formation of methionine from homocystine was thus demonstrated.

Vitamin B<sub>12</sub> and pteroylglutamic acid both appear to "spare" the requirement of the chick for choline and to improve the utilization of homocystine by the chick on methionine-deficient diets.

Vitamin B<sub>12</sub> appears to catalyze the formation of the purine and pyrimidine deoxyribosides which are present in deoxyribonucleic acid. These deoxyribosides can replace vitamin B<sub>12</sub> in the growth of certain bacteria including *L. leichmannii*.

The vitamin is formed by certain bacteria in the digestive tract and by soil and marine microorganisms. Its formation in the rumen doubtless accounts for its presence in beef liver. Vitamin B<sub>12</sub> is characteristically present in the internal organs and muscular tissues of animals and absent from the higher plants. The more important dietary sources of the vitamin are liver, kidney, lean meat, fish, clams, oysters, milk, and egg yolk.

**Chemistry of the Cobalamins.** The molecule consists of a large, highly stable cobalt complex (R'Co) esterified through phosphoric acid to a ribofuranoside group which in turn is linked through N to R, which is 5,6-dimethylbenzimidazole (as in vitamins B<sub>12</sub>, B<sub>12b</sub>, and B<sub>12c</sub>) or adenine (as in "pseudo vitamin B<sub>12</sub>"). An anion R'', which may be CN

(in B<sub>12</sub>), OH (in B<sub>12b</sub>), NO (in B<sub>12c</sub>), etc., and which is apparently not related to the biological activity of the substance, is attached by coordi-

<sup>259</sup> Bennett: *Science*, **110**, 589 (1949).

<sup>260</sup> Shive: *Ann. N. Y. Acad. Sci.*, **52**, 1212 (1950).

nate linkage to the cobalt atom. Prolonged acid hydrolysis splits the phosphate linkages and also liberates two D-1-amino-2-propanol groups from R'. Catalytic hydrogenation of vitamin B<sub>12</sub> leads to the production of a brownish pigment which has an absorption band at 315 m $\mu$ .<sup>261</sup> Upon prolonged exposure to air, the brown pigment becomes converted to hydroxocobalamin (vitamin B<sub>12b</sub>) which in turn may be changed to cyanocobalamin (vitamin B<sub>12</sub>) by treatment with cyanide.

The composition of vitamin B<sub>12</sub> is approximately C<sub>61-64</sub>H<sub>86-92</sub>N<sub>14</sub>O<sub>13</sub>-PCo. It forms dark-red, needle-shaped crystals which in solution have absorption spectrum maxima at 278, 361, and 550 m $\mu$ . The crystals of vitamin B<sub>12b</sub> are almost black, and absorption spectrum maxima occur at 274, 351, and 525 m $\mu$ . Both substances are readily soluble in water and insoluble in ether. They may be crystallized from acetone. They are readily destroyed by alkali. Dilute acid converts B<sub>12</sub> to B<sub>12b</sub>, and strong acid causes hydrolytic decomposition as described above. The cobalamins are readily adsorbed on charcoal, from which they may be eluted with appropriate solvents, and they may be purified by chromatography on silicic acid.

An analog, "pseudovitamin B<sub>12</sub>," was produced by anaerobic fermentation of an organism isolated from bovine rumen contents.<sup>262</sup> Acid hydrolysis of this analog yielded adenine in place of the 5,6-dimethylbenzimidazole which is obtained from vitamin B<sub>12</sub>; the other hydrolytic products could not be distinguished from those yielded by vitamin B<sub>12</sub>. Pseudovitamin B<sub>12</sub> was active for *L. leichmannii*, *E. coli*, and *Euglena gracilis*, but was inactive in pernicious anemia and for chicks and rats. Other microbiologically active derivatives of cobalamin, inactive for animals, have been detected in the feces of animals.<sup>263</sup> These substances may be breakdown products of vitamin B<sub>12</sub>.

**Determination of Vitamin B<sub>12</sub>.** This is usually carried out by biological assay. Among the organisms used are rats, chicks, *Euglena gracilis*, *L. leichmannii*, and *E. coli* mutant No. 113-3. A correction for purine and pyrimidine deoxyribosides must be made if *L. leichmannii* is used. Chemical procedures have been described based on the addition of cyanide to cobalamin and the subsequent photolytic liberation of the cyanide, followed by its collection and determination.

**Method of U.S. Pharmacopeia XIV—Modified.**<sup>263a</sup> In the determination of vitamin B<sub>12</sub> more than usual care must be taken, owing to the minute amount of the vitamin used in the assay tubes. All glassware must be carefully washed, then rinsed ten times or more with distilled water. To remove last traces of contaminants from glassware it is well to heat it in an oven at 200° C. for an hour.

**TEST SOLUTION OF MATERIAL TO BE ASSAYED.** For liquid preparations or pharmaceutical products, place a sample of suitable size, accurately measured, in a 500-ml. flask, add water to make 400 ml., adjust pH to 6.0, and make to volume of 500 ml. For food or feed products, heat in an autoclave for 15 minutes at 121° C., one g. or

<sup>263</sup> Wijmenga: Thesis, University of Utrecht, 1951; Ford, *et al.*: *Nature*, **171**, 150 (1953).

<sup>263a</sup> Grateful acknowledgment for permission to use this method is made to Dr. Lloyd C. Miller and the Board of Trustees of the U.S. Pharmacopeia, Inc.

ml. of sample in 25 ml. of a freshly prepared bisulfite solution (13.6 g. monobasic potassium phosphate and 10 g. sodium metabisulfite, dissolved in water and made to 1 liter). After cooling, dilute an aliquot of the clear supernatant with water so that the final test solution contains vitamin B<sub>12</sub> activity approximately equivalent to 0.02 millimicrogram of cyanocobalamin. The bisulfite aids in stabilizing naturally occurring analogs of the vitamin. The amount of bisulfite in the assay tube should not exceed 0.10 mg. (or 0.02 mg. per ml.).

**STANDARD CYANOCOBALAMIN SOLUTION.** Prepare a stock solution by dissolving in 25 per cent alcohol an accurately weighed quantity of U.S.P. Cyanocobalamin Reference Standard, so that each ml. contains 1.0 millimicrogram of cyanocobalamin. On the day it is to be used, dilute 10 ml. of the Stock Solution to 500 ml. with water. Each ml. contains 0.02 millimicrogram of cyanocobalamin.

BASAL MEDIUM STOCK SOLUTION

| Ascorbic Acid.....                                                                                          | 1 g.   |

Dissolve the dextrose, sodium acetate, and ascorbic acid in the solutions, previously mixed; add about 50 ml. of water, adjust to a pH of 6.0 with sodium hydroxide solution, and finally add water to make 250 ml.

**ACID-HYDROLYZED CASEIN SOLUTION.** Mix 100 g. vitamin-free casein with 500 ml. dilute hydrochloric acid (1 in 2) and reflux the mixture for 8 to 12 hours. Remove the hydrochloric acid from the mixture by distillation under reduced pressure until a thick paste remains. Redissolve the resulting paste in water, adjust the solution to a pH of 3.5 ( $\pm 0.1$ ) with sodium hydroxide solution, and add water to make 1000 ml. Add 20 g. activated charcoal, stir for 1 hour, and filter. Repeat the treatment with activated charcoal, stir for 1 hour, and filter. Repeat the treatment with activated charcoal. Store under toluene in a refrigerator at a temperature not below 10° C. Filter the solution if a precipitate forms upon storage.

**CYSTINE-TRYPTOPHAN SOLUTION.** Dissolve 400 mg. each of L-cystine and D,L-tryptophan in 100 ml. N HCl.

**ASPARAGINE SOLUTION.** Dissolve 2.0 g. L-asparagine in water to make 200 ml. Store under toluene in a refrigerator.

**ADENINE-GUANINE-URACIL SOLUTION.** Dissolve 0.2 g. each adenine sulfate, guanine hydrochloride, and uracil, with the aid of heat, in 10 ml. 20 per cent hydrochloric acid, cool, and add water to make 200 ml. Store under toluene in a refrigerator.

**XANTHINE SOLUTION.** Suspend 0.2 g. xanthine in 30 to 40 ml. water, heat to about 70° C., add 6.0 ml. ammonia Test Solution, and stir until the solid is dissolved. Cool, and add water to make 200 ml. Store under toluene in a refrigerator.

**RIBOFLAVIN-THIAMINE-BIOTIN-NICOTINIC ACID SOLUTION.** Prepare a solution in 0.02 N acetic acid, each ml. to contain 25  $\mu$ g. riboflavin, 25  $\mu$ g. thiamine hydrochloride, 0.2  $\mu$ g. biotin, and 50  $\mu$ g. nicotinic acid. Store, protected from light, under toluene in a refrigerator.

***p*-AMINO BENZOIC ACID-CALCIUM PANTOTHENATE-PYRIDOXINE-PYRIDOXAL-PYRIDOXAMINE-FOLIC ACID SOLUTION.** Prepare a solution in 25 per cent neutralized alcohol, each ml. to contain 50  $\mu$ g. *p*-aminobenzoic acid, 25  $\mu$ g. calcium pantothenate, 100  $\mu$ g. pyridoxine hydrochloride, 100  $\mu$ g. pyridoxal hydrochloride, 20  $\mu$ g. pyridoxamine dihydrochloride, and 5  $\mu$ g. folic acid. Store in a refrigerator.

**SALT SOLUTION A.** Dissolve 10 g. monobasic potassium phosphate and 10 g. dibasic potassium phosphate in water to make 200 ml. Add 2 drops of hydrochloric acid, and store under toluene.

**SALT SOLUTION B.** Dissolve 4.0 g. magnesium sulfate, 0.2 g. sodium chloride, 0.2 g. ferrous sulfate, and 0.2 g. manganese sulfate in water to make 200 ml. Add 2 drops of hydrochloric acid, and store under toluene.

**POLYSORBATE 80 SOLUTION.** Dissolve 20 g. polysorbate 80 in sufficient alcohol to make 200 ml. Store in a refrigerator.

**TOMATO JUICE PREPARATION.** Centrifuge 1000 ml. commercially canned tomato juice. Suspend 5 to 10 g. analytical filter-aid in the supernatant liquid and filter under reduced pressure, through a layer of analytical filter-aid of sufficient thickness so that a clear, straw-colored filtrate is obtained. Store under toluene in a refrigerator.

**CULTURE MEDIUM.** Dissolve 0.75 g. water-soluble yeast extract, 0.75 g. peptone, 1 g. anhydrous dextrose, and 0.2 g. potassium biphosphate in 60 to 70 ml. water. Add 10 ml. tomato juice preparation and 1 ml. polysorbate 80 solution. Adjust the solution to pH 6.8 with sodium hydroxide solution, and add water to make 100 ml. Place 10-ml. portions of the solution in test tubes, and plug with cotton. Sterilize the tubes and contents in an autoclave for 15 minutes at 121° to 123° C. (exhaust-line temperature).

**SUSPENSION MEDIUM.** Dilute a measured volume of basal medium stock solution with an equal volume of water. Place 10-ml. portions of the diluted medium in test tubes. Sterilize and cool as directed above for the culture medium.

**STOCK CULTURE OF THE *Lactobacillus leichmannii*.** To 100 ml. culture medium add 1.0 to 1.5 g. agar, and heat the mixture, with stirring, on a steam bath, until the agar dissolves. Add approximately 10-ml. portions of the hot solution to test tubes, plug the tubes with cotton, sterilize for 15 minutes in an autoclave at 121° to 123° C. (exhaust-line temperature), and allow the tubes to cool in an upright position. Prepare a stab culture from the pure culture of *L. leichmannii*, obtained from American Type Culture Collection<sup>264</sup> (No. 7830). Incubate 6 to 24 hours at any constant temperature between 30° and 37° C. Activate a newly obtained culture by making several daily transfers before use in an assay. Maintain the culture in an active state by transfer at least three times weekly.

**INOCULUM.** Make a transfer of cells from the stock culture to a sterile tube of culture medium, and incubate 6 to 24 hours at a constant temperature between 30° and 37° C. Under aseptic conditions centrifuge the culture, decant the supernatant, and suspend the cells in 10 ml. sterile suspension medium.

**Procedure.** Cleanse hard glass test tubes, about 20  $\times$  150 mm. in size, and other necessary glassware meticulously by suitable means because of the high sensitivity of the test organism to minute amounts of vitamin B<sub>12</sub> activity and to traces of many cleansing agents.

To test tubes add in triplicate, 0.0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, and 5.0 ml., respectively, of the Standard Cyanocobalamin Solution. To each tube add 5.0 ml. of basal medium stock solution and sufficient water to make 10 ml.

To similar test tubes add, in triplicate, respectively 1.0, 2.0, 3.0, and 4.0 ml.

<sup>264</sup> American Type Culture Collection, 2029 M Street, N.W., Washington 6, D.C.

of the test solution of the material to be assayed. To each tube add 5.0 ml. of basal medium stock solution and sufficient water to make 10 ml.

After mixing, cover the tubes suitably to prevent bacterial contamination, and sterilize the tubes and contents in an autoclave for 5 minutes at 121° to 123° C. (exhaust-line temperature) arranging to reach this temperature in not more than 10 minutes. Cool as rapidly as practicable to avoid color formation resulting from overheating the medium. Take precautions to maintain uniformity of sterilizing conditions throughout the assay.

Aseptically inoculate each tube (except three tubes containing no Standard Cyanocobalamin Solution-uninoculated blank) with 1 drop of inoculum. Incubate for 6 to 24 hours, until maximum turbidity is obtained, as demonstrated by a lack of significant change during a two-hour period in the tubes containing the highest level of Standard Cyanocobalamin Solution (0.1 millimicrogram). Maximum turbidity is ordinarily obtained in 14 to 24 hours. Read the turbidity of the tubes in a suitable instrument, at a specific wavelength that is optimal for the instrument used. This will lie between 540 and 660  $m\mu$ . In taking the instrument reading, thoroughly mix the contents of each tube and transfer to optical glassware. Agitate each tube or cuvette to obtain a uniform suspension. A few seconds after agitation a steady state is reached in which the galvanometer needle remains constant for 30 seconds or more, allowing sufficient time for an instrument reading. A little practice will establish the proper time interval. With the inoculated blank in the instrument, set the meter to read 100 per cent transmittancy, read the transmittancy of the inoculated blank (the inoculated tubes to which no Standard Cyanocobalamin solution has been added). Disregard the results of an assay if contamination with a foreign organism is evident, or if the inoculated blank tubes give a reading of less than 90 per cent transmittancy (Evelyn or Lumetron), 80 per cent (Coleman), or 65 per cent (Beckman), thereby indicating interference due to vitamin B<sub>12</sub> activity in the basal medium stock solution or inoculum. Then with the inoculated blank in the instrument set the meter to read 100 per cent transmittancy. Read the transmittancy of the tubes of the standard and sample series. Disregard the results of an assay if the transmittancy of the tubes containing the highest level of Standard Cyanocobalamin Solution (0.1 millimicrogram) is more than 65 per cent (Evelyn or Lumetron) or 50 per cent (Beckman or Coleman).

**CALCULATION.** Prepare a standard concentration response curve by plotting the per cent transmittancy readings for each level of the Standard Cyanocobalamin Solution used, against millimicrograms of cyanocobalamin contained in the respective tubes. Draw the smooth curve which by visual inspection appears to fit best the plotted points.

From this standard curve, determine by interpolation for each tube the amount of cyanocobalamin equivalent to the vitamin B<sub>12</sub> activity of each ml. of the test solution of the material to be assayed.

Since in microbial assays occasional inexplicable aberrant values are obtained in individual tubes, inspect the series of values and set aside any which vary markedly from most of the series. Strike a provisional average of the remaining values, and set aside any of the latter which are less than 90 per cent and more than 110 per cent of the provisional average. If less than 10 of the 15 original values remain, the data are insufficient for calculating the potency; if 10 or more values remain, calculate the potency from the average of them. If the calculated potency of an assay is less than 75 per cent or more than 125 per cent of the assumed potency, the result is out of the critical range; for greater accuracy a reassay at a level more closely approximating the true value is necessary.

**Determination of Cobalamin (Pad-Plate Method of Williams and Co-workers):**<sup>265</sup> **Principle.** Cobalamin is determined by measurement of growth of *E. coli* mutant. The diameter of the growth zones on agar plate is measured and evaluated on a standard curve.

**Distribution of Cobalamins.** Good food sources include liver, kidney, lean meat, fish, milk, and oysters. The higher plants contain little or no vitamin B<sub>12</sub>, but it is produced by many microorganisms, including molds of the *Streptomyces* group which are used for its industrial production. Ruminating animals appear to obtain the vitamin from fermentations which are carried out by the microflora of their digestive tract; this accounts for the presence of cobalamins in beef liver and also for the fact that in ruminants a lack of cobalt leads to a wasting disease caused by a deficiency of vitamin B<sub>12</sub>.

### THIOCTIC ACID (PROTOGEN, LIPOIC ACID)

This coenzymatic factor has not been shown to be essential in the diet of animals and should not, strictly speaking, be classified as a vitamin. However, thioctic acid has biochemical functions which relate it closely to the B vitamins.

The protozoon *Tetrahymena geleii* was shown by Dewey and Kidder<sup>266</sup> to need an unidentified factor present in liver and other natural materials. This factor was shown to contain a component which differed from the known vitamins and was named "protogen." Two chemically distinct forms were shown to exist.<sup>267</sup> In other investigations extracts prepared from yeast were found to be interchangeable with acetate in promoting the growth of *L. casei*<sup>268</sup> and to be needed for the oxidation of pyruvate by resting cells of a strain of *S. fecalis*.<sup>269</sup>

The crystallization and study of one form of the acetate-replacing factor, which was renamed " $\alpha$ -lipoic acid," showed the presence of sulfur<sup>270</sup> and a similar compound obtained from liver was also found<sup>271</sup> to contain sulfur. The synthesis of DL-6,8-dithiooctanoic acid (abbreviated to "6-thioctic acid") was accomplished following studies of the structure of the natural compound.<sup>272</sup> The biological activity of 6-thioctic

acid is high; 0.4 parts per billion of purified culture medium is sufficient to produce half-maximum growth of *T. geleii*. It was suggested that the compound may be present in biological systems in acid amide linkage with thiamine pyrophosphate.<sup>273</sup> Oxidation and reduction of 6-thioctic acid give rise respectively to an oxide (protogen B or  $\beta$ -lipoic acid) and a dithiol:

**Physiological Aspects of Thioctic Acid.** The interchangeability of protogen with acetate in the nutrition of *S. fecalis* and the role of protogen in the oxidation of pyruvate were early observations which indicated the coenzymatic functions of the substance and its probable relation to co-carboxylase (diphosphothiamine). Approximately 6 moles of protogen and 1 mole of diphosphothiamine were found to be present in  $\alpha$ -ketoglutaric acid oxidase,<sup>274</sup> and the presence of protogen in pyruvic oxidase was also noted,<sup>275</sup> suggesting a possibility that steps of the following type might occur in the oxidation of keto acids:<sup>276</sup>

Oxidation of (B), the dihydrothioctic acid form of the coenzyme, restores the latter to its original condition.

**Chemistry of Thioctic Acid.** 6-Thioctic acid is a light-yellow crystalline solid, M.P. 60°–61° C. (Fig. 283). It is insoluble in water but readily dissolves in alcohol, acetone, ether, and many other organic solvents. The sodium salt is freely soluble in water. Thioctic acid is comparatively stable, but solutions tend to become oxidized by air to thiosulfinyloctanoic acid (oxythioctic acid, protogen B, or  $\beta$ -lipoic acid). The ultraviolet absorption spectrum shows a peak at 332 m $\mu$  (molar extinction coefficient  $\pm 160$ ). Calvin and Massini<sup>277</sup> have suggested that light shifts the equilibrium of the thioctic-acid-containing coenzyme toward the reduced (dithiol) form, thus rendering it incapable of oxidatively decarboxylating pyruvic acid (newly formed from CO<sub>2</sub>) to give rise to acetyl-coenzyme A required to bring this carbon into the tricarboxylic acid cycle. It was

further suggested<sup>278</sup> that a biradical formed by dissociation of the disulfide bond in a strained five-membered disulfide-containing ring, such as in thioctic acid, is the form in which light energy travels from chlorophyll to the chemical reactions concerned with the fixation of carbon dioxide in photosynthesis (see also p. 58).

## DETERMINATION OF THIOCTIC ACID

**Microbiological Assay.** A number of microorganisms are now known which under appropriate conditions require thioctic acid for growth. *Corynebacterium bovis* (Strain B-187) has been shown by Stokstad *et al.*<sup>279</sup> to be suitable for the microbiological assay. The procedure is as follows:

### THIOCTIC ACID STANDARD SOLUTION.

(a) *Preparation.* A water solution containing 1  $\mu$ g. DL-6,8-dithiooctanoic acid per ml. is prepared. An aliquot of this standard solution is diluted to 1.0 millimicrogram per ml.

(b) *Assay Levels of Diluted Standard Solutions.* 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0 ml.

The preparation of the various constituents of the medium is as follows:

**VITAMIN-FREE, ACID-HYDROLYZED CASEIN.**<sup>280</sup> Reflux 300 g. Labco "vitamin-free" casein at least 12 hours with 3 liters of 20 per cent HCl. Evaporate it under vacuum to a thick syrup, then dilute to 3 liters with distilled water. This concentration procedure is repeated twice. The final concentrate is diluted to 1 liter. The pH is adjusted to 2.5 with KOH. The mixture is stirred with 30 g. of activated carbon (Darco G 60) for 15 minutes, then filtered with the aid of "Filter-cel." The pH is adjusted to 6.8 with KOH after the volume of solution is brought to 3 liters, and the charcoal treatment and filtration are repeated. One ml. of the solution contains the equivalent of 100 mg. of original casein.

<sup>278</sup> Calvin and Barltrop: *J. Am. Chem. Soc.*, **74**, 6153 (1952).

<sup>279</sup> Stokstad, *et al.*: *Proc. Soc. Exptl. Biol. Med.*, **74**, 571 (1950).

<sup>280</sup> Kitay, McNutt, and Snell: *J. Bact.*, **59**, 727 (1950).

ADENINE AND GUANINE. These are dissolved together in a small amount of 1.0 N HCl with heat and diluted to 1 mg. per ml.

URACIL. Dissolve in dilute NH<sub>4</sub>OH and dilute to 1 mg. per ml.

TRYPTOPHAN. Dissolve in a small amount of 1.0 N HCl and dilute to 10 mg. per ml.

ASPARAGINE. Dissolve 1 g. asparagine in 100 ml. water.

VITAMINS. Dissolve 100 mg. *i*-inositol, 100 mg. choline chloride, 10 mg. calcium pantothenate, 10 mg. thiamine hydrochloride, 10 mg. nicotinamide, 10 mg. riboflavin,

| L-cystine                   | 100 mg.                                          | <i>p</i> -Aminobenzoic acid | 0.5 “                                            |
| Adenine sulfate             | 10 mg.                                           | Pteroylglutamic acid        | 0.5 “                                            |
| Guanine hydrochloride       | 10 mg.                                           | Biotin                      | 0.5 “                                            |
| Uracil                      | 10 mg.                                           |                             |                                                  |

Combine ingredients, adjust to pH 6.8 and make up to 500 ml. with water.

10 mg. pyridoxine hydrochloride, 10 mg. *p*-aminobenzoic acid, 10 mg. pteroylglutamic acid, and 10 mg. biotin in 100 ml. distilled water, and store in the cold room under toluene. Add 1 ml. of this solution per 100 ml. of double-strength medium.

**Preparation of Sample Solutions.** If the thioctic acid in the test sample is in a “bound form,” the sample should be autoclaved at 15 pounds pressure for 2 hours with 2 volumes of 8 N sulfuric acid, cooled, neutralized, and filtered to give a clear filtrate for assay. The assay samples, together with the standard dilutions of thioctic acid, are pipetted into 12 × 100 mm. test tubes and brought to a volume of 1 ml. with water; 1 ml. double-strength basal medium is added per tube, the tubes are capped with metal or glass caps, and then are sterilized for 15 minutes at 15 pounds pressure. After cooling to room temperature the tubes are inoculated as described below.

**Preparation of the Inoculum.** An inoculum is prepared by growing the organism at 25° C. for 48 hours on the basal medium plus 10 mg. Wilson’s liver fraction L<sup>281</sup> per tube. The cells are centrifuged, resuspended in an equal volume of saline, and 1 drop is used per 2-ml. assay tube. The assay tubes are incubated at 25° C. for 72–88 hours. The growth response is measured by recording the optical density of the cultures with the photoelectric turbidimeter. From these data a curve can be plotted relating growth to thioctic acid concentration, and from this response curve the potency of the unknown samples can readily be calculated.

<sup>281</sup> Other crude liver extracts may be used.

**Distribution of Thioctic Acid.** The substance is widely distributed in biological materials. Liver, pancreas, yeast, green leaves, and soybean meal have been reported to be good sources. The thioctic acid content of the chick embryo increases rapidly during the final days of incubation, presumably indicating synthesis by the tissues.

### PARA-AMINOBENZOIC ACID

The earliest indications of the nutritional importance of *p*-aminobenzoic acid were observations that the compound counteracted the bacteriostatic effect of sulfanilamide.<sup>282</sup> Its importance in the nutrition of microorganisms and of higher animals was established shortly thereafter, as well as its presence in certain natural materials, particularly yeast.<sup>283</sup>

**Physiological and Clinical Aspects of *p*-Aminobenzoic Acid.** *p*-Aminobenzoic acid is the "bridge" between pteric and glutamic acids in the structure of folic acid. Although *p*-aminobenzoic acid (PABA) is frequently classed among the vitamins there is little to justify the belief that it plays a direct role in human nutrition. Evidence points rather to its essential role in microbial nutrition and hence to its stimulating effect on vitamin synthesis by intestinal microflora. Direct evidence of such bacterial synthesis is seen in the observation that excretion of *p*-aminobenzoic acid greatly exceeded dietary intake. (See p. 812.)

An excess of *p*-aminobenzoic acid inhibits the bacteriostatic effect of sulfonamides, possibly because of structural similarities (see Chapter 36). This antagonism obeys the mass action law, thus indicating that the inhibition is competitive. The antisulfonamide effect of the vitamin has been noted *in vitro*<sup>284</sup> as well as *in vivo* in mice infected with *Streptococcus hemolyticus*. Sulfonamide-resistant strains of *Staphylococcus* have been developed in which the resistance is proportional to the ability of the microorganism to synthesize *p*-aminobenzoic acid. *p*-Aminobenzoic acid interferes with the malaricidal action of sulfanilamide drugs, but not with that of quinine and atropine, which probably attack the microorganism through a different channel. The use of *p*-aminobenzoic acid derivatives as local anesthetics and their possible incompatibility with sulfonamides administered subsequently as bacteriostatic agents has been considered. Observations relating to the behavior of *p*-aminobenzoic acid under physiological conditions, however, indicate that *p*-aminobenzoic acid therapy probably does not interfere with subsequent administration of sulfonamides. Furthermore, it has been found that small amounts of *p*-aminobenzoic acid often potentiate sulfonamides.

*p*-Aminobenzoic acid is essential for normal growth<sup>285</sup> in the non-lactating rat,<sup>286</sup> for lactation in albino rats and in sows,<sup>287</sup> and for the

<sup>284</sup> Woods: *loc. cit.*

<sup>285</sup> Ansbacher: *Science*, **93**, 164 (1941).

<sup>286</sup> Unna, Richards, and Sampson: *J. Nutrition*, **22**, 553 (1941).

<sup>287</sup> Sure: *J. Nutrition*, **22**, 499 (1941).

maintenance of hair color in the black rat.<sup>288</sup> The injection of hydroquinone in cats or mice results in graying of the fur, which can be prevented or cured by *p*-aminobenzoic acid. The use of PABA in the treatment of nutritional achromotrichia in man, reported to be successful in a few isolated cases, has been refuted on the basis of more carefully controlled studies.<sup>289</sup> Anti-gray-hair properties have also been demonstrated for pantothenic acid, biotin, and folic acid. Stimulation of the growth of microorganisms by the administration of one of the vitamin B complex may cause an increased synthesis or utilization of another member by the intestinal flora. This makes it difficult to ascribe particular physiological effects to specific B vitamins when administered orally. Thus the action of *p*-aminobenzoic acid in the prevention of achromotrichia has been ascribed by some observers to alterations in the intestinal flora promoting the synthesis of pteroylglutamic acid or of other factors concerned with melanin formation.

In some species, *p*-aminobenzoic acid has been found to increase the physiological potency of insulin and penicillin. It may also play a role in the metabolism of hormones—for example, by inhibiting the production of thyroid hormones. In addition, the rate of enzymatic inactivation of stilbestrol by mushroom tyrosinase, as well as the oxidative destruction of epinephrine, are inhibited by *p*-aminobenzoic acid.

*p*-Aminobenzoic acid absorbs ultraviolet radiations (maximum 297.5  $m\mu$ ) in the range which produces sunburn and suntan in human skin.

*p*-Aminobenzoic acid participates in certain detoxication reactions. In rats PABA detoxifies high doses of pentavalent and trivalent arsenical drugs used in the treatment of various forms of syphilis, without interfering with their bacteriostatic potency. It has also been claimed to detoxify antimony compounds used in tropical diseases.

Large doses of *p*-aminobenzoic acid are toxic to dogs and mice. The oral administration of more than 1 g. per kg. body weight in dogs is fatal. On the other hand, the administration of 1.4 g. per kg. body weight to rats is nontoxic. Moderate doses are acetylated by man and excreted in the urine.

**Distribution of *p*-Aminobenzoic Acid.**<sup>290</sup> *p*-Aminobenzoic acid is present in most tissues. It occurs in nature in both the free and the combined form. Relatively high concentrations (several micrograms per gram) are found in yeast, liver, rice bran, rice polishings, and whole wheat. In the last it is present mostly in the germ. Milk contains about 0.1 mg. per liter.

**Chemistry of *p*-Aminobenzoic Acid.** *p*-Aminobenzoic acid was synthesized by Fischer<sup>291</sup> as early as 1863, by reduction of *p*-nitrobenzoic acid with ammonium sulfide. It crystallizes in colorless needles which

melt at 186° C. It is soluble in water to the extent of 0.5 per cent at room temperature, but is freely soluble in alcohol or boiling water.

### DETERMINATION OF *p*-AMINOBENZOIC ACID

No satisfactory chemical method is available for the determination of *p*-aminobenzoic acid. It reacts with *p*-dimethylaminobenzaldehyde in glacial acetic acid to produce a compound having a yellow color. However, this reaction, as well as other coupling reactions, is nonspecific and is given by isomers of *p*-aminobenzoic acid as well as by aniline and its derivatives, and by sulfonamides. In the analysis of biological materials, the bound vitamin must first be freed by strong acid or alkaline hydrolysis.

*p*-Aminobenzoic acid is required for the growth of several microorganisms, including *Brucella abortus*, *Streptococcus hemolyticus*, and *Clostridium acetobutylicum*. Microbiological methods for the determination of PABA are based upon the growth stimulation of *Acetobacter suboxydans*<sup>292</sup> and of a *p*-aminobenzoicless mutant of *Neurospora crassa*.<sup>293</sup> Determinations may also be made employing organisms which do not require an external supply of the vitamin by measuring the degree of inhibition of the bacteriostatic effect of sulfa drugs resulting from the addition of *p*-aminobenzoic acid.

### CHOLINE

Choline has occupied a prominent place in biochemical literature because of its relationship both to the phospholipides and to its acetyl ester. Acetylcholine, first studied as a synthetic product, then found in plant and animal tissues, plays an important role in the humoral transmission of parasympathetic and other nerve impulses to effector organs. More recently, choline has achieved added significance because of its role in the process of transmethylation (see below and p. 1029).

Choline, probably of phospholipide origin, was isolated independently by numerous investigators, and has been variously designated sinkalin, bilineurine, fagin, amanitin, and neurine, the latter term being now reserved for the unsaturated base, trimethylvinylammonium hydroxide.

Because of its biochemical function and its distribution in foods, choline is usually considered along with the vitamins of the B group. However, it not only lacks the specificity characteristic of the vitamins but is actually a structural component of fat and nerve tissue. Moreover it is not known to participate as a cofactor in an enzyme system. Hence choline is not, strictly speaking, a vitamin. Part of the syndrome of

<sup>292</sup> Cheldelin and Bennett: *J. Biol. Chem.*, **161**, 751 (1945).

<sup>293</sup> Agarwala and Peterson: *Arch. Biochem.*, **27**, 304 (1950).

choline deficiency in animals can be cured by the administration of other methyl group donors, (e.g. methionine, betaine) or of vitamin B<sub>12</sub> which plays a role in methyl group transfer.

**Physiological Properties of Choline.** Choline is essential for normal growth of the rat, chick, and dog, and for lactation in the rat. Dietary deficiency has been demonstrated to be responsible for paralysis in the hind legs of nursing rats, inhibition of egg production in hens, slipped tendon (perosis) in chicks and young turkeys, and fatty liver in rats, dogs, rabbits, and pigs. The last-mentioned symptom is not observed in guinea pigs, whose low requirement for choline is attributed to a lack of hepatic choline oxidase. Choline deficiency in young rats produces an acute hemorrhagic lesion of the kidneys. Even after short exposure to this condition and subsequent restoration to an adequate diet, such rats have been reported later in life to develop hypertension with cardiac enlargement and persistent renal damage.<sup>294</sup>

Choline performs several physiological functions. It enters into the molecular structure of phospholipides and acetylcholine, and supplies labile methyl groups for transmethylation reactions. Phospholipides are concerned with the mobilization of fat in the body. In the absence of choline, neutral fat, and to some extent cholesterol esters, accumulate in the liver. Choline is also lipotropic in that it prevents fatty livers in depancreatized dogs. However, this condition, when induced in rats by high-cholesterol feeding, does not respond to choline feeding.

Certain specific compounds with labile methyl groups, or otherwise related in structure, can replace choline in some of its biological functions. Methionine mobilizes liver fat in a manner similar to choline, and both the D- and L-forms are equally effective. The mechanism probably involves the transfer of labile methyl groups from methionine to ethanolamine with the formation of choline. In support of this hypothesis is the observation that choline containing deuterium may be isolated from the animal organism after feeding methionine whose labile methyl group contains deuterium. Betaine and other lipotropic factors may also supply methyl groups to ethanolamine. Conversely, methionine, an essential amino acid, can be replaced by homocystine when choline, betaine, or dimethylethylammonium chloride is fed. The methyl-diethyl and the triethyl homologs do not support growth, but are strong lipotropic agents, and prevent the occurrence of hemorrhagic kidneys. Arsenocholine and sulfocholine likewise have lipotropic action and prevent renal hemorrhage, but neither of these compounds can methylate homocystine. There is no diminution of activity when phosphorus is substituted for the nitrogen of choline. The hydroxyl group must be free, however, since ethers are inactive. The methyl groups of creatine, S-methyl cysteine, or of the betaines from threonine, serine, or allo-threonine, are not available for transmethylation.

Choline serves as a methylating agent in the physiological process: guanidoacetic acid → creatinine. Here, too, methionine and betaine can replace choline.

---

<sup>294</sup> Hartercroft and Best: *Brit. Med. J.*, 1, 423 (1949).

Choline is involved in the transmission of nerve impulses in the form of its acetyl ester, acetylcholine, a powerful agent which lowers the blood pressure. The organism maintains a delicate balance between acetylcholine and choline (the latter having only slight vasodilator effect) by means of specific enzyme systems which can acetylate to acetylcholine or hydrolyze to free choline when necessary.

**Storage and Synthesis of Choline.** Choline is present in the animal organism chiefly in the form of the phosphatides; i.e., the lecithins and sphingomyelins. The fatty matter of brain, kidney, and liver is distinguished from that of adipose tissue by the fact that it consists largely of phosphatides. Lecithin is the glyceryl ester of a pair of fatty acids and a substituted phosphoric acid group attached to a choline radical. Sphingomyelin contains a fatty acid, sphingosine, and a choline-phosphoric acid group. In beef liver, only 2 per cent of the total choline is present in the free form.

As discussed above, choline may be synthesized *in vivo* from ethanolamine and a methyl donor, methionine or betaine. Rats on a diet containing ample methionine, for example, need no dietary supply of choline.

**Distribution of Choline.**<sup>295</sup> The concentration of choline in animal tissues is proportional to their phospholipide constituents. Thus egg yolk, liver, kidneys, brain, heart, and nervous tissue are rich sources. Good sources of choline are muscle tissue, green, leafy and leguminous vegetables, seed oil meals, and grain germs. In corn meal, 75 per cent of the choline is concentrated in the germ, while 50 per cent of the choline in wheat is lost in the preparation of white flour. In general, seed meals and seeds are considerably better sources than the cereal grains. Butter, lard, and refined vegetable oils are almost devoid of choline. Mixed diets of man have been shown to provide 0.5 to 1.0 g. of choline per day, an order of magnitude more nearly resembling that of individual amino acids than that of vitamins.

**Chemistry of Choline.** Choline was first isolated by Strecker in 1849 and synthesized by Wurtz in 1867. It possesses the following structure:

The free base is a colorless, crystalline, extremely hygroscopic compound. It is a stronger base than ammonia and easily forms salts with acids. Pure choline, when heated, decomposes to trimethylamine and ethylene glycol. Aqueous solutions containing less than 4 per cent choline may be heated without decomposition, but losses occur in more concentrated media. Choline is more stable to heat in acid than in neutral or alkaline solution. Choline dihydrogen citrate, choline chloride, and carbamyl choline chloride are used medicinally.

<sup>295</sup> For quantitative data see Rhian, Evans, and St. John: *J. Nutrition*, **25**, 2 (1943); Engel: *ibid.*, **25**, 441 (1943); McIntire, Schweigert, and Elvehjem: *ibid.*, **28**, 219 (1944); Glick: *Cereal Chem.*, **22**, 95 (1945); Willstaedt, Borggard, and Lieck: *Z. Vitaminforsch.*, **18**, 25 (1946); also reference footnote 296.

Choline is readily soluble in water, methyl alcohol, ethyl alcohol, and formaldehyde; slightly soluble in dry amyl alcohol, dry acetone, and chloroform; and insoluble in dry ether, petroleum ether, benzene, toluene, carbon bisulfide, and carbon tetrachloride. The salts are soluble in water and alcohol, forming aqueous solutions which are nearly neutral.

Choline may be precipitated from aqueous solution by potassium triiodide, phosphotungstic acid, phosphomolybdic acid, or reinecke salt. These precipitants, especially the last, have been employed in quantitative methods for its determination. Choline chloride also forms characteristic double salts with the chlorides of platinum, gold, and mercury.

## DETERMINATION OF CHOLINE

### **Microbiological Assay (Method of Horowitz and Beadle):<sup>296</sup> Principle.**

Choline may be measured by the growth stimulation of a mutant strain of *Neurospora crassa* designated as *cholineless*, produced artificially by exposure to ultraviolet radiation. Methionine, which can replace choline for the microorganism, is removed by adsorption of the extract on "Permutit" followed by elution with sodium chloride solution. The microbiological procedure for the determination of choline is far more sensitive and possibly more specific than the chemical procedure.<sup>297</sup> The latter involves precipitation and isolation of the reineckate, followed by colorimetric measurement of the red pigment at 520 m $\mu$  in acetone solution.

**Procedure.** Heat 100 mg. of sample in an autoclave for 2 hours at 15 pounds pressure in 10 ml. 3 per cent sulfuric acid, or reflux for 7 hours. Neutralize to congo red with saturated barium hydroxide solution. Centrifuge and filter the supernatant through a Whatman No. 50 paper. Add 3 ml. distilled water to the precipitate and bring to a boil with stirring. Cool, centrifuge, and add the washing to the previous supernatant. Neutralize the solution to litmus with 1 N sodium hydroxide solution and dilute with distilled water to a concentration of approximately 15  $\mu$ g. per ml. Pass 5 ml. of the neutralized extract<sup>298</sup> through a column 100 mm. long and 5 mm. wide (internal diameter) containing 1 g. of Permutit. Wash the column with 5 ml. of 0.3 per cent sodium chloride and discard the filtrate and washings. Elute the choline with 10 ml. of 5 per cent sodium chloride.<sup>299</sup>

Prepare a basal medium having the following composition in g. per liter: ammonium tartrate 5, ammonium nitrate 1, monobasic potassium phosphate 1, magnesium sulfate·7H<sub>2</sub>O 0.5, sodium chloride 0.1, calcium chloride 0.1, sucrose 20, biotin 5  $\times 10^{-6}$ . In addition, add the following trace elements as salts in mg. per liter: boron 0.01, molybdenum 0.02, iron 0.2, copper 0.1, manganese 0.02, and zinc 2.0.

Maintain stock cultures of the *cholineless* mutant No. 34486 of *Neurospora crassa* on agar slants composed of the basal medium plus 1.5 per cent agar, 0.2 per cent Difco yeast extract, 0.2 per cent malt extract, and 1  $\mu$ g. per ml. of choline. For inoculum, prepare a spore suspension in a few ml. of distilled water.

Pipet 0.5, 1.0, and 2.0 ml. aliquots of the sodium chloride eluate in duplicate into 250-ml. Erlenmeyer flasks, and dilute each to 25 ml. with basal

<sup>296</sup> Horowitz and Beadle: *J. Biol. Chem.*, **150**, 325 (1943).

<sup>297</sup> U.S. Pharmacopoeia XIII.

<sup>298</sup> If the solution is known to contain less than 3  $\mu$ g. of choline per ml., pass 10 ml. through the column.

<sup>299</sup> If more filtrate is required in case the approximate choline content is unknown, adsorb two or more portions of the solution simultaneously on separate columns.

medium. The final concentration of choline should lie between 2.0 and 20  $\mu\text{g.}$  per 25 ml. At the same time set up a series of standards having 0, 2, 4, 8, 12, 16, 20, 25, and 30  $\mu\text{g.}$  of choline per flask. Autoclave the solutions at 15 pounds pressure for 10 minutes, cool, and add 1 drop of inoculum to each. Incubate at 25° C. for 3 days. At the end of this period, collect the mold pads on tared, fritted glass filters of medium porosity, and wash with distilled water. Dry in an oven at 90° C. and determine the dry weight.

CALCULATION. Prepare a reference curve from the data obtained with the standard series, plotting  $\mu\text{g.}$  of choline as the abscissa and weight of dry mold as the ordinate. From this curve read off the choline concentration,  $C$ , per ml. of eluate. Then

$$C \times \frac{10}{A} \times \frac{V}{0.1} = \mu\text{g. choline per g. of sample}$$

where  $V$  is the volume to which the original extract was diluted, and  $A$  is the volume of the aliquot which was passed through the "Permutit" column.

## INOSITOL

Though inositol was long known to be a constituent of heart muscle, and of many plants (in the form of phytin, the calcium-magnesium salt of inositol hexaphosphate), its functional similarity to the vitamins was not recognized until recently. Eastcott<sup>300</sup> isolated from yeast the factor previously known as bios I and demonstrated its identity with inositol. The biologically active compound is optically inactive (designated *i*-inositol or *meso*-inositol) as distinguished from its biologically inert stereoisomers. In addition to its role as a yeast growth factor, inositol has been identified with the mouse alopecia factor of Woolley,<sup>301</sup> and the rat anti-spectacled-eye factor of Pavcek and Baum.<sup>302</sup>

**Physiological Properties of Inositol.** Though the metabolism or mode of action of inositol has not yet been elucidated, its importance in the nutrition of several species has been demonstrated. An external source is required by some yeasts and fungi, but not by all. Young mice on a deficient diet suffer an inhibition of growth and loss of hair, both of which are corrected by supplementation with inositol. Growth of a transplanted mouse tumor has been inhibited by inositol. It is also essential for proper growth in the chick and rat. The spectacled-eye condition in rats due to loss of hair about the eyes is a result of dietary deficiency. The vitamin also has lipotropic properties for this species, but more for the "cholesterol" than the "fat" type of fatty livers. Inositol stimulates gastrointestinal peristalsis in dogs. Though the vitamin must be present in the free state to be available to yeast, it is readily utilized by the mouse in natural bound forms such as phytin and soybean cephalin, as well as synthetic methyl inositol and inositol hexaacetate.

The metabolism of inositol is related to that of other vitamins. It has been suggested that pantothenic acid regulates absorption of inositol from the intestine, for a diet containing inositol produces symptoms of

<sup>300</sup> Eastcott: *J. Phys. Chem.*, **32**, 1094 (1928).

<sup>301</sup> Woolley: *J. Biol. Chem.*, **136**, 113 (1940).

<sup>302</sup> Pavcek and Baum: *Science*, **92**, 384 (1940).

inositol deficiency if pantothenic acid is lacking. A relationship to *p*-amino-benzoic acid has also been established. In one series of experiments, black rats showed little signs of deficiency when both inositol and *p*-amino-benzoic acid were either absent or present, but exhibited typical symptoms when either nutrient alone was eliminated from the diet.

Because of its similarity in structure both to the carbohydrates and to the aromatics, inositol has been designated as a possible physiological link between these two classes of compounds.

**Storage and Synthesis of Inositol.** The wide distribution and variety of forms of inositol in animal and plant tissues indicate that it is present for some physiological purpose rather than merely for storage of phosphoric acid or hydroxyl groups. It has been reported that inositol may be synthesized by intestinal flora, a process stimulated by the presence of pantothenic acid.

**Distribution of Inositol.**<sup>303</sup> In animal tissues, high concentrations are found in kidney, heart, spleen, thyroid, and testes. Inositol is found in the free form in muscle and other tissues; hence the name muscle sugar. In liver and heart muscle it is found combined, probably with a protein. Excellent dietary sources are cereal brans and seeds (in the form of phytin) and fruits, particularly of the citrus variety. A compound of inositol has been found in the phosphatide fraction of the soybean.

**Chemistry of Inositol.** *meso*-Inositol is one of the eight *cis-trans* isomers of hexahydrocyclohexane, one of which occurs in optically active forms, making nine in all. It is a sweet-tasting crystalline compound and is isomeric in molecular formula with the hexose sugars. It crystallizes as the anhydride (M.P. 225°–226°) from water at temperatures above 50° C. and from anhydrous solvents. Below 50°, the dihydrate (M.P. 215°–216°) appears. The molecule is stable to strong acid and alkaline hydrolysis. It is very soluble in water but insoluble in absolute alcohol or ether. *meso*-Inositol is optically inactive.

**Determination of Inositol.** The microbiological method for determination of vitamin B<sub>6</sub>, depending on the growth stimulation of *Saccharomyces cerevisiae* (p. 1185) or *carlsbergensis*<sup>304</sup> may be used for the determination of inositol by simple modification of the basal medium to exclude inositol and include an excess of pyridoxine. High specificity is

claimed for the microbiological assay using the *inositol-less* mutant of *Neurospora crassa* (No. 37401).<sup>305</sup>

### ASCORBIC ACID (VITAMIN C)

Scurvy was once extremely common particularly among navigators on long voyages. Its etiological relationship to the absence of fresh fruits and vegetables was forecast as far back as the sixteenth century, when the curative value of a decoction of spruce needles, an herb called scurvy grass, and especially of "sower Oranges and Lemmons" were recognized. The regulation requiring British vessels to carry a supply of lemons or limes for their crews gave rise to the name Limehouse for London's shipping district, whence the term "limey" or "lime juicer" for a sailor.

The dietary origin of the disease was confirmed experimentally in guinea pigs by Holst and Frölich<sup>306</sup> in 1907, and the deficient factor was among the first to receive the designation of a vitamin. Outbreaks of scurvy among infants, prisoners, explorers, troops, and in war-ridden countries where the diets are restricted or unbalanced, continue to be reported. Frank scurvy is comparatively rare. Far more prevalent is the incidence of subclinical vitamin C deficiency manifested by vague and indefinite symptoms and diagnosed only with the aid of accurate dietary histories and laboratory determinations of the blood levels or urinary excretion of the vitamin. Several studies of the ascorbic acid nutrition of large population groups have revealed widespread subclinical vitamin C deficiency. In the examination of large segments of the population in Puerto Rico and Newfoundland, 58 and 72 per cent respectively of the individuals examined showed low plasma ascorbic acid levels.<sup>307</sup> The status of ascorbic acid nutrition shows seasonal variation, and depends upon the fluctuation of available dietary supplies. Because of the relatively high cost of fresh fruits and vegetables as compared with the less expensive cereal grains, subclinical vitamin C deficiency is more prevalent among low-income groups.

The isolation of crystalline vitamin C from lemon juice was first announced in 1932 by King and Waugh.<sup>308</sup> Szent-György<sup>309</sup> concluded from his own studies on adrenal cortex, cabbage, and citrus juices that vitamin C was identical with "hexuronic acid," but later, with the collaboration of Haworth, established a different structural configuration and named vitamin C "ascorbic acid" because of its antiscorbutic properties. Shortly after the structure of the vitamin was established, its synthesis was reported.<sup>310</sup> Ascorbic acid is an important article of commerce today not only for its nutrient and medicinal value but because it is a powerful antioxidant.

**Physiological and Clinical Aspects of Ascorbic Acid.** Vitamin C is concerned fundamentally with the formation of intercellular substances, including the collagen of fibrous tissue structures, the matrices of bone, cartilage, and dentin, and all nonepithelial cement substance, including that of the vascular endothelium. In the absence of the protection afforded by this vitamin, the condition known as scurvy develops.

The onset of the disease is gradual in humans, a period of indolence, fleeting pains in the joints, and shortness of breath being followed by decline in weight and anemia. Soon the complexion becomes sallow, subcutaneous hemorrhages occur upon slight injury, the gums become spongy and bleed easily, the teeth become loose and fragile, and often there is marked edema of the extremities. Hemorrhage is a predominating feature of the disease, and when it occurs internally it is frequently the cause of death. Various methods have been devised to measure the reduction in capillary resistance which occurs (not exclusively, however) in scurvy. These tests<sup>311</sup> are based on the production of small, subcutaneous hemorrhages (*petechiae*) by applying suction or pressure to circumscribed skin areas.

Histological studies have emphasized the importance of the vitamin C content of the diet on tooth development.<sup>312</sup> Scurvy is attended by profound pathological changes in the teeth and gums, affecting particularly the vascular pulp and the periodontal and gingival tissues. Resorption of normal dentin and cementum occurs. In scurvy, bone formation stops, but resorption continues so that there is a resultant atrophy and bone fragility. Skeletal defects are demonstrated first at the costochondral junctions, where the lesions are similar to those of rickets.

The severity of the lesions observed in scurvy is dependent upon other factors, such as growth and mechanical stress. Gum damage occurs only when there are teeth, and hemorrhages appear chiefly from mechanical injuries or from the irritation of clothing. Bone lesions appear mainly at the joints and are particularly severe in infants and children. The response of scorbutic patients to treatment with ascorbic acid is dramatic. Histological evidence of bone repair may be observed within a few hours after administration of the vitamin, and signs of connective tissue regeneration in 24 hours. Evidence has been presented that an optimal level of ascorbic acid nutrition favors rapid repair of tissues in wounds and bone fractures, and is an important factor in determining resistance to infection. An outline of the clinical symptoms of ascorbic acid deficiency is given in the American Medical Association syllabus on p. 1292.

Ascorbic acid may play a role in endowing the organism with increased powers of resistance. This is suggested by studies with guinea pigs receiving injections of diphtheria toxin following graded allowances of ascorbic acid,<sup>313</sup> and by experiments in which sensitized guinea pigs fed liberal

<sup>313</sup> King and Menten: *J. Nutrition*, **10**, 129 (1935); Greenwald and Harde: *Proc. Soc. Exptl. Biol. Med.*, **32**, 1157 (1935).

doses of ascorbic acid showed diminished skin hypersensitivity to arshenamine.<sup>314</sup> The protective effect of ascorbic acid against arsenical toxicity has been reported to be greatly augmented by the simultaneous administration of the flavonoid derivative, hesperidin methyl chalcone.<sup>315</sup>

An increased requirement for vitamin C in man has been reported in Hodgkin's disease, protracted fevers, active rheumatic heart disease, and tuberculosis. In rats the synthesis and excretion of ascorbic acid is stimulated by feeding certain cyclic ketones related to the terpenes and certain simple aliphatic ketones.<sup>316</sup> This increased synthesis may be related to greater requirements for detoxification purposes. The beneficial effects of vitamin C in the detoxification of other unrelated poisons have been reported; e.g., lead and arsenic compounds, benzene, and the toxins of several pathogenic microorganisms.

Under normal conditions a dietary supply of ascorbic acid is required only by man, other primates, guinea pigs, and some microorganisms. However, the vitamin is essential for the normal development of most species, and is produced endogenously, thus resembling a hormone. Interference with the normal synthesis of the vitamin in the bovine species results in the impairment of the reproductive functions of both the male and female. Dietary deficiency of vitamin A results in decreased synthesis of ascorbic acid in the rat, though this relationship with vitamin A has not been observed in mature hens or bulls. In the latter species, the administration of chlorobutanol stimulates the synthesis of ascorbic acid, raises the plasma level, and restores fertility in the deficient animals.

The reduction of the blood level of ascorbic acid and the occurrence of a scurvylike syndrome in rats on a vitamin A- and C-free diet suggest a functional relationship between these vitamins.<sup>317</sup> Addition of ascorbic acid to the diet prevented or delayed the appearance of symptoms. Similar observations have been reported in foxes.<sup>318</sup> That ascorbic acid participates in the metabolism of other vitamins as well is indicated by its capacity for increasing the urinary excretion of citrovorum factor in rats and human subjects,<sup>319</sup> its influence on the storage of folic acid in the liver of chicks,<sup>320</sup> and its effect of relieving deficiency symptoms of rats on a ration lacking thiamine, riboflavin, or pantothenic acid.<sup>321</sup>

Synergism between ascorbic acid and vitamin A has been noted in the rat as well as between C and E in the guinea pig. Ascorbic acid enhances the growth-promoting effect of vitamin A in the rat in a manner similar to tocopherol. The mechanism may be through stabilization of vitamin A in the gastrointestinal tract. The administration of vitamin E increases the storage of dietary ascorbic acid in the organs of the guinea pig.

The ease with which ascorbic acid undergoes reversible oxidation-reduction has suggested that the vitamin plays a role in cellular respiration. The oxidation of ascorbic acid is catalyzed by ascorbic oxidase, found in plant juices. The reverse reaction, the reduction of dehydroascorbic acid to reduced ascorbic acid, is catalyzed by ascorbic reductase (an enzyme found in plant juices)<sup>322</sup> in the presence of reduced glutathione. Though no similar enzyme systems have been observed in animal tissues, the administration of dehydroascorbic acid to man is followed by increased urinary excretion of reduced vitamin C in an amount comparable to that which is excreted when the reduced form of the vitamin is fed. It is believed that this reduction occurs in the liver.

Certain *in vitro* findings lend credence to the view that ascorbic acid functions *in vivo* in oxidation-reduction reactions. Vitamin C plus minute amounts of iron cause a considerable increase in the oxygen uptake by phospholipides and by brain and liver suspensions. There is evidence, both *in vitro* and *in vivo*, that ascorbic acid functions as a coenzyme in the metabolism of tyrosine, although the exact nature of this action is not fully established.<sup>323</sup> A similar role is attributed to folic acid, the requirement for which appears to be increased in ascorbic acid deficient animals.

The action of urease, an enzyme which catalyzes the decomposition of urea to ammonia and carbon dioxide, is inhibited by vitamin C. This inhibition has been found to be due to the presence of small quantities of dehydroascorbic acid, and is prevented by cysteine, which reduces the dehydro form. Quinone, another oxidizing agent, can inhibit urease activity.

The recommended dietary allowances of ascorbic acid are shown on p. 1108. Approximately 1 mg. per day per kg. body weight is required for the maintenance of tissue saturation. These allowances are quite liberal, since clinical signs of scurvy do not appear even at considerably lower levels of intake. Considerable controversy exists as to the level of dietary intake of ascorbic acid necessary to insure adequate operation of the manifold functions in which this vitamin plays a role. Hence the recommendations of the National Research Council (p. 1108) provide for a substantial margin of safety. When healthy subjects have been subsisting on diets containing the recommended levels of intake for prolonged periods, the administration of a test dose of ascorbic acid (400 to 1000 mg.) is followed in the next 24 hours by an increase in the urinary excretion of from 25 to 50 per cent of the test dose. At lower levels of intake for prolonged periods there is a tendency for the body to conserve the test dose of the vitamin and lower excretion values are noted, indicating that body tissues are unsaturated.

No toxic symptoms are observed in man following the administration of large doses of ascorbic acid. One to 6 g. have been given orally and intravenously. Though ascorbic acid has been found in sweat, the amount lost through this channel even in excessive physical labor and in hot

---

<sup>322</sup> Crook and Morgan: *Biochem. J.*, **38**, 10 (1944); Bukin: *Biochimia*, **8**, 60 (1943).

<sup>323</sup> Bessey, Lowe, and Salomon: *Ann. Rev. Biochem.*, **22**, 545 (1953).

climates is not significant when the dietary intake approximates the recommended allowances.

**Storage and Synthesis of Ascorbic Acid.** As previously stated, all animal species other than man, monkeys, and guinea pigs, as well as higher plants and many microorganisms, are capable of synthesizing vitamin C. The promptness with which scurvy develops when the susceptible species are deprived of vitamin C would seem to indicate the absence of a large store in their bodies. In man, a diminished intake of ascorbic acid results in a prompt fall in the blood level of ascorbic acid, though tissue stores may not yet be depleted. Guinea pigs show histological symptoms of ascorbic acid deficiency after one week on a vitamin-C-free diet. Higher concentrations of the vitamin are found in tissues of high metabolic activity—e.g., the adrenal and pituitary glands and the intestinal wall. It is likely that the vitamin is present in these depots in order to meet tissue requirements, rather than for the purpose of storage. Certain animals which synthesize vitamin C store it in their livers in sufficient amounts to meet their immediate requirements. The fruits and vegetables consumed by man as sources of ascorbic acid represent storage depots for plants which synthesize the vitamin.

**Distribution of Ascorbic Acid.**<sup>324</sup> The outstanding sources of vitamin C are fresh fruits and vegetables. Special mention may be made of cabbage, cauliflower, kohlrabi, spinach, parsley, kale, broccoli, cresses, peppers, oranges, lemons, grapefruit, tangerines, limes, strawberries, and gooseberries. Other excellent dietary sources are cantaloupe, currants, papaya, persimmons, pineapple, asparagus, lima beans, green snap beans, and Brussels sprouts. Unfortunately, much of the vitamin C originally present in foods is lost through processing, so that for practical purposes the fruits and vegetables which are consumed raw contribute a major portion of the dietary ascorbic acid. For economic reasons, these are outside the reach of low-income groups which obtain their vitamin C from the relatively inexpensive potato. During the germination of legumes as well as of cereal grains, marked synthesis of vitamin C takes place from an unidentified precursor within the seed. Meat is low in vitamin C, although blood and glandular organs contain more than muscle. Milk varies in its content according to the cow's ration and hence the season of the year. Fresh raw milk is a good source of vitamin C, but most of it is lost in pasteurization, evaporation, or dehydration. Where milk is a major constituent of the diet, as it is for children, it is best to provide antiscorbutic protection from other sources; e.g., orange juice or synthetic ascorbic acid. The megaloblastic anemia observed in infants fed proprietary milk preparations has been explained as being due to a deficiency of folic acid secondary to chronic vitamin C deficiency. The leaves and flowers of the gladiolus, nettle, hip, and paprika are exceptionally rich in vitamin C. During World War II, rose hips, green walnuts, and wild cherries were used in Europe for the preparation of vitamin C concentrates.

**Chemistry of Ascorbic Acid.** Ascorbic acid crystallizes in white

---

<sup>324</sup> For ascorbic acid values of foods, see Appendix III.

needles or plates having a melting point of  $190^{\circ}$  to  $192^{\circ}$  C. One g. dissolves in 3 ml. water, in 50 ml. absolute ethyl alcohol, and in 100 ml. glycerol. The vitamin is insoluble in benzene, ethyl ether, petroleum ether, and most organic solvents. Ascorbic acid possesses two asymmetric carbon atoms. The vitamin has a specific rotation  $[\alpha]_D^{20} = +21^{\circ}$  in water and  $+48^{\circ}$  in methanol. D-Ascorbic acid, which differs from the L-isomer only in its configuration about the fourth carbon atom, is physiologically inactive. The acidic properties of ascorbic acid are due not to the carboxyl group, which is tied up in lactone form, but to ionization of the enol group on the third carbon atom. The vitamin is a comparatively strong acid, as indicated by the acidic dissociation constants,  $pK_1 = 4.17$  and  $pK_2 = 11.57$ . A one-half per cent solution of ascorbic acid in water has a pH of approximately 3. At neutrality, the vitamin has an absorption maximum in the ultraviolet region of the spectrum at  $265\text{ m}\mu$  which shifts toward the shorter wavelengths with decreasing pH. Ascorbic acid is precipitated by lead ion at pH 7.6, but the salt can be redissolved in mineral acid at pH 2.

Ascorbic acid crystals are stable in air for years. In solution the vitamin is easily oxidized, the instability increasing with increasing pH. Mild oxidation such as that produced by air, hydrogen peroxide, ferric chloride, quinone, iodine in acid or neutral solutions, or 2,6-dichlorophenol indophenol converts the vitamin to dehydroascorbic acid as shown in the reaction below. Dehydroascorbic acid retains the biological activity of the vitamin and is reduced in animal tissues, a reaction in which sulfhydryl compounds like glutathione play an important part. The reduction of the dehydroascorbic acid may be accomplished *in vitro* by means of hydrogen sulfide. Above pH 5 dehydroascorbic acid readily undergoes a

rearrangement in which the lactone ring is split. The product, diketogulonic acid, is no longer biologically active and is not reducible by hydrogen sulfide. Treatment with hydrogen iodide, however, converts this compound to dehydroascorbic acid, which may subsequently be reduced with hydrogen sulfide to ascorbic acid. Once the lactone ring has opened, the molecule readily undergoes further oxidation and may be degraded to oxalic acid. The oxidation of ascorbic acid by molecular oxygen is catalyzed by cupric and silver ions. Plant tissues contain several enzymes, including ascorbic acid oxidase, polyphenol oxidase,

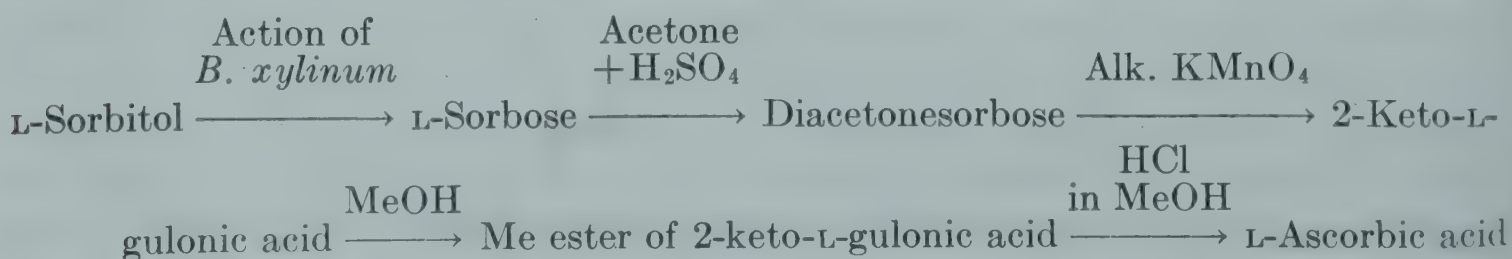

and peroxidase, which even more strongly catalyze the oxidation of the vitamin by molecular oxygen to dehydroascorbic acid. It is interesting to note that ascorbic acid oxidase is a copper-protein complex and that cupric ion in the presence of nonspecific protein is a stronger oxidation catalyst for vitamin C than cupric ion alone. Ascorbic acid is a strong reducing agent; its capacity to reduce silver nitrate, iodine, ferricyanide, methylene blue, and 2,6-dichlorophenol indophenol serves as the basis of methods for its histological detection and chemical estimation. The ease of oxidation of ascorbic acid is responsible for substantial losses during the processing of foods, which may be diminished by such measures as blanching (heat denaturation of enzymes), the use of an inert atmosphere (nitrogen or carbon dioxide), and storage at low temperatures. The ready solubility of ascorbic acid in water is also responsible for processing losses through extraction of the vitamin by the cooking water.

The destruction of ascorbic acid is catalyzed by light, especially in the presence of flavins. The vitamin reacts with niacin (or niacinamide) when the two are mixed in a thick paste, forming a colored compound. Ascorbic acid undergoes a similar reaction with other pyridine and quinoline compounds. The reaction is not attended by a decrease in the reducing properties of vitamin C. It has not been established whether any loss in the biological activity of either ascorbic acid or niacin occurs during the reaction.

Ascorbic acid exhibits optical specificity. The L-configuration about the fourth carbon atom is essential for biological activity, the D compound being biologically inactive. D-Araboascorbic acid (isoascorbic acid) which differs from L-ascorbic acid in the D configuration about the fifth carbon atom, possesses only one-twentieth of its activity. 6-Deoxy-L-ascorbic acid, which lacks the hydroxyl group on the sixth carbon atom, has one-fifth the activity of L-ascorbic acid. Other analogs of vitamin C, L-glucoascorbic acid, L-fucoascorbic acid, and D-glucoheptoascorbic acid have one-fortieth, one-fiftieth, and one-hundredth of the activity of vitamin C, respectively. However, the only naturally occurring forms of vitamin C are L-ascorbic acid and dehydroascorbic acid, both of which have equal biological activity. The sodium, copper, manganese, iron, monoethanolamine, and quinine salts of ascorbic acid are biologically active.

The synthesis of ascorbic acid can be effected by enolization of keto-hexonic acids or by condensation of lower aldehydes or of oxyesters. A commercial synthesis is represented by the following scheme:

Though the synthetic methods involving the 2-keto-hexonic acids are economically more practical, the preparation of vitamin C concentrates from natural materials received considerable attention in Europe during World War II.

## DETERMINATION OF ASCORBIC ACID

Chemical methods for the determination of vitamin C are based, for the most part, upon the reducing properties of the vitamin. These procedures include titration of an acid extract with iodine, methylene blue in the presence of light, 2,6-dichlorophenol indophenol, or other oxidizing agents. Various acids have been used for the extraction, including acetic, trichloroacetic, metaphosphoric, and oxalic. The latter two acids serve not only to reduce the pH of the extracting medium, thereby stabilizing vitamin C, but also to form complexes with metallic ions, e.g., copper, thereby preventing the catalytic oxidation of the vitamin. Titration with an oxidizing agent is not a specific reaction: other reducing materials interfere, e.g., stannous and ferrous sulfate, sulfhydryl compounds, sulfides, thiosulfates, and reducing materials found in caramelized and fermented foods. Errors arise particularly in food products because of the presence of reductinic acid and reductones. Actually, reductone is hydroxypyruvic aldehyde, a compound formed by the alkaline hydrolysis of sugars. Reductinic acid is formed when pentoses are treated with acids. The terms reductone and reductinic acid, however, have been used rather loosely to signify other reducing compounds formed during heat-processing and storage of foods.

Numerous attempts have been made to increase the specificity of the oxidation-reduction methods, particularly that employing the 2,6-dichlorophenol indophenol dye. A number of these are based on the fact that ascorbic acid reacts very rapidly with the oxidizing agent whereas many of the interfering substances react more slowly. The simplest expedient for increasing the specificity is to conduct the titration very rapidly, though it presents little improvement over the original method. A more satisfactory procedure involves measurement of the rate of reaction by means of a photoelectric colorimeter. When observations are made five and ten seconds after mixing the ascorbic acid solution with the oxidant, and the values are extrapolated to "zero-time," the determination possesses sufficient specificity for vitamin C in most food products.

Modifications of the indophenol titration have been aimed particularly at eliminating the interference of reductones and reductinic acid. These compounds are similar to vitamin C in structure, stability, and chemical reaction. Like ascorbic acid, their oxidative destruction is catalyzed by copper and by ascorbic acid oxidase. A number of procedures for eliminating their interference involve condensation of the reducing substances with formaldehyde, which eliminates the reducing properties of ascorbic acid, reductones, and reductinic acid; but the interfering compounds may be differentiated from the vitamin by conducting the condensations at different pH levels.<sup>325</sup> There is no doubt that these procedures increase the specificity of indophenol titration, though the interference of reductone or reductinic acid is not completely eliminated. Moreover, errors arise because the procedures fail to take into account the presence of

---

<sup>325</sup> Lugg: *Nature*, **150**, 577 (1942); *Australian J. Exptl. Biol. Med. Sci.*, **20**, 273 (1942); Mapson: *Nature*, **152**, 13 (1943).

materials which affect the rate of combination of L-ascorbic acid with formaldehyde.<sup>326</sup>

One method of improving the specificity of the determination of vitamin C involves the destruction of ascorbic acid with ascorbic acid oxidase, thereby providing a blank correction value.<sup>327</sup> This procedure, however, is based on the assumption that the action of ascorbic acid oxidase is specific for vitamin C; whereas reductones are also destroyed.<sup>328</sup> Natural pigments and stubborn turbidities frequently interfere with the determination of vitamin C. Several modifications of the indophenol methods may eliminate these interferences since they involve extraction of the excess of unreacted dye with organic solvents (e.g. xylene) immiscible with water.<sup>329</sup>

Dehydroascorbic acid, the reversibly oxidized, biologically active form of vitamin C, does not possess reducing properties. Since this form of the vitamin is frequently present in considerable proportion in processed foods,<sup>330</sup> it must first be reduced before it can be determined with oxidizing agents. Hydrogen sulfide has been used most frequently for this purpose, but this reagent has been criticized on the ground that it creates other reducing materials which interfere with the procedure. This objection is valid when simple titrimetric methods are employed for the determination of vitamin C. However, little interference arises from this source when the photometric method involving measurements at five and ten seconds is employed. Other methods for reducing the dehydroascorbic acid have been suggested but are not widely employed. These include the reduction of the oxidized vitamin by a resting suspension of *E. coli*<sup>331</sup> and by electrolytic reduction.<sup>332</sup>

Dehydroascorbic acid and its inactive oxidation product, diketogulonic acid, couple with 2,4-dinitrophenylhydrazine to yield an osazone which gives a red color with strong sulfuric acid. By means of appropriate oxidation and reduction reactions, Roe and his associates<sup>333</sup> have adapted the dinitrophenylhydrazine reaction to the measurement of reduced and dehydroascorbic acids (both biologically active) as well as diketogulonic acid. This permits estimation of the extent to which the original vitamin C content of foods has undergone oxidation. Since fresh or well-preserved foods usually contain less than 5 per cent diketogulonic acid,<sup>334</sup> the dinitrophenylhydrazine method is usually used in its simpler form adapted to the measurement of only the biologically active forms of

ascorbic acid. If oxidation during processing or storage is suspected, failure to account for diketogulonic acid may lead to serious errors.<sup>335, 336</sup>

The determination of ascorbic acid in blood and urine is employed in the diagnosis of clinical and subclinical vitamin C deficiency. These values fluctuate widely even in normal individuals depending upon the ascorbic acid intake just prior to the test. For this reason blood tests are conducted preferably when the subject is in a fasting state. A serum or plasma level greater than 0.7 mg. per 100 ml. is regarded as normal whereas values less than 0.4 mg. are observed in scurvy. Some clinicians set 1.2 mg. per 100 ml. as the minimum normal level. Individuals in a normal state of nutrition excrete from 20 to 50 mg. of ascorbic acid when fed a diet containing 100 mg. per day. Since both blood levels and urinary excretion values depend upon the ascorbic acid intake for one or two days prior to the test, a more satisfactory index of ascorbic acid nutrition may be obtained by measurement of the response of the subject to a large dose (500 to 1000 mg.) of ascorbic acid. Saturated subjects excrete approximately 25 to 50 per cent of the test dose in 24 hours, and show a continued high blood level for hours following dosage. In one saturation test, an excretion of 20 mg. of ascorbic acid in the four-hour period following the ingestion of 200 mg. is regarded as normal.

Plasma ascorbic acid values fall very rapidly when a deficient diet is consumed, though tissue stores including those of blood cells have not yet become depleted. It has been suggested that the ascorbic acid content of the leukocytes or of whole blood<sup>337</sup> is a better index of the state of vitamin C nutrition of the tissues than the blood plasma level. Oxyhemoglobin interferes with the determination of ascorbic acid in whole blood by oxidation-reduction procedures unless it is saturated with carbon monoxide<sup>337</sup> or reduced.<sup>338</sup> The 2,4-dinitrophenylhydrazine method (see p. 1237) is suitable for determination of ascorbic acid in whole blood.

One procedure intended for clinical diagnosis of ascorbic acid deficiency is based on intradermal injection of 2,6-dichlorophenol indophenol followed by measurement of the rate of decolorization of the dye.<sup>339</sup>

**Modified Titrimetric Method of Bessey:**<sup>340</sup> **Principle.** The method depends on the stoichiometric reduction of the dye 2,6-dichlorophenol indophenol to a colorless compound by ascorbic acid. The titration is conducted in the presence of acetic and metaphosphoric acids in order to inhibit aerobic oxidation catalyzed by certain metallic ions, to inactivate enzymes, and to precipitate proteins and liberate protein-bound ascorbic acid. A modification of this method is based on the addition of an excess of the dye and measurement of the unreacted portion. In the presence of interfering pigmentation or turbidity, the dye can be removed by xylene extraction and read in a photometer.<sup>341</sup> It is necessary however, to guard against the extraction of xylene-soluble pigments present in some heat-processed foods, and certain non-vitamin-C substances (e.g., betanin of beets) which react with the dye.

<sup>335</sup> Penney and Zilva: *Biochem. J.*, **37**, 39 (1943).

<sup>336</sup> Pijoan and Gerjovich: *Science*, **103**, 202 (1946).

<sup>337</sup> Butler and Cushman: *J. Clin. Investigation*, **19**, 459 (1940); Roe and Kuether: *loc. cit.*

<sup>338</sup> Kuether and Roe: *Proc. Soc. Exptl. Biol. Med.*, **47**, 487 (1941).

<sup>339</sup> Reddy and Sastry: *Indian Med. Gaz.*, **76**, 476 (1941).

<sup>340</sup> Bessey: *J. Assoc. Official Agr. Chem.*, **27**, 537 (1944).

<sup>341</sup> See footnote 329, p. 1234.

**Procedure.** Macerate an aliquot of the sample containing 5 to 50 mg. ascorbic acid with 150 ml. metaphosphoric-acetic acid solution<sup>342</sup> in a Waring Blendor. Dilute to 200 ml. and filter. Titrate a 10- to 100-ml. aliquot with standard indophenol solution.

**Preparation of Standard Indophenol Solution.** Dissolve 42 mg. sodium bicarbonate and 52 mg. sodium 2,6-dichlorophenol indophenol in 50 ml. water. Dilute to 200 ml. Filter and store in the refrigerator not more than three days. Dissolve 100 mg. crystalline ascorbic acid in 100 ml. metaphosphoric-acetic acid solution. Dilute a 10-ml. aliquot with 25 ml. metaphosphoric-acetic acid solution, and titrate with indophenol solution until the pink color persists for 5 seconds. Calculate and express the strength of the indophenol solution as mg. ascorbic acid equivalent per ml. reagent. Repeat the standardization each day with a freshly prepared standard ascorbic acid solution.

CALCULATION. Calculate the ascorbic acid content of the sample using the formula,

$$V \times S \times D = \text{mg. ascorbic acid per g. of sample}$$

where  $V$  is ml. of dye used to titrate the unknown,  $S$  is the standardization value expressed in mg. ascorbic acid per ml., and  $D$  is the dilution factor.

**Interpretation.** The simple titrimetric method is applicable to the determination of ascorbic acid only in the absence of other reducing substances, and where only the reduced form of the vitamin is present. Thus it may be applied to fresh orange, grapefruit, lemon, lime, or tomato juice and to some pharmaceutical preparations. For heat-processed materials and other foods, it is necessary to eliminate interfering substances and to determine the reversibly oxidized, biologically active form of the vitamin, dehydroascorbic acid. Ferrous ion reduces the dye in the presence of metaphosphoric acid. Pharmaceutical preparations containing reduced iron may be titrated in 8 per cent acetic acid solution free from metaphosphoric acid. On the other hand, ferric ion interferes with the end point in the absence of metaphosphoric acid; hence the metaphosphoric-acetic acid mixture should be employed as the titration medium when testing pharmaceutical preparations containing oxidized iron.<sup>343</sup>

**Determination of Ascorbic Acid in Plant Tissues (Modified Colorimetric Method of Roe and Kuether):**<sup>344</sup> **Principle.** Ascorbic acid is oxidized to dehydroascorbic acid by shaking with "Norit" in the presence of acetic acid. After coupling with 2,4-dinitrophenylhydrazine, the solution is treated with sulfuric acid to produce a red color which is measured photometrically.

**Procedure.** Grind 10 g. of sample in sufficient 5 per cent metaphosphoric-10 per cent acetic acid solution to produce a concentration of 5-15  $\mu\text{g}$ . ascorbic acid per ml. Filter. To a 15-ml. aliquot of the clear filtrate, add 0.75 g. acid-washed "Norit"<sup>345</sup> and shake vigorously. Filter. To a 4-ml. aliquot of the

<sup>342</sup> Dissolve 15 g. of stick metaphosphoric acid in a mixture containing 40 ml. glacial acetic acid and 450 ml. water. Filter, and store in the refrigerator. Discard after 10 days.

<sup>343</sup> Gawron and Berg: *Ind. Eng. Chem., Anal. Ed.*, **16**, 757 (1944).

<sup>344</sup> Roe and Kuether: *loc. cit.*; Roe and Oesterling: *loc. cit.*

<sup>345</sup> Suspend 100 g. "Norit" in 500 ml. 10 per cent hydrochloric acid. Heat to boiling, then filter with suction. Remove the cake of "Norit," stir it up with 500 ml. of water, and filter again. Repeat this procedure until the washings give a negative or faint test for ferric ions. Dry overnight in an oven at 110°-120° C.

filtrate in a test tube, add 1 drop 10 per cent thiourea solution, and 1 ml. 2,4-dinitrophenylhydrazine reagent.<sup>346</sup> Place the tube in a water bath maintained at 37° C. for exactly 3 hours. Remove and place in an ice-water bath along with a blank tube containing 4 ml. of "Norit" filtrate and 1 drop thiourea solution. To each tube in the bath add dropwise 5 ml. 85 per cent sulfuric acid<sup>347</sup> with stirring. Finally add 1 ml. 2,4-dinitrophenylhydrazine reagent to the blank. Remove the tubes from the bath and allow to stand 30 minutes. Read the colors in a photoelectric colorimeter with a filter transmitting maximally at 540 m $\mu$ , setting the instrument at 100 per cent transmittance with the blank tube.

**CALCULATION.** Prepare a calibration curve by testing 4-ml. aliquots of appropriate standards containing 0.25–15.0  $\mu$ g. ascorbic acid per ml. carried through the entire procedure. Plot photometric density against  $\mu$ g. ascorbic acid per ml. From the curve, estimate the ascorbic acid concentration of the "Norit" filtrate of the unknown and multiply this by the dilution factor to obtain the ascorbic acid content of the sample.

**Interpretation.** The 2,4-dinitrophenylhydrazine procedure measures total ascorbic acid. This may be partitioned into the reduced and dehydro forms by including a simultaneous test in which the "Norit" treatment is omitted. The latter procedure measures only dehydroascorbic acid. The reduced ascorbic acid content is obtained by difference. Reductones, degradation products of sugars, and diketogulonic acid interfere with the determination of ascorbic acid by this procedure.

*Determination of Ascorbic Acid in Whole Blood, Plasma, or Urine: Method of Roe and Kuether.*<sup>348</sup>

**Procedure.** Add 5 ml. whole blood or plasma, dropwise with stirring, to 15 ml. 6 per cent trichloroacetic acid in a 50-ml. centrifuge tube. Stir to obtain a fine suspension. Allow to stand 5 minutes, then centrifuge. Add 0.75 g. acid-washed "Norit" (see above) to the clear supernatant solution, and shake vigorously. Filter. Test 4-ml. aliquots by the 2,4-dinitrophenylhydrazine procedure as directed above.

To 2 ml. urine, add 38 ml. 4 per cent trichloroacetic acid solution. (A greater dilution should be made if the sample is expected to contain more than 300 mg. ascorbic acid per liter.) Add 1.5 g. acid-washed "Norit" (see above), shake vigorously, and filter. Test 4-ml. aliquots by the 2,4-dinitrophenylhydrazine procedure as directed above.

**Photometric Method of Hochberg, Melnick, and Oser:**<sup>349</sup> **Principle.** Ascorbic acid is determined in the presence of other reducing substances by photometric measurement of the rate of decolorization of the dye 2,6-dichlorophenol indophenol. Dehydroascorbic acid is determined after reduction by hydrogen sulfide.

**Procedure.** Conduct all manipulations under an atmosphere of nitrogen and make all extractions and dilutions with solutions previously deaerated with a stream of nitrogen. Homogenize the sample with an equal weight of 6 per cent metaphosphoric acid solution.<sup>350</sup> (Fresh vegetables and materials

<sup>346</sup> Dissolve 2 g. 2,4-dinitrophenylhydrazine in 100 ml. 9 N sulfuric acid and filter.

<sup>347</sup> To 100 ml. distilled water, add 900 ml. concentrated sulfuric acid, sp. gr. 1.84.

<sup>348</sup> Roe and Kuether: *loc. cit.*

<sup>349</sup> Hochberg, Melnick, and Oser: *Ind. Eng. Chem., Anal. Ed.*, **15**, 182 (1943).

<sup>350</sup> Metaphosphoric acid changes slowly in solution to orthophosphoric acid. The extractant should be stored in the refrigerator where it is stable for several weeks.

containing active oxidases should first be blanched by adding the sample directly to boiling 6 per cent metaphosphoric acid. After boiling for 5 minutes, cool and homogenize.) Dilute to a convenient volume with 3 per cent metaphosphoric acid. Shake mechanically for 15 minutes, then centrifuge. To 50 ml. of the clear supernatant fluid, add 14 ml. of citrate solution.<sup>351</sup> Measure reduced ascorbic acid in this aliquot as directed below.

FIG. 284. PIPET USED FOR ADDITION OF ASCORBIC ACID EXTRACT TO DYE SOLUTION.

Convert dehydroascorbic acid to the reduced form by treating the metaphosphoric-citric acid extract with a slow stream of hydrogen sulfide for 20 minutes. Allow to stand for 2 hours, then flush out the hydrogen sulfide with a vigorous stream of wet nitrogen (bubbled through water) for 2 hours.

**Colorimetric Measurement.** Determine the volume of extract necessary to decolorize 15 ml. 2,6-dichlorophenol indophenol solution.<sup>352</sup> To obtain optimal concentration for measurement in a photoelectric colorimeter, dilute this volume of extract to 30 ml. with metaphosphoric-citric acid solution.<sup>353</sup>

Place a colorimeter tube containing 5 ml. of standard dye solution in the instrument. Add 5 ml. of the diluted extract from a rapid delivery pipet<sup>354</sup> (Fig. 284) and measure the residual photometric density<sup>355</sup> 5 and 10 seconds later. Determine the blank absorption of extraneous pigments in the extract by adding a few crystals of ascorbic acid to completely de-

colorize the residual dye.

Obtain the residual photometric density at 5 and 10 seconds with standard solutions of ascorbic acid containing 1 to 6  $\mu\text{g.}$  per ml. in metaphosphoric-citric acid solution.

**CALCULATION.** Plot the photometric densities for the standard solutions (ordinates) against time. Extrapolate the readings linearly to zero time. This calibrates the ordinates in terms of ascorbic acid concentration.

Calculate the ascorbic acid concentration of the unknown as follows: Subtract the photometric density of the blank from those at 5 and 10 seconds. Plot the values as above and extrapolate to zero time. Estimate the ascorbic acid concentration of the extract from the intercept on the vertical axis, calibrated as described above. Multiply by the dilution factor to obtain the ascorbic acid content of the original sample.

<sup>351</sup> *Citrate Solution.* Dissolve 21 g. citric acid in 200 ml. 1.0 N sodium hydroxide and dilute to 250 ml.

<sup>352</sup> *2,6-Dichlorophenol Indophenol Solution.* Dissolve 8.0 mg. 2,6-dichlorophenol indophenol sodium salt in hot water and filter. Wash the filter paper several times with cold water and dilute the combined filtrate and washings with distilled water so that 5 ml. dye plus 5 ml. metaphosphoric-citric acid transmit 40 per cent of the incident light in the photoelectric colorimeter. The final volume is approximately 500 ml. Set the instrument at 100 per cent transmittance with distilled water.

<sup>353</sup> *Metaphosphoric-Citric Acid Solution.* Add 70 ml. citrate solution to 250 ml. 3 per cent metaphosphoric acid solution.

<sup>354</sup> The pipet should deliver exactly 5 ml. of extract in a period of less than one second. To prevent formation of air bubbles, the solution should be delivered against the side of the tube.

<sup>355</sup> The photoelectric colorimeter must be of the direct reading (not null-point) type and its galvanometer must be rapid and critically damped. Set the instrument at 100 per cent transmittancy with distilled water. The concentrations of ascorbic acid and dye and the volumes employed are those recommended when the Evelyn photoelectric colorimeter (Rubicon Company, Philadelphia) is employed.

**Interpretation.** This photometric method measures both reduced and dehydroascorbic acid. Appreciable concentrations of the latter are frequently found in processed and stored foods. The method is applicable to the determination of ascorbic acid in the presence of other reducing materials, which interfere minimally in this procedure.

## BIOLOGICAL METHODS

Because of its nondependence on a dietary source of ascorbic acid, the rat cannot be used for vitamin C assay. The animal employed is the guinea pig, since it is extremely sensitive to the lack of this factor in the diet. The techniques used are based either on the determination of the minimum dose necessary for protection against or cure of gross scorbutic symptoms,<sup>356</sup> or on the histological examination of the incisor teeth<sup>357</sup> after a test period of 14 days. The latter method requires equipment not always available in nutrition laboratories, though it has proved satisfactory for the determination of minimum protective dose where large enough groups are used to compensate for variations encountered. About twice as much ascorbic acid is required for protection of the dental pulp of guinea pigs as for prevention of gross scurvy.<sup>358</sup> The histological method has the advantages of high specificity and a short test period. Nevertheless, because of the special facilities required it has not been as widely used as the procedures based on prophylaxis or cure of gross symptoms.

The minimum daily allowance of a food which provides a guinea pig with complete protection from scurvy is a measure of its vitamin C potency. It has been suggested by Sherman, La Mer, and Campbell that by rating the pathological effects observed in the living animal and at autopsy, the fraction of complete protection afforded by subminimal doses may be estimated. While this method allows more animals to be considered in interpreting a given experiment, considerable experience is required in diagnosing and scoring the extent of the lesions.

## ASSAY FOR VITAMIN C

**Biological Method of Sherman, La Mer and Campbell.** Guinea pigs, 6 to 8 weeks old and weighing from 250 to 300 g., are fed *ad lib.* the following scurvy-producing diet:<sup>359</sup>

---

<sup>356</sup> Sherman, La Mer, and Campbell: *J. Am. Chem. Soc.*, **44**, 165 (1922); Coward and Kassner: *Biochem. J.*, **30**, 1719 (1936).

<sup>357</sup> Höjer: *Brit. J. Exptl. Path.*, **7**, 356 (1926); Goettsch: *Quart. J. Pharm.*, **1**, 168 (1928); Key and Elphick: *Biochem. J.*, **25**, 888 (1931); Fish and Harris: *Proc. Roy. Soc. London*, **223**, 489 (1933).

<sup>358</sup> Eddy: *Am. J. Pub. Health*, **19**, 1309 (1929).

<sup>359</sup> Diets containing fat must be prepared fresh weekly, as guinea pigs reject rancid food. Other scorbutigenic diets which have proved useful are:

(a) *Cambridge Nutrition Laboratory* (Harris *et al.*). Bran 80, oats 720, dried egg yolk 40, salts 8.4, codliver oil 1.

(b) Demole: *Z. Vitaminforsch.*, **3**, 89 (1934). Rolled oats 2 kg., dried whole milk 1 kg. (previously dried at 120° C. for 2 hr.). Mix and make into paste with whites of 6 eggs and water. Mold into cakes 5 cm. diam. and bake 20–25 min. on a tin greased with olive oil. Supplement with 0.2 ml. codliver oil weekly.

(c) *Purina Rabbit Chow* (Purina Mills, St. Louis, Mo.) produces scurvy in guinea pigs unless supplemented with a source of ascorbic acid.

|                                                |    |
|------------------------------------------------|----|
| Ground whole oats <sup>360</sup> .....         | 59 |
| Heated nonfat milk solids <sup>361</sup> ..... | 30 |
| Fresh butterfat <sup>362</sup> .....           | 10 |
| Salt .....                                     | 1  |

This diet may be reinforced with yeast and codliver oil.

FIG. 285. SCORBUTIC GUINEA PIG, SHOWING "SCURVY POSITION."

In order to provide assurance of the health of the guinea pigs and their capacity to grow, a short preliminary period may be included during which some source of vitamin C is fed, such as a leafy vegetable or orange juice.

FIG. 286. GUINEA PIG WITH SCURVY, SHOWING "FACE-ACHE POSITION."

Special Report of British Medical Research Committee, No. 38, 1919.

Following this period the food to be assayed is fed in graded doses as the sole source of vitamin C. Feed 0.5 ml. 0.1 per cent ascorbic acid or 5 ml. orange or lemon juice to positive control animals as a supplement.

In the absence of antiscorbutic vitamin, growth ceases in about 2 weeks, and a rapid decline in weight is followed by death in 4 to 5 weeks. During the second or third week, the external symptoms of scurvy become evident.<sup>363</sup>

The joints become tender, causing the guinea pig to wince or squeal when pressure is applied to the wrists. The paws become edematous and hemorrhagic. The animal becomes lethargic instead of excitable, and usually assumes an unnatural position such as holding up a tender hind leg (the "scurvy position," Fig. 285) or lying with the side of its face resting on the floor (the "face-ache position," Fig. 286). The characteris-

<sup>360</sup> A mixture of equal parts of commercial rolled oats and wheat bran may be used instead of the ground whole oats.

<sup>361</sup> Heated in shallow open pans at 110° C. until all the vitamin C is destroyed, as determined by chemical assay. The powder assumes a brownish color.

<sup>362</sup> The butterfat may be replaced by vegetable oil 8 + codliver oil 2.

<sup>363</sup> The symptomatology of scurvy in guinea pigs is fully described by Cohen and Mendel: *J. Biol. Chem.*, 35, 425 (1918).

tic postmortem findings are apt to be more pronounced when the deficiency is not quite complete, because the lesions have time to reach an exaggerated state. These findings include hemorrhages (which may be subcutaneous, intramuscular, or intraabdominal), loosening of the teeth, fragility of the bones and teeth, and enlargement of the costochondral junctions of the ribs (beading).

Supplying a source of vitamin C to a guinea pig in even an advanced state of scurvy usually will bring about prompt recovery, unless intercurrent disease has set in. About 0.5–0.6 mg. is required daily for complete protection or cure.

The vitamin C content is calculated from the minimum daily allowance which affords complete protection from scurvy to a standard guinea pig, as above described. Comparison of this dose with the corresponding allowance of the crystalline L-ascorbic acid enables one to express the result of the bioassay on a mg. basis instead of in now obsolete International Units. The International Standard is crystalline L-ascorbic acid, of which 0.05 mg. equals one International Unit of vitamin C.

### BIOFLAVONOIDS

In 1936, Szent-György<sup>364</sup> prepared an extract from paprika and subsequently from citrus juice, which he claimed to have value beyond that of ascorbic acid in reducing capillary bleeding in man and in guinea pigs. The name vitamin P was applied to this factor in the belief that it was a dietary factor necessary for the maintenance of normal capillary permeability. Interest in various hemorrhagic conditions which do not respond to vitamin K or ascorbic acid has led to widespread investigation of concentrates high in the active permeability factor.

**Physiological and Clinical Aspects of Bioflavonoids.** Although the literature is confusing on this point, a distinction should be drawn between capillary fragility caused by a change in the structural integrity of the capillary walls (e.g., loss of intercellular cement substance as in scurvy) and increased permeability without apparent tissue damage. Clear differentiation is not possible in the usual tests based on subcutaneous petechial hemorrhage induced by negative pressure.

Cumulated evidence has demonstrated the existence of a considerable number of flavonoid or related compounds having the protective effect on capillary resistance associated with vitamin P activity. Some of the preparations used in animal and clinical studies, e.g., citrin, are actually mixtures of only partially identified compounds. Effective doses vary over a wide range. In view of such considerations it is believed that the activity of the flavonoids is a pharmacological one rather than a specific physiological function for which a dietary factor is essential. Since continued application of the term "vitamin P" to one or another of these polyphenolic substances would lead only to confusion, it was recommended<sup>365</sup> that the term be no longer employed. The term "bioflavonoids" has been proposed for this class of compounds.<sup>366</sup>

Scarborough<sup>367</sup> describes the characteristic syndrome of petechial

<sup>364</sup> Szent-György and Rusznyák: *Nature*, **138**, 27 (1936).

<sup>365</sup> Joint Committee on Nomenclature, American Society of Biological Chemists and American Institute of Nutrition: *Science*, **112**, 628 (1950).

<sup>366</sup> Oser: cited by Bryant: *J. Am. Pharm. Assoc.*, **39**, 480 (1950).

<sup>367</sup> Scarborough, et al.: *Biochem. J.*, **33**, 1400 (1939); *Lancet* **2**, 610 (1938); 644 (1940); *Edinburgh Med. J.*, **50**, 85 (1943).

bleeding as accompanied by pain across the shoulders and in the legs, lassitude and undue fatigue, low capillary resistance, slightly prolonged bleeding time, and low serum calcium. The bioflavonoids are effective in relieving this syndrome but pure ascorbic acid is not.

It has been postulated by the French workers<sup>368</sup> that epinephrine is the compound directly responsible for the maintenance of capillary integrity and that the protective action of the bioflavonoids is an indirect one, based on their inhibitory effect on the oxidation of epinephrine (demonstrable both *in vivo* and *in vitro*). Certain flavonoids have been shown to produce a fall in arterial blood pressure in animals<sup>369</sup> and to inhibit hyaluronidase<sup>370</sup> and histidine decarboxylase,<sup>371</sup> but whether these effects are causally related to capillary resistance, and how, have not been established.

There is conflicting evidence in the literature regarding the clinical value of these compounds, which probably results from the fact that there are many factors responsible for the maintenance of normal capillary resistance. Clinical methods of measuring capillary fragility are inadequate because of diurnal variations and differences in subcutaneous capillary beds in different areas of the body. The dosages employed clinically depend upon the purity of the extracted flavones; the crystalline glycosides have been administered in divided dosage in the order of 50 to 150 mg. per day.

**Occurrence of the Bioflavonoids.** Citrin or similar glycosides having bioflavonoid activity have been isolated from paprika, juice or peel of citrus fruits, buckwheat, black currants, cured tobacco, and the leaves of a wide variety of plants.

**Chemistry of the Bioflavonoids.** Most if not all of the active flavonoids occur in nature as glycosides, either alone or in combination. Citrin from lemon peel is said to be a mixture of the flavonone glycosides, hesperidin and eriodictin (the corresponding aglycones being hesperetin and eriodictyol, respectively) although its exact composition has not been clearly established. The relation of flavanones and flavonols to the parent nucleus of flavone (2-phenyl-1,4-benzopyrone) is shown by the following structural formulas.

The chemical relationship of the aglycones and glycosides to each other is shown in the following tabulation.

**Determination of Bioflavonoids.** The varied chemical structure of naturally occurring bioflavonoids and their active derivatives has militated against the possibility of a chemical assay correlated with the specific type of biological activity. However analytical methods have been described for flavonoids in certain plant or animal tissues. The biological assay is based upon the observation of petechial hemorrhages under controlled conditions similar to the procedure employed for the diagnosis of "vitamin P" deficiency in man. Bacharach, Coates, and Middleton<sup>372</sup> have described a guinea pig assay in which crystalline hesperidin is used as the reference standard. The critical petechial pressure is determined from the negative pressure required to produce hemorrhages when a suction cup, furnished with a glass window for visibility, is applied to the prepared area of skin.

## VITAMIN D

Early in the history of vitamins, antirachitic activity was ascribed to fat-soluble vitamin A, but the work of McCollum and his collaborators<sup>373</sup>

<sup>372</sup> Bacharach, Coates, and Middleton: *Biochem. J.*, **36**, 407 (1942); See also Bourne: *Nature*, **152**, 659 (1943).

<sup>373</sup> McCollum, *et al.*: *J. Biol. Chem.*, **50**, 5 (1922); **51**, 41 (1922); **53**, 293 (1922).

established the distinction between the growth-promoting, antiophthalmic vitamin A and the antirachitic factor to which the name vitamin D was assigned. The specific role of this vitamin in the prevention and cure of rickets (rachitis) is integrated with the metabolism of calcium and phosphorus; in fact, in some species, e.g., the rat, the absence of vitamin D from the diet does not result in rickets unless the normal dietary ratio of Ca:P is disturbed. A condition analogous to human rickets may be produced experimentally in this species by feeding a diet high in calcium, low in phosphorus, and free from vitamin D. On a low-calcium, high-phosphorus diet, the bones develop an osteoporotic condition resembling osteomalacia. The function of vitamin D appears to be to mobilize these calcifying elements, so as to make possible their most efficient utilization even when the dietary supply is inadequate or disproportionate. It has been shown that even if calcium and phosphorus are fed in proper quantity and ratio, the absence of vitamin D, especially if prolonged, will result in poorer calcification of the bones than obtains under normal conditions.<sup>374</sup>

Mild cases of rickets are often unrecognized, though they are quite prevalent, and may not have serious consequences until later years. The work of Jeans and his associates has emphasized that the requirement of vitamin D for optimum growth exceeds the antirachitic requirement. Rickets in its more severe manifestations is seen more frequently among urban children of poor economic status. In regions where sunshine is prevalent and customs permit bodily exposure, the disease is of rare occurrence. In India rickets is less common among the poor who live an outdoor existence than among the wealthy who observe the rite of seclusion (*purdah*).

**Physiological and Clinical Aspects of Vitamin D.** Rachitic bones are characterized by a lower content of mineral matter and an apparent overgrowth of osteoid cartilage, in consequence of which normal rigidity is absent. The sequelae of this condition in children are misshapen bones (e.g., bowlegs), epiphyseal enlargement (e.g., knock-knees and beading of the ribs, the "rachitic rosary"), delayed closure of the fontanelle, retarded eruption of the teeth, disturbances of respiration due to deformity of the thoracic cavity (pigeon breast), etc. In later life, difficult childbirth may be encountered because of pelvic deformities. The changes in bone composition are illustrated in the table on p. 1245.

The calcium phosphate compound in all bones, normal or rachitic, appears to be  $\text{Ca}_3(\text{PO}_4)_2$ , which in the normal adult rat is accompanied by  $\text{CaCO}_3$  to the extent of about 15 per cent of the total calcium.<sup>375</sup> The ratio of tertiary phosphate to carbonate is reduced in the rachitic animal. From evidence based partly on solubility product studies, it has been suggested that primary calcification differs in composition from old

COMPOSITION OF NORMAL AND RACHITIC BONES (SCHABAD)<sup>376</sup>  
(IN PER CENT OF DRY FAT-FREE MATTER)

| Bone         |          | Water     | Ash       | Organic Matter | Calcium   | Phosphorus |
|--------------|----------|-----------|-----------|----------------|-----------|------------|
| Rib. . . . . | Normal   | 14.4–32.9 | 40.2–46.6 | 26.9–39.1      | 15.5–18.1 | 5.4–8.3    |
|              | Rachitic | 42.4–66.4 | 7.9–32.0  | 20.7–22.4      | 3.0–12.0  | 1.4–5.6    |
| Occiput. .   | Normal   | 13.0–16.1 | 47.6–51.7 | 32.2–36.5      | 18.8–19.9 | 7.9–9.0    |
|              | Rachitic | 29.0–35.9 | 34.3–40.6 | 26.1–31.6      | 13.6–17.2 | 6.0–7.8    |

bone.<sup>377</sup> Refractive index and x-ray studies show that the solid inorganic phase of bone consists of minute crystals which are normally oriented lengthwise along the bone, but in rickets the cement substance (collagen) is broken down and the x-ray diffraction pattern indicates a disoriented crystalline structure.<sup>378</sup>

Many suggestive facts are known, but no complete explanation of the mechanism of vitamin D activity is available. The diminished retention and altered paths of elimination of calcium and phosphorus in rickets (illustrated in the table on p. 1246) provide the basis for the conception that vitamin D acts by promoting the absorption of calcium and phosphorus from the small intestine. A causal relation between the intestinal pH (probably only in the cecum and colon) and the retention of the calcifying elements is suggested by the greater alkalinity (and hence the precipitation of calcium salts) in rickets, but it is not known which of these is the determining factor and, if it is the former, what ultimate mechanism is responsible for its alteration in rickets. While the effect seems to be mediated through an increase in permeability, vitamin D does not appear to influence the excretion of calcium into the intestine, except indirectly. Vitamin D is claimed to increase gastric secretion and thus facilitate calcium absorption. The sharper peaked blood sugar tolerance curve after vitamin D administration is also suggestive of an effect on intestinal absorption.

A significant agent in ossification is the enzyme alkaline phosphatase.<sup>379</sup> This enzyme occurs in bone, ossifying cartilage, the kidneys and intestinal mucosa, and in low concentration (5 to 15 units per 100 ml.) in blood. By hydrolyzing phosphoric acid esters in bone it liberates inor-

<sup>376</sup> Prepared by Orgler (*Ergebnisse inn. Med. Kinderheilk.*, 8, 142 (1912)) from the data of Schabad (*Arch. Kinderheilk.*, 52, 47 (1909); 53, 380 (1910); 54, 83 (1911)) and cited by Hess (see Bibliography, p. 1296).

ganic phosphate which modifies the calcium and phosphate ion concentrations to the extent that the solubility product is exceeded and excess calcium phosphate is deposited. The optimum pH range of alkaline phosphatase is 8.4 to 9.4.

The fact that phosphatase is concentrated in the ossifying centers of bone cartilage, even in rickets, would tend to indicate that in this disease

\* From unpublished data obtained in the senior author's laboratories. Similar observations are reported by Shohl, Bennett, and Weed: *J. Biol. Chem.*, **79**, 257 (1928).  
Period I: A 5-day period in the fourth week of a high-Ca, low-P rachitogenic diet.  
Period II: A 5-day period during the succeeding week, after the Ca:P ratio was diminished by substituting  $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$  for  $\text{CaCO}_3$ .

the supply of substrate may be at fault. In rickets there is not only overproduction of osteoid matrix but also proliferation of cartilage cells which are an abundant source of phosphatase. The small amount of this enzyme normally found in plasma is greatly increased in generalized bone disorders, probably by diffusion from the osseous tissue (see p. 253) in which a compensatory stimulation of osteoblastic activity occurs. It has been suggested that two mechanisms operate in bone formation: the phosphatase mechanism which produces in the bone matrix fluid a condition of supersaturation with respect to bone phosphate; and an "inorganic" mechanism which favors deposition of this salt from supersaturated solutions.

New light has been cast on the biochemical role of alkaline phosphatase in rickets by the work of Zetterstrom and Ljunggren,<sup>380</sup> who studied the action of the water-soluble phosphorylated derivative of vitamin D<sub>2</sub> ("D<sub>2</sub>P"). They showed that D<sub>2</sub>P has a remarkable capacity to activate phosphatase, especially from bone. It would appear therefore that vitamin D may function as an activator of alkaline phosphatase not only in the intestinal absorption of phosphate but also in bone deposition and in renal

<sup>380</sup> Zetterstrom and Ljunggren: *Acta Chem. Scand.*, **5**, 283 (1951)

tubular reabsorption, all of which are involved in clinical rickets. A more general role for vitamin D in carbohydrate oxidation is suggested by *in vitro* studies<sup>381</sup> in which D<sub>2</sub>P was shown to have an activating effect on the oxygen uptake of kidney mitochondria. The respiratory enzyme complex here involved is known to be concerned in the tricarboxylic acid cycle and in fatty acid oxidation.

Efforts have been made to correlate the action of vitamin D with the important role played by the parathyroid hormone in the maintenance of calcium equilibrium in the serum. Hyperparathyroidism is accompanied by high serum calcium, and apparent dissolution of this element from the bones which, when prolonged, may lead to osteomalacia. Parathyroid extract does not cure rickets. Though there are similarities in the effects of vitamin D and parathyroid hormone on calcium mobilization, evidences of differences in their mode of action—e.g., in tetany or when given in overdosage—make doubtful a direct hormonal role in vitamin D activity.

The vitamin D requirement of man is influenced by age, color, pregnancy, lactation, the mineral content of the diet, and conditions which affect intestinal absorption. The vitamin D needs of adults and older children may be satisfied by sufficient exposure to ultraviolet radiation. According to the National Research Council, the recommended daily allowance of this vitamin is 400 units daily, except during pregnancy, lactation, and the first year of childhood, when it is increased to 800 units. See p. 1108. Vitamin D may be administered not only subcutaneously or intraperitoneally<sup>382</sup> but by direct absorption through the skin,<sup>383</sup> although the dosage requirements under these conditions are not well defined.

Even when massive doses are given, the transfer of vitamin D to human or cow's milk is limited to only a few per cent. The administration of 40,000 units per day during early lactation of mothers increased the vitamin D content from very low or zero levels to a range of 125 to 583 units per liter. Vitamin D milk of commerce is produced by direct addition of irradiated sterols or concentrates; formerly "metabolized vitamin D milk" was obtained by controlled dosage of cows.

Some success has been claimed for the more or less empirical use of large doses of vitamin D in the treatment of arthritis, but the reports in the literature are conflicting and the physiological mechanism involved is not known.

The belief that excessive doses of vitamin D were toxic owed its origin in part to unfortunate experiences with an early German product "Vigantol," which probably contained an excessive proportion of toxisterol (see p. 1252) due to overirradiation of the sterol. Later studies have shown that the margin between the therapeutic and the minimum toxic dose of vitamin D is very wide. Several hundred times ordinary therapeutic doses

must be administered daily for several weeks before toxic effects are noted. It has been suggested that infants be given doses of 250,000 units twice a year for protection against rickets. The chief symptoms of toxicity due to overdosage of vitamin D are anorexia and polyuria. Calcification of soft tissues, and particularly of the renal arterioles and the aorta, are observed in advanced stages, although hypertension is not encountered. Vitamin D overdosage is indicated by a rise in serum calcium. The toxic effects disappear upon discontinuance of the dosage.

The calcium content of the blood serum of rachitic children is normal (9–11 mg. per 100 ml.) or only slightly lower, but the inorganic phosphorus content may be reduced to half the normal values of 4–5 mg., or even lower in severe cases. There are seasonal variations in the blood phosphate values, the minimum occurring in late winter and early spring, and the maximum in midsummer. These changes run parallel to the seasonal variation in solar ultraviolet radiation and coincide with the variations in the incidence of clinical rickets. They may also account for the spontaneous healing often observed in summer.

These observations as well as the well-known geographical distribution of rickets, have been attributed to the effect of exposure to sunlight. The therapeutic value of the sun's rays in rickets was noted by Hulschinsky, who also studied the use of artificial sources of ultraviolet radiation. Certain of these rays cause a synthesis of vitamin D from a precursor (7-dehydrocholesterol) in the skin, and a similar synthesis can be produced in animal and plant oils from this or other provitamins.

For further discussion of the clinical aspects of vitamin D, see the American Medical Association syllabus, p. 1292.

**Ultraviolet Radiation.** The visible region of the spectrum comprises only a small portion of the entire scale of radiant energy. The colors in the visible spectrum result from differences in the frequency—or inversely, the wavelength—of the radiations. In the invisible regions of electromagnetic vibrations, there are the longer radiations (infrared or heat rays, Hertzian, and radio waves) and the shorter radiations (ultraviolet rays, gamma rays, x-rays, etc.). The relation between these forms of radiant energy is illustrated in Fig. 287.

The antirachitic region of the spectrum extends from about 256  $m\mu$  to about 313  $m\mu$ , whereas the shortest solar radiation is about 290  $m\mu$ . It is only when the atmosphere is free from smoke, fog, dust, clouds, etc., that solar energy of wavelength shorter than 300  $m\mu$  reaches the earth, and even then its intensity is very slight. On a clear day at sea level the energy distribution is approximately 1 to 2 per cent ultraviolet, 42 to 53 per cent visible and 57 to 63 per cent infrared. The limited antirachitic protection offered from this source helps explain the frequency of rickets and the need for dietary sources of preformed vitamin D. Ultraviolet radiation exerts its maximum activating power at the wavelength of maximum absorption by the provitamin, e.g., at 281  $m\mu$  (range = 275 to 300  $m\mu$ ) in the case of ergosterol. The energy required for activation is  $7.5 \times 10^{13}$  quanta per unit of vitamin D.

Ultraviolet energy emanates from incandescent solids. The distribution and intensity of this energy depends on the nature of the incandescent

source. The most widely used sources of ultraviolet radiation in experimental or therapeutic work are the carbon arc and the quartz mercury arc. Carbon arc lamps are provided with carbons containing metallic cores of definite composition. The quartz mercury-vapor lamp consists of a quartz chamber in which an arc discharge takes place between electrodes of mercury or of mercury and tungsten. The ultraviolet component of the radiation from these lamps depends on the energy input and, in the case of the mercury vapor arc, diminishes with the age of the lamp.

FIG. 287. CHART SHOWING DISTRIBUTION OF RADIANT ENERGY.  
The figures indicate the wavelengths, expressed in millimicrons.<sup>384</sup>

Ordinary window glass is opaque to ultraviolet radiation but quartz is transparent. Various makes of glass of special composition permit the transmission of antirachitic radiation and are used in schools, hospitals, solaria, etc. Certain plastic films are also transparent to the antirachitically active rays, and these have been used in windows of poultry houses.

The variation in distribution and intensity of ultraviolet radiation from the sun or from artificial sources makes necessary some means of measurement. No satisfactory method has been developed for analyzing the antirachitic region alone, and of the biological and photochemical methods it may be said that no two of them measure exactly the same region and none of them gives an index of the distribution of energy. The only accurate methods are those based on a physical measurement of the energy, such as those employing a thermopile and galvanometer. Radiation of any region of wavelength, selected by optical filters or a quartz monochromator, may be absorbed by a thermocouple, causing a flow of current which can be measured by a galvanometer previously standardized

<sup>384</sup> One micron ( $\mu$ ) = 0.001 mm.; one millimicron ( $m\mu$ ) = 0.001  $\mu$ ; one Ångstrom unit ( $\text{\AA}$ ) = 0.1  $m\mu$ .

against radiation of known intensity. Such a method, while nonselective and reliable, is beyond the scope of most biological laboratories.

Of the photochemical methods<sup>385</sup> there may be mentioned (1) *Clark's*, in which the number of minutes required for a paste of lithopone, or preferably pure zinc sulfide, to darken to a definite shade is taken as the index and expressed as lithopone or ZnS units of ultraviolet energy; (2) *Pohle's*, in which the index is the time required for the ultraviolet energy to produce a blue color in a solution containing potassium iodide, sodium thiosulfate, and starch; (3) *Webster, Hill, and Eidinow's* in which the fading of the blue color in an acetone-methylene blue solution is measured by comparison with known standards; and finally (4) the method of *Anderson and Robinson*, given below.

**Photochemical Method for Measuring Ultraviolet Intensity: Principle.** In the presence of a uranium salt which acts as a catalyst, a solution of oxalic acid is decomposed by ultraviolet, but not by visible, radiation. The degree of decomposition is determined by titration with potassium permanganate.

**Procedure.** A solution containing exactly 6.3 g. c.p. oxalic acid ( $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ ) and 4.27 g. uranyl sulfate ( $\text{UO}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$ ) per liter of distilled water is prepared and kept protected from the light. Place 25 ml. of this solution in a fused quartz cell  $3.35 \times 10$  cm. in area and 1.65 cm. thick.<sup>386</sup> The unshielded area of the cell is exposed directly to the source of ultraviolet energy for a definite period. In the case of solar measurements a one-hour exposure is used, the angle of the cell being changed every 5 minutes to keep the rays perpendicular to the surface.

After the exposure the contents of the cell are rinsed into a flask with 50 ml. distilled water, and 2 ml. concentrated sulfuric acid are added. The solution is then boiled and titrated while hot with a solution of potassium permanganate standardized to be equivalent to the oxalic acid solution (theoretically 3.16 g.  $\text{KMnO}_4$  per liter).

CALCULATION.  $(25 - \text{ml. of } \text{KMnO}_4 \text{ used}) \times 0.63 = \text{mg. oxalic acid decomposed}$ . Duplicate determinations should agree within 0.06 mg. The maximum value found by Tonney for sunlight at Chicago was 7.12 mg. per hour. Sunburn of untanned skin (the "erythema reaction") was observed whenever the intensity exceeded half this maximum value.

**Storage of Vitamin D.** The animal body is able to maintain a reserve of vitamin D, the amount depending on the dietary supply and on the extent of exposure to the synthesizing influence of ultraviolet radiations. The rate of depletion of the bodily store of vitamin D, when a supply of this factor is lacking, is affected by the ratio of calcium to phosphorus in the diet, which under normal conditions should be between 1:1 and 2:1.

<sup>385</sup> Clark: *Am. J. Physiol.*, **69**, 200 (1924); *Science*, **68**, 165 (1928); Pohle: *J. Am. Med. Assoc.*, **86**, 318 (1926); Webster, Hill, and Eidinow: *Lancet*, **1**, 745 (1924); Hill: *Lancet*, **2**, 299 (1924). A set of standard blue gauges, quartz tubes, and solution for use in this test is marketed by Siebe, Gorman and Co., Ltd., London, S.E. 1, England. Anderson and Robinson: *J. Am. Chem. Soc.*, **47**, 718 (1925); Tonney: *J. Prevent. Med.*, **2**, 493 (1928).

The photochemical methods have been calibrated against the radiometric method and critically reviewed by Mayerson (*Am. J. Hygiene*, **22**, 106 (1935)) with the conclusion that the oxalic acid-uranyl sulfate method is reliable and most convenient.

<sup>386</sup> Obtainable from the Hanovia Chemical and Manufacturing Co., Newark, N. J. The cell walls are covered with opaque paper except for a 10 sq. cm. area on the face to be exposed to the light source.

Young animals acquire some degree of antirachitic protection by virtue of the transfer of vitamin D into the mother's milk, although the efficiency of this transfer is very low (about 1 to 2 per cent). By feeding fish liver oil or irradiating the mother during the periods of gestation and lactation, the vitamin D potency of the milk can be increased somewhat, but ordinarily both cow's milk and human milk are poor sources of the antirachitic vitamin. The fortification of cow's milk with vitamin D is discussed on p. 1256.

**Chemistry of Vitamin D.** Five years after Huldschinsky's<sup>387</sup> demonstration of the therapeutic value of ultraviolet irradiation on rickets, Hess<sup>388</sup> and Steenbock<sup>389</sup> in 1924 independently revealed the discovery that antirachitic activity could be induced in foods by exposure to ultraviolet radiation. It was soon demonstrated that the antirachitic factor was contained in the nonsaponifiable fraction of activated oil, just as in the case of codliver oil. Interest then centered on the activability of phytosterol and cholesterol, the important unsaponifiable lipides of plant and animal tissue, respectively. At first it appeared that cholesterol was the specific precursor of vitamin D, but later work revealed other sterols to function in this role, viz., *ergosterol* in the lipide fraction of plants, yeasts, and fungi, and *7-dehydrocholesterol* in animal sources. Ergosterol had originally been isolated from ergot, the fungus of rye. Following the discovery of its provitamin nature it was extracted commercially from yeast. 7-Dehydrocholesterol was originally obtained from brain tissue, crustaceans, mussels, and other shellfish, but is now produced synthetically. The activated product of ergosterol is called vitamin D<sub>2</sub> or *calciferol*, whereas that of 7-dehydrocholesterol is vitamin D<sub>3</sub>. From the structural formulas it will be seen that activation of these sterols involves opening of the B ring and conversion of the methyl group between the A and B rings to methylene.

The synthesis of vitamin D from ergosterol is independent of the wavelength of the ultraviolet radiation over the range of selective absorption (about 256 to 313 m $\mu$ ), but is a function only of the absorbed energy.<sup>390</sup> It is therefore possible to activate ergosterol by exposure to the unobstructed rays of the sun in spite of the fact that radiation of such short wavelength, even under ideal conditions, hardly ever exceeds 0.1 per cent of the total solar energy.<sup>391</sup> The efficiency of solar irradiation may be affected by a relative preponderance of inactive decomposition products produced by the longer waves.<sup>392</sup> Activation is also induced by means of electronic streams, x-rays, radioactive emanations, and high-frequency alternating current.

<sup>392</sup> Lahousse and Gonnard, cited by Bills: *Physiol. Revs.*, **15**, 1 (1935).

In the ultraviolet activation of ergosterol a series of products is formed depending on the wavelength of the radiation, the duration of exposure, overheating, the nature of the solvent, the presence of oxygen, etc. The changes induced in the absorption spectrum of ergosterol by irradiation

FIG. 288. EFFECT OF PROLONGED IRRADIATION ON THE ULTRAVIOLET ABSORPTION SPECTRUM OF ERGOSTEROL.

Courtesy, Bills, Honeywell, and Cox: *J. Biol. Chem.*, 80, 557 (1928).

are shown in Fig. 288. The following scheme summarizes the sequence in which the isomeric products of irradiation appear:

The designation vitamin D<sub>1</sub> was applied to what was later found to be an equimolecular addition compound of lumisterol and calciferol; calciferol itself has been called vitamin D<sub>2</sub>. Of these irradiation products only calciferol is antirachitic. Toxisterol, as its name implies, has pronounced toxic-calcifying properties. The isomeric conversion of ergosterol to calciferol is now believed to be characterized by the opening of the B ring at C<sub>9-10</sub>, resulting in a fourth unsaturated linkage, the methyl group going to

methylene. A similar change occurs in the activation of 7-dehydrocholesterol (p. 1254).

tion,<sup>395</sup> including, in addition to the natural precursors ergosterol and 7-dehydrocholesterol, 22-dihydroergosterol, 7-hydroxycholesterol, and 7-dehydrositosterol. There is also evidence for the chemical activation of cholesterol (by forming cholesterylene sulfonic acid) and of ergosterol (by treatment with nitrite).

The products of irradiation of 7-dehydrocholesterol are analogous to those of ergosterol, the antirachitic substance being identical with the naturally occurring vitamin in fish liver oils. 7-Dehydrocholesterol can be synthesized by mammals and is present in subcutaneous tissue. Chemically it differs from ergosterol only in the side chain at position 17, which in this case is saturated and has one less  $\text{CH}_3$  group. The initial ultraviolet absorption curves and the transitional changes during irradiation of ergosterol and 7-dehydrocholesterol are identical.

From an extensive series of comparative rat-chick assays of the liver oils of many species of fish, Bills demonstrated the existence of more than one form of natural vitamin D. For example, the liver oil of bluefin tuna was found to be only about one-sixth as effective antirachitically for the chick as for the rat, whereas that of white sea bass was two or three times as effective, rat unit for rat unit. For the vitamin content of various fish liver oils, see the table on p. 1115.

The resistance of vitamin D to oxidation is shown by the failure of aeration of hot codliver oil or of treatment with hydrogen peroxide for 18 days to effect appreciable loss of antirachitic potency. The vitamin is not readily destroyed by gentle hydrogenation,<sup>396</sup> or by the action of such reducing agents as hydrogen sulfide, sulfur dioxide, or formaldehyde; on the other hand, nitrous fumes cause destruction.<sup>397</sup>

Vitamin D is thermostable in approximately neutral medium, as is indicated by its ability to withstand the direct steaming process used in rendering cod livers. Ninety minutes' autoclaving at  $130^\circ\text{C}$ . caused practically no destruction; at  $140^\circ$  to  $145^\circ\text{C}$ . the loss was slight; and at  $165^\circ$  to  $170^\circ\text{C}$ . destruction was complete.<sup>397</sup> In acid medium, however, gradual destruction takes place, the rate depending on the reaction and the temperature.<sup>398</sup> Vitamin D can withstand treatment with strong alkali even at elevated temperatures.

<sup>395</sup> Bills: *Cold Spring Harbor Symp. Quant. Biol.*, **3**, 328 (1935); *J. Am. Med. Assoc.*, **108**, 13 (1937); *J. Nutrition*, **13**, 435 (1937).

<sup>398</sup> Bills: *J. Biol. Chem.*, **64**, 1 (1925).

**Distribution of Vitamin D.** The most abundant natural source of vitamin D is codliver oil. Nevertheless, whereas ordinary codliver oil possesses a vitamin D activity of approximately 100 to 200 U.S.P. units per gram, the liver oils of certain other species of fish may be many times more potent.<sup>399</sup> Some liver oils which are blended for medicinal use are high in vitamin D, e.g., those from various species of tuna. Other oils, e.g., those of the swordfish and halibut, are also high in vitamin A. (See table, p. 1115.) The vitamin potency of fish liver oils is affected by spawning (and hence the season of the catch and the oil content of the livers) and by the age of the fish. Varying amounts of vitamin D are also found in the body oils of many marine animals, among them salmon, herring, sardine, shrimp, oysters, etc.<sup>400</sup>

Whether fish are able to synthesize vitamin D, as indicated by the experiments of Bills,<sup>399</sup> or whether it is derived from the caplin and other forms of food they consume, has not been definitely settled. There is evidence<sup>401</sup> that the vitamins of codliver oil are derived indirectly from unicellular marine organisms via copepods, larval decapods, and mollusca present in marine plankton, which in turn is consumed by the cod. However, Leigh-Clare<sup>402</sup> failed to demonstrate the presence of vitamin D in these diatomaceous organisms, although other investigators report the presence of the vitamin in marine plankton<sup>403</sup> especially during the summer months when it is abundant near the surface of the water.

When the livers of cod are in the process of becoming spent, the vitamin D potency of the oil bears an inverse relation to the oil content.<sup>404</sup> This has been attributed to the relatively rapid depletion of the glycerides during the starvation period, leaving behind the more resistant anti-rachitic factor. In a large-scale experiment conducted at the Norwegian fishing grounds, however, the senior author found that at the spawning season, when the livers were rich in oil, there was no demonstrable difference in antirachitic potency between the oil of male and female cod. The livers of the females had a somewhat lower oil content but were larger than those of the males.<sup>405</sup>

No increase in the vitamin D content of codliver oil is observed after ultraviolet irradiation, excess exposure being destructive not only of vitamin A but of vitamin D as well.

<sup>405</sup> Hawk: Reported before the American Chemical Society, Minneapolis Meeting, 1929. Of 1779 livers examined, those from female cod (58.6 per cent of the total) averaged about 288 ml. in size and contained 37.1 per cent oil, while those from the male averaged 163 ml. and contained 43.3 per cent oil.

Vitamin D has a very limited distribution among the common food-stuffs. Of these, egg yolk probably takes first rank, although this source is quite variable, depending upon the hen's ration and upon the amount of exposure to ultraviolet radiation. The vitamin D content of butterfat is relatively low, in contrast to its vitamin A content, but is likewise somewhat higher in summer than in winter. Human milk is an even poorer source of the antirachitic vitamin than cow's milk.

Processes used for increasing the antirachitic potency of whole or evaporated cow's milk include: (a) feeding activated yeast or sterols to cows, a small fraction of the vitamin D being transmitted to the milk; (b) ultraviolet irradiation of the milk; (c) fortification of the milk with natural or synthetic vitamin D.<sup>406</sup> The last is the principal method in use in this country today. Vitamin D milk produced by direct fortification is standardized to contain 400 U.S.P. units per quart (whole milk) and provides adequate safeguard against rickets.

Antirachitic activation of foods by ultraviolet irradiation is dependent upon the presence of the provitamin. Hence certain food products—e.g., milk, egg yolk, yeast—are capable of much greater activation than others, like cornstarch, egg white, or certain cereals. Careful control is required in irradiation processes to avoid the development of rancidity or disagreeable odors, and to guard against destruction of vitamin A, riboflavin, pyridoxine, and (by overirradiation) of the vitamin D which is formed.

Plant foods and vegetable oils are notoriously deficient in vitamin D. Excellent sources of vitamin A though they are, the green leafy vegetables lack the antirachitic factor in significant amounts even when grown in the summer months. Sun-drying of hay or alfalfa results in a considerable increase in antirachitic potency. Some activation occurs during fermentation of cocoa, owing to solar radiation of the sterols present in contaminating yeasts or fungi.

Certain cereals, notably oatmeal, contain a factor which actively inhibits calcification.<sup>407</sup> Not only is part of their phosphorus content nonassimilable, but it occurs in the form of inositol hexaphosphoric acid or phytin<sup>408</sup> which binds calcium and iron and thus interferes with their absorption.

## DETERMINATION OF VITAMIN D

### CHEMICAL METHODS

The determination of vitamin D by physical and chemical methods is complicated by the multiplicity of forms in which it may occur and by the interference of inactive sterols and of vitamin A in the color reactions. By chromatographing the unsaponifiable extract and measuring the

spectrophotometric absorption of the eluate at 265 m $\mu$ , chemical assay of irradiated sterols or similar high-potency materials is possible.<sup>409</sup> Similar methods employing modified antimony trichloride reagents have been used for the assay of fish liver oils, but with less success owing to their lower vitamin D potency and the interference of vitamin A. The antimony trichloride reaction differentiates between ergosterol and 7-dehydrocholesterol, which are indistinguishable spectrophotometrically.<sup>410</sup>

Green has developed a promising chemical procedure for vitamin D in fish liver oils<sup>411</sup> involving a series of steps designed to eliminate the interference by sterols and vitamin A with color reactions. The unsaponifiable extract is chromatographed on acid-activated flordin to destroy vitamin A; the carbon tetrachloride eluate is evaporated to dryness and taken up in 72 per cent ethanol to precipitate interfering provitamins and sterols; the filtrate is dried and taken up in chloroform, and the vitamin D ("apparent calciferol") is estimated spectrophotometrically after reacting with the antimony trichloride-acetyl chloride reagent of Nield, Russell, and Zimmerli.<sup>412</sup> While the method is claimed to give good agreement with bioassays, the "detailed steps necessary for the analysis of vitamin A-containing oil have generally to be decided for each particular sample" on the basis of the ratio of vitamin A to vitamin D and the percentage of unsaponifiable matter. By means of an iodine trichloride reaction the method has been adapted for the partial analysis of the irradiation products of ergosterol and 7-dehydrocholesterol, some of which remain unidentified.<sup>413</sup>

### BIOLOGICAL METHODS

The quantitative study of vitamin D activity is based on the determination of the comparative amounts of test materials and of standard vitamin D preparations necessary to induce healing of rickets in rats or to maintain normal calcification in chicks. The production of experimental rickets of a moderate but uniform degree of severity within a definite period of time is the primary requisite for reproducibility of results. Various methods differ in respect to the composition of the rachitogenic diet, the criteria for the establishment of the presence and degree of rickets, and the basis for judging the degree of healing. The rat curative assay (U.S.P.) is employed for the evaluation of the vitamin in foods or pharmaceutical products intended for human (or other mammalian) use; because of the relative insensitivity of fowl to vitamin D<sub>2</sub>, the chick method (A.O.A.C.) is employed in the assay of vitamin D intended for feeding poultry.

Ordinarily diets used for the production of experimental vitamin-deficiency diseases are characterized by being complete in all respects (i.e., as regards proteins, calories, minerals, and vitamins) except for

<sup>412</sup> Nield, Russell, and Zimmerli: *J. Biol. Chem.*, **136**, 73 (1940).

To prepare this reagent dissolve 18 g. antimony trichloride in 100 ml. purified chloroform, filter, and add 2 ml. redistilled acetyl chloride. Prepare fresh daily.

<sup>413</sup> Green: *Biochem. J.*, **49**, 232 (1951).

the absence of the vitamin in question. This, however, is not so in the case of the vitamin D assay with rats because decalcification does not occur readily in the absence of vitamin D unless the normal calcium:phosphorus ratio is disturbed. The analog of clinical rickets may be produced experimentally in rats by feeding a vitamin-D-free diet possessing a Ca:P ratio of about 4.5:1 instead of the normal ratio ranging from 1:1 to 2:1.

FIG. 289. (*Left*) ACTIVE RICKETS.

Roentgenograph of knee joint of rat on Steenbock rachitogenic diet No. 2965 for 17 days. Note especially broad bands of uncalcified cartilage near ends of tibia and femur.

FIG. 290. (*Right*) HEALED RICKETS.

Roentgenograph of knee joint shown in Fig. 289 after the rat had been fed a codliver-oil concentrate 14 days.

After 18 to 21 days on a standard rachitogenic diet, the animals develop a decalcified zone in the epiphyseal region of the long bones (the so-called "rachitic metaphysis") which may be readily demonstrated roentgenographically (see Fig. 289). At this time gross symptoms of rickets, such as shambling gait or enlargement of the knee joint, are not yet apparent. Hence it is desirable in order to establish the presence of the rachitic lesions that the animals be x-rayed or fluoroscoped or that some of them be sacrificed and their leg bones examined histologically.

After three weeks the bone ash values, expressed on a dry fat-free basis, drop from 35–45 per cent, the value at the time the rats are placed on the rachitogenic diet, to 25–35 per cent. At this age the normal ash content should be about 50–60 per cent. Similarly, the inorganic phosphorus content of the blood decreases from the normal level (for rats) of 8–10 mg. per 100 ml. of serum, to about 2–3 mg.<sup>414</sup> During this period the

animals continue to grow, but at a somewhat subnormal rate, the more rapidly growing animals exhibiting rickets of greater severity.

Following the preparatory period, the animals are fed the same diet plus the material to be assayed, which may be incorporated in the diet or preferably fed as a supplement. Negative controls are allowed to continue on the basal diet without antirachitic supplements, while positive controls receive a daily dose of a standard source of vitamin D, viz., the International or U.S. Pharmacopeia Vitamin D Reference Oil. It is important that food materials fed as supplements do not appreciably alter the Ca:P ratio of the diet. In the event of this possibility the assay should be controlled by including the ash of the test material in the diet of the negative controls, or preferably feeding the supplement in the form of its ether extract.

Rats which lose weight or fail to consume sufficient food must be discarded, because starvation is attended by a remobilization of tissue phosphate and spontaneous healing of rickets. The animals must be shielded against exposure to sunlight or even against undue exposure to filtered daylight.

The duration of the test period depends upon the criterion employed for healing. In the roentgenographic method, a six-day curative period may be used.<sup>415</sup> (See Figs. 289 and 290.) This method has the advantage of permitting each animal to serve as its own control, and may be conveniently combined with the histological technique as prescribed by the U.S. Pharmacopeia. The examination of stained sections of the leg bones (Line Test, see Fig. 291) is conducted at the end of the assay period.

The feces of rats on a rachitogenic diet tend to become alkaline, but return to the normal slightly acid condition during the process of healing.<sup>416</sup> The increase in pH is localized in the cecum and colon rather than in the small intestine, which is the main site of calcium and phosphorus absorption. A concomitant shift of urinary pH occurs in the opposite direction. These pH changes in rickets are reversible with vitamin D therapy.<sup>417</sup> Efforts to adapt fecal pH shift to the quantitative estimation of vitamin D<sup>418</sup> have failed owing to the small (about one pH unit) and variable difference and the interfering effect of extraneous factors.

Fish liver oils and vitamin D concentrates are important constituents of poultry rations. Since the rat assay is an inadequate measure of the vitamin D value of certain fish oils and sterols for avian species, a quantitative method of vitamin D assay employing chicks has been adopted by the Association of Official Agricultural Chemists.<sup>419</sup> This is a preventive

technique based on a comparison of the average bone-ash content of the assay group with that of reference groups receiving graded doses of the Standard. *One A.O.A.C. chick unit* of vitamin D is equal in biological activity for the chick to one unit of vitamin D in the U.S.P. Reference Standard.

FIG. 291. CHART FOR INTERPRETATION OF LINE TEST OF TIBIA.

Based on 7-day line test responses according to the U.S. Pharmacopeia procedure. Note that on this scale of numerical ratings 0.5 corresponds to minimal recalcification ("positive macroscopic evidence of calcification"); 4.0 corresponds to a narrow continuous "line" of calcification along the metaphyseal junction; and 12 falls somewhat short of complete healing, but is the maximal response in a 7-day test.

## ASSAYS FOR VITAMINS A AND D

**Biological Methods of the U.S. Pharmacopeia XIV.**<sup>420</sup>

DEFINITIONS. As used herein, unless the context otherwise indicates, the term *assayer* means the individual immediately responsible for the interpretation of the assay; the term *assay group* means the group of rats to which the assay oil shall be administered during the assay period; the term *assay oil* means the oil under examination for its vitamin potency; the term *assay period for the vitamin A assay* means the interval in the life of a rat between the last day of the depletion period and the twenty-ninth day thereafter or between the last day of the depletion period and the death of the rat; the term *assay period for the vitamin D assay* means the interval in the life of a rat between the last day of the depletion period and the eighth day thereafter; the term *assemble* means the procedure by which rats are selected and assigned to groups for the purpose of feeding, care, and observation; the term *control group* means the group of rats receiving no assay oil during the assay period; the term *declining weight* means the condition of a rat when its body weight on any given day is equal to or less than the body weight of the rat on the seventh day prior to the given day;<sup>421</sup> the term *depletion period* means the interval in the life of a rat between the last day of the preliminary period and the first day of the assay period; the term *dose* means the quantity of the U.S.P. Vitamin A Reference Standard or of the assay oil to be fed at specified intervals to a rat during the assay period; the term *fed* means made readily available to the rat or administered to the rat by mouth; the term *ground gluten* means the clean, sound product made from wheat flour by the almost complete removal of starch, and contains not more than 10 per cent of moisture, and, calculated on the water-free basis, not less than 14.2 per cent of nitrogen, not less than 15 per cent of nitrogen-free extract (using the protein factor 5.7), and not more than 5.5 per cent of starch (as determined by the diastase method<sup>422</sup>); the term *group for the vitamin A assay* (biological) means six or more rats maintained on the same required dietary regimen during the assay period; the term *group for the vitamin D assay* means seven or more rats maintained on the same required dietary regimen during the assay period; the term *ophthalmia* means a pathological state of the eye and/or the conjunctiva and/or the tissues anatomically related to the eye, readily discernible macroscopically and usually associated with vitamin A deficiency; the term *preliminary period* means the interval in the life of a rat between the seventh day after birth and the first day of the depletion period; the term *rachitogenic diet* means a uniform mixture of the food materials, and in the proportions named, in either of the following formulas:

## Rachitogenic Diet No. 1

Whole Yellow Maize, ground 33 per cent  
 Whole Wheat, ground.....33 per cent  
 Ground Gluten.....15 per cent  
 Gelatin.....15 per cent  
 Calcium Carbonate (U.S.P.) 3 per cent  
 Sodium Chloride (U.S.P.).... 1 per cent

## Rachitogenic Diet No. 2

Whole Yellow Maize, ground 76 per cent  
 Ground Gluten.....20 per cent  
 Calcium Carbonate (U.S.P.) 3 per cent  
 Sodium Chloride (U.S.P.)... 1 per cent

<sup>420</sup> Grateful acknowledgment for permission to reproduce these methods is made to Dr. Lloyd C. Miller and the Board of Trustees of the U.S. Pharmacopeial Convention, Inc.

<sup>421</sup> In this connection it is well to remember that rats manifest a diurnal variation in body weight averaging about 2 g. Because of the severity of avitaminosis and the high mortality that often results when rats remain too long on the depletion diet, many workers prefer to reduce the period of "declining weight" to four or five days. Differences in pathological symptoms which arise at the end of the depletion period are responsible for much of the variation encountered in biological assays for vitamin A. It has therefore been suggested that preventive, rather than curative, technique might yield more uniform results.

<sup>422</sup> Association of Official Agricultural Chemists: *Official and Tentative Methods of Analysis*, 6th ed., 1945, p. 410, method II; p. 577, method 34.53.

The term *vitamin A test diet* means a food material consisting of the following proportions of the named ingredients of the quality specified:

Vitamin A Test Diet

|                                |             |
|--------------------------------|-------------|
| Casein.....                    | 18 per cent |
| Salt Mixture (see below).....  | 4 per cent  |
| Yeast, dried (U.S.P.).....     | 8 per cent  |
| Starch.....                    | 65 per cent |
| Cottonseed Oil (U.S.P.).....   | 5 per cent  |
| Vitamin D, a sufficient amount |             |

No less than 3 U.S.P. Units of vitamin D shall be provided in each gram of diet and this vitamin shall be carried by the yeast or the cottonseed oil. The ingredients of the vitamin A test diet shall be free from vitamin A or shall have been treated so as to reduce the vitamin A content to such a degree that when the vitamin A test diet is fed to the control group two-thirds or more of the rats shall manifest, prior to the eleventh day of the assay period, symptoms of vitamin A deficiency characterized by both declining weight and ophthalmia.

Salt Mixture

|                                                    |           |
|----------------------------------------------------|-----------|
| Calcium Carbonate (U.S.P.).....                    | 68.6 g.   |
| Calcium Citrate (U.S.P. Reagent).....              | 308.3 g.  |
| Calcium Biphosphate (U.S.P. Reagent).....          | 112.8 g.  |
| Magnesium Carbonate (U.S.P.).....                  | 35.2 g.   |
| Magnesium Sulfate, Anhydrous (U.S.P. Reagent)..... | 38.3 g.   |
| Potassium Chloride (U.S.P.).....                   | 124.7 g.  |
| Dibasic Potassium Phosphate (U.S.P. Reagent).....  | 218.8 g.  |
| Sodium Chloride (U.S.P.).....                      | 77.1 g.   |
| Cupric Sulfate (U.S.P.).....                       | 0.48 g.   |
| Ferric Ammonium Citrate (U.S.P.).....              | 96.71 g.  |
| Manganese Sulfate (U.S.P. Reagent).....            | 1.24 g.   |
| Ammonium Alum (U.S.P. Reagent).....                | 0.57 g.   |
| Potassium Iodide (U.S.P.).....                     | 0.25 g.   |
| Sodium Fluoride (U.S.P. Reagent).....              | 0.75 g.   |
| To make.....                                       | 100.00 g. |
| To make.....                                       | 1000.0 g. |

Mix the finely powdered salts uniformly.

The biological assay of an oil for vitamin A and vitamin D potency shall be by comparison with the U.S.P. Vitamin A Reference Standard<sup>423</sup> and U.S.P. Vitamin D Reference Standard, respectively, by assay procedures conforming in all respects to the following specifications:

Assay for Vitamin A—Biological Method

For products for which the spectrophotometric method of vitamin A assay is not applicable use the biological method which follows:

The Vitamin A biological assay, comprising the recording of observations of groups of rats throughout specified periods of their lives, while being maintained on specified dietary regimens, and the interpretation of such data, is as follows:

<sup>423</sup> The U.S.P. Vitamin A Reference Standard consists of an encapsulated solution of crystalline vitamin A acetate in cottonseed oil.  
This oil solution is assigned a value of 10,000 U.S.P. vitamin A units per gram. The content of each capsule is assigned a value of 2500 U.S.P. vitamin A units.

**PRELIMINARY PERIOD.** Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the supply of vitamin A, or precursors of vitamin A, shall be limited to such a degree that rats weighing between 40 and 50 g. and not exceeding 28 days of age and subsisting on a suitable vitamin A deficient ration and water for an interval not exceeding 45 days shall manifest symptoms characteristic of vitamin A deficiency.

**DEPLETION PERIOD.** A rat shall be suitable for the depletion period when the age of the rat does not exceed 28 days, and if the body weight of the rat shall exceed 39 g., and does not exceed 50 g., and if the animal manifests no evidence of injury, or disease, or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the vitamin A test diet and water (U.S.P.), ad libitum, and during this period no other dietary supplement shall be available to the animal.

**ASSEMBLING RATS INTO GROUPS FOR THE ASSAY PERIOD.** Rats which are suitable for the assay period shall be assembled into groups. For each assay oil there shall be one or more assay groups. In the assay of one assay oil there shall be provided at least one control group and at least one reference group, but one control group and one reference group may be used for the concurrent assay of more than one assay oil. The interval of assembling rats into groups shall not exceed 60 days but the depletion period of rats in any one litter shall not vary by more than 14 days. On any one day during the interval of assembling rats into groups, the total number of rats that shall have been assigned to make up any one group shall not exceed by more than two the number of rats that shall have been assigned to make up any other group. When the assembling of all groups shall have been completed, the total number of rats in each group shall be the same, and the number of rats of one sex in each group shall be the same. Not more than three rats from one litter shall be assigned to one group. When the assembling of all groups shall have been completed, the average weight of the rats in any one group on the day beginning the assay period shall not exceed by more than 10 g. the average weight of the rats in any other group on the day beginning the assay period.

**ASSAY PERIOD.** A rat shall be suitable for the assay period, provided that the depletion period shall have exceeded 18 days and shall not have exceeded 45 days, and provided that a rat shall manifest evidence of vitamin A deficiency characterized by declining weight and/or ophthalmia. Throughout the assay period each rat of the control, reference, and assay groups shall be kept in an individual cage and shall be provided with the vitamin A test diet and water (U.S.P.), ad libitum. Throughout the assay period each rat in any assay group shall be fed two doses each week of the assay oil, and throughout the assay period each rat in any one reference group shall be fed two doses each week of the U.S.P. Vitamin A Reference Standard. The first dose of the assay oil or of the U.S.P. Vitamin A Reference Standard shall be fed on the day beginning the assay period, and succeeding doses shall be fed at intervals of not less than 3 nor more than 4 days. The U.S.P. Vitamin A Reference Standard and/or the assay oil may be diluted before feeding with cottonseed oil (U.S.P.). Diluted oil shall be stored in the dark at a temperature not exceeding 10° C. The period of storage shall not exceed 7 days. Not more than 0.2 ml. of the diluted oil shall be fed in a single dose. During the assay period all conditions of environment shall be maintained as uniformly as possible with respect to the assay, reference, and control groups.

**RECORDING OF DATA.** On the day beginning the depletion period and at intervals of not more than 7 days for the first 21 days of that period, there shall be a record made of the body weight of each rat. From the twenty-first day of the depletion period until the end of the assay period a record shall be made of the body weight and eye condition of each rat at intervals not exceeding 5 days. The eye condition shall be

designated as normal, watery, sensitive to light, swollen, bloody exudate, purulent, opacity of cornea, or any combination of these terms. A record shall be made of the failure of a rat to consume the prescribed daily dose of Reference Standard or assay oil.

**VITAMIN A POTENCY OF THE ASSAY OIL.** In determining the vitamin A potency of the assay oil, the performance of the rats of the assay and reference groups shall be calculated for each group on the basis of the difference between the average weight of the surviving rats and the average weight of the same rats on the day beginning the assay period. The data from the reference group shall be considered valid for establishing the vitamin A potency of the assay oil only when two-thirds or more of the total number of animals comprising a reference group shall have made individually between the beginning day of the assay period and the twenty-eighth day thereafter an increase in body weight which shall equal or exceed 12 g. and shall not exceed 60 g., and the data from an assay or reference group shall be considered valid for establishing the vitamin A potency of the assay oil only when two-thirds or more, but not less than 6, of the rats of an assay or reference group have survived 28 days of the assay period. The data from an assay group shall be considered valid for establishing the vitamin A potency of an assay oil only when two-thirds or more, but not less than 6 rats, shall have made individually between the beginning day of the assay period and the twenty-eighth day thereafter an increase in body weight which shall equal or exceed 12 g. The data from a rat shall be considered valid for establishing the average performance of a reference or assay group only on the condition that the rat has consumed the prescribed doses during the assay period. A vitamin A biological assay shall not be considered valid unless two-thirds or more of the total number of animals comprising the control group shall, prior to the eleventh day of the assay period, manifest symptoms of vitamin A deficiency characterized by both declining weight and ophthalmia.

#### CALCULATION OF VITAMIN A POTENCY

Let  $R$  equal the total quantity of U.S.P. Vitamin A Reference Standard in milligrams fed to each rat in a reference group and necessary to produce in a reference group an average gain in weight,  $G$ , of not less than 12 g. nor more than 60 g.

Let  $A$  equal the total quantity of assay oil in milligrams fed to each rat in an assay group and necessary to produce in an assay group an average gain in weight equal to or greater than  $G$ .

**MINIMUM STANDARD.** If the product of  $\left(\frac{R}{A}\right) \times$  (units per g. of vitamin A contained in the U.S.P. Vitamin A Reference Standard) is equal to or greater than the minimum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the minimum standard for vitamin A potency.

**MAXIMUM STANDARD.** If the product of  $\left(\frac{R}{A}\right) \times$  (units per g. of vitamin A contained in the U.S.P. Vitamin A Reference Standard) is equal to or less than the maximum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the maximum standard for vitamin A potency.

#### ASSAY FOR VITAMIN D—BIOLOGICAL METHOD

The vitamin D biological assay, comprising the recording of observations of groups of rats, throughout specified periods of their lives, while being maintained on specified dietary regimens, and the interpretation of such data, is as follows:

**PRELIMINARY PERIOD.** Throughout the preliminary period each rat shall be raised under the immediate supervision of, or according to directions specified by, the assayer. Throughout the preliminary period the rats shall be maintained on a dietary regimen which shall provide for normal development in all respects, except that the supply of vitamin D shall be limited to such a degree that rats, weighing between 40 and 60 g. at an age of 21 to 30 days, and subsisting for an interval of 3 weeks on a suitable rachitogenic diet, shall manifest evidence of severe rickets.

**DEPLETION PERIOD.** A rat shall be suitable for the depletion period when the age of the rat does not exceed 30 days, and if the body weight of the rat shall exceed 44 g., and does not exceed 60 g., and if the animal manifests no evidence of injury, or disease, or anatomical abnormality which might hinder growth and development. Throughout the depletion period each rat shall be provided with the rachitogenic diet and water (U.S.P.), ad libitum, and during this period no other dietary supplement shall be available to the animal.

**ASSEMBLING RATS INTO GROUPS FOR THE ASSAY PERIOD.** Rats which are suitable for the assay period shall be assembled into groups. For each assay oil there shall be one or more assay groups. In the assay of one assay oil there shall be provided at least one reference group, but one reference group may be used for the concurrent assay of more than one assay oil. The interval of assembling rats into groups shall not exceed 60 days. On any one day during the interval of assembling rats into groups, the total number of rats that shall have been assigned to make up any one group shall not exceed by more than two the number of rats that shall have been assigned to make up any other group. When the assembling of all groups shall have been completed, the total number of rats in each group shall be the same. Not more than three rats from one litter shall be assigned to the assay group unless an equal number of rats from the same litter are assigned to the reference group. When the assembling of all groups shall have been completed, the average weight of the rats in any one group on the day beginning the assay period shall not exceed by more than 8 g. the average weight of the rats in any other group on the day beginning the assay period.

**ASSAY PERIOD.** A rat shall be suitable for the assay period, provided that the depletion period shall have exceeded 18 days and shall not have exceeded 25 days, and provided that a rat shall manifest evidence of rickets characterized by a distinctive, wobbly, rachitic gait and by enlarged joints. The presence of rickets may also be established by examination of a leg bone of one member of a litter by the "line test" described below. Each rat shall be kept in an individual cage and shall be provided with the rachitogenic diet and water (U.S.P.), ad libitum. On any calendar day of the assay period, the assay and reference groups shall receive a rachitogenic diet compounded from the same lots of ingredients. On the first and fourth calendar days of the assay period each rat in any one assay group shall be fed one-half the total dose of the assay oil, and on the first and fourth calendar days of the assay period each rat in any one reference group shall be fed one-half the total dose of the U.S.P. Vitamin D Reference Standard, except that when the fourth calendar day of an assay period is a holiday, the dose of the assay oil or the U.S.P. Vitamin D Reference Standard may be fed on the preceding day. At the termination of the assay period, each rat shall be killed and one or more leg bones examined for healing of the rachitic metaphysis according to the "line test" described below. The reference oil and/or the assay oil may be diluted before feeding with cottonseed oil (U.S.P.). The diluted oil shall be stored in the dark at a temperature not exceeding 10° C., the storage period not to exceed 30 days. Not more than 0.2 ml. of the diluted oil shall be fed in a single dose. During the assay period all conditions of environment (particularly with reference to physiologically active radiations) shall be maintained as uniformly as possible with respect to the assay and reference groups.

**LINE TEST.** The line test shall be made on the distal end of the radius.<sup>424</sup> The end of the bone is removed from the animal and cleaned of adhering tissue. A longitudinal median section shall be made through the end of the bone with a clean, sharp blade to expose a plane surface through the junction of the epiphysis and diaphysis. Both

---

<sup>424</sup> Many assayers prefer the use of the tibia and it is probable that this will be optional in the next revision of the U.S.P. assay for vitamin D. A chart showing the healing responses in the tibia is shown in Fig. 291, although the U.S. Pharmacopeia XIV prescribes and illustrates the responses in the radius. More significant than the particular bone used in the line test is the arbitrary scoring scale which should yield a linear dose: response curve.

sections of the bone shall be rinsed in distilled water and shall then immediately be immersed in a 2 per cent aqueous solution of silver nitrate for 1 minute. The sections shall then be rinsed in distilled water and the sectioned surfaces of the bone shall be exposed in water to daylight or other source of actinic light until the calcified areas have developed a clearly defined stain without marked discoloration of the uncalcified areas.

Records shall be made immediately of the extent and degree of calcification of the rachitic metaphysis of every section. It shall be permissible to use modifications of the described procedure for staining, provided that such modified procedures clearly differentiate between calcified and uncalcified areas.

**RECORDING OF DATA.** On the day beginning the assay period and on the seventh day thereafter, a record shall be made of the body weight of each rat. A record shall be made of the quantity of rachitogenic diet consumed per rat during the assay period. Numerical values shall be assigned to the extent and degree of calcification of the rachitic metaphysis of the bones examined by the line test so that it will be possible to average the performance of each group. A Line Test Chart, that may be used for this purpose, is presented below.<sup>425</sup>

**VITAMIN D POTENCY OF THE ASSAY OIL.** In determining the vitamin D potency of the assay oil, the average performance of groups with respect to healing of the rachitic metaphysis shall be considered, provided that the average performance of a reference group with respect to calcification of the rachitic metaphysis shall be determined by the data from rats which individually show an extent and degree of calcification in the rachitic metaphysis as determined by the line test equal to or greater than a condition described as a positive macroscopic evidence of calcification, but no greater than an extent and degree of calcification represented by the value 8 in the Line Test Chart<sup>425</sup> presented below. The data from a reference group shall be considered valid for establishing the vitamin D potency of the assay oil only when two-thirds or more, but not less than seven rats, show individually an extent and degree of calcification of the rachitic metaphysis equal to or greater than a condition described as positive macroscopic evidence of calcification, but no greater than an extent and degree of calcification represented by the value 8 in the Line Test Chart<sup>425</sup> presented below. The data from an assay group shall be considered valid for establishing the vitamin D potency of an assay oil only when two-thirds or more, but not less than seven rats, show individually an extent and degree of calcification of the rachitic metaphysis equal to or greater than a condition described as positive macroscopic evidence of calcification. The data from a rat shall be considered valid for establishing the average performance of a group only on the condition that the weight of the rat at the termination of the assay period shall equal or exceed the weight of the rat on the beginning day of the assay period and that the rat has consumed 28 g. or more of the rachitogenic diet during the assay period and on the condition that the rat has consumed each prescribed dose of assay oil within 24 hours from the time it was fed.

#### CALCULATION OF VITAMIN D POTENCY

Let  $R$  equal the total quantity of U.S.P. Vitamin D Reference Standard in milligrams fed to each rat in a reference group and necessary to produce in a reference group an average extent and degree of calcification,  $C$ , not less than a condition described as positive macroscopic evidence of calcification but less than the degree of calcification represented by the value 8 in the Line Test Chart.

Let  $A$  equal the total quantity of assay oil in milligrams fed to each rat in an assay group and necessary to produce in an assay group an average extent and degree of calcification equal to or greater than  $C$ .

---

<sup>425</sup> This chart of the line test responses as seen in the radius has been omitted. See footnote 424, p. 1265.

**MINIMUM STANDARD.** If the product of  $\left(\frac{R}{A}\right) \times$  (units per g. of vitamin D contained in the U.S.P. Vitamin D Reference Standard) is equal to or greater than the minimum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the minimum standard for vitamin D potency.<sup>426</sup>

**MAXIMUM STANDARD.** If the product of  $\left(\frac{R}{A}\right) \times$  (units per g. of vitamin D contained in the U.S.P. Vitamin D Reference Standard) is equal to or less than the maximum standard in U.S.P. units per g. for the oil assayed, then the assay oil meets the maximum standard for vitamin D potency.<sup>426</sup>

## VITAMIN E (TOCOPHEROLS)

The essentiality of vitamin E for optimum nutrition has been demonstrated in more than fifteen vertebrate species by restricting the dietary intake of this vitamin and noting deficiency symptoms. The discovery of vitamin E in 1922 was based upon experiments of H. M. Evans, of the University of California, showing that for normal reproductive function rats required a new fat-soluble factor present in crude vegetable oils and subsequently identified as isomers of tocopherol. Later studies showed that this new vitamin was also essential for normal muscle metabolism, to maintain the integrity of the central nervous system and the vascular system, and for a variety of other physiological functions. The pathology of the symptoms of vitamin E deficiency has been described in great detail, particularly by Pappenheimer and Goettsch and by Mason. However, the exact biochemical mechanism whereby vitamin E functions in diverse metabolic processes in the body is still unknown. This and the direct experimental production and recognition of vitamin E deficiency in human subjects constitute two of the most important problems in the field of vitamin E research. Estimates of the human requirements for this vitamin are based upon indirect evidence, such as the mean daily per capita consumption of vitamin E and the similarity of tissue pathology seen in premature infants and adults suffering from faulty fat absorption to that seen in vitamin E deficient animals.

**Physiological and Clinical Aspects of Vitamin E.** Not all of the tocopherol in foods is completely available when ingested. The  $\alpha$  form is more efficiently absorbed than the non- $\alpha$ -tocopherols. Tocopherols in cereal grains, leafy vegetables, and practically any natural foodstuff are bound in such a way that during passage through the digestive tract some of the tocopherol is excreted in the feces. Balance studies in normal human beings show as much as 60 per cent of ingested  $\alpha$ -tocopherol appearing in the feces. Conditions interfering with fat absorption (biliary diseases, pancreatic insufficiency, mineral-oil ingestion, etc.) further reduce the amount of this vitamin absorbed. No free or conjugated tocopherol is excreted in the urine. Both tocopherol and tocopherol esters, when ingested, appear in the blood and are transported as the free form.

$\alpha$ -Tocopherol is deposited in all tissues. The pituitary and adrenal glands have especially high concentrations of tocopherol, over 30 mg. per

---

<sup>426</sup> The U.S.P. Unit of vitamin D is defined as the activity of 0.025  $\mu$ g. of vitamin D<sub>3</sub>, contained in the U.S.P. Vitamin D Reference Standard.

cent, but the bulk of the body stores of tocopherol is in the adipose tissues and muscles.

Vitamin E deficiency symptoms develop in different tissues and at different rates depending upon species. The rabbit and lamb show muscular lesions and paralysis within a few weeks on a tocopherol-free diet. The rat develops testicular degeneration and the chick shows softening of the brain (encephalomalacia) within six weeks. However, the lamb, rabbit, and herbivores in general eventually develop reproductive dysfunction; the rat shows muscle dystrophy and paralysis in about 12 to 18 months; and the chicken eventually develops both muscular and reproductive abnormalities. No common denominator of physiological function of  $\alpha$ -tocopherol or of reasons for species specificity and tissue susceptibility has been established; this makes it necessary to consider separately the physiology of individual tissues and organs.

Complex biochemical changes in the muscle tissue in chronic vitamin E deficiency are followed by histological lesions characteristic of muscular dystrophy. The muscle shows either a gradual necrosis and replacement of muscle fibers with fat and connective tissue, or an explosive form of dystrophy involving larger portions of the muscle and accompanied by edema, leukocytic infiltration, and fragmentation of muscle fibers. The former is typified by the muscular paralysis which develops in the adult hamster and has its histological counterpart in humans in progressive muscular dystrophy and dermatomyositis. The explosive type of syndrome is exemplified by paralysis in suckling rats late in lactation and by muscle dystrophy in guinea pigs and rabbits. Heart muscle is affected like skeletal muscle by vitamin E deficiency and rats, rabbits, sheep, and cows have all shown typical lesions of degeneration, pigment deposition, electrocardiogram changes, and functional failure. Vascular abnormalities develop during the production of vitamin E deficiency in all species studied. The dog in particular, when subjected to a high-fat diet combined with kidney injury, develops a reversible arteritis resembling that seen in human arteriosclerosis.

Demyelination, gliosis, and distortion of the axon pattern in the spinal cord are seen in vitamin E deficient rats, giving rise to hypalgesia and progressive paresis.

The vitamin E deficient male animal shows testicular atrophy and sterility due to irreversible degeneration of the seminiferous tubules and to failure of spermatogenesis. In the vitamin E deficient female, a reversible type of reproductive dysfunction occurs. Ovarian function is normal but uterine physiology is disturbed. There is partial failure of implantation, and those fertilized ova successfully implanted grow and develop only to a certain stage, at which time the fetuses show generalized hemorrhage, die, and are aborted or resorbed. Administration of  $\alpha$ -tocopherol during the first half of gestation permits normal fetal development and parturition. This reversibility of reproductive function in the female rat serves as the basis for the bioassay method most generally used to evaluate vitamin E potency.

The normal resistance of red blood cells to rupture, both *in vivo* and *in vitro*, is markedly reduced in vitamin E deficiency. Administration of

$\alpha$ -tocopherol to the patient or addition of  $\alpha$ -tocopherol to the *in vitro* system returns the resistance of the erythrocytes to normal. This improvement in function of red blood cells by  $\alpha$ -tocopherol serves as the basis for a bioassay for vitamin E activity.

The finding that vitamin E metabolism plays an essential role in cardiovascular pathology in lower animals has resulted in attempts to employ tocopherols therapeutically. Cases of angina pectoris, coronary insufficiency, peripheral vascular diseases, etc. have been reported by some investigators to improve under  $\alpha$ -tocopherol therapy, but others have failed to observe any benefit in similar clinical trials.

Fatal massive liver necrosis occurs in animals maintained on diets low in vitamin E and sulfur-containing amino acids. Under conditions in which the intestinal flora of the animal are eliminated (germ-free environment, antibiotic treatment), liver necrosis does not develop but the animal dies from lung hemorrhage.  $\alpha$ -Tocopherol administration prevents both the liver necrosis and the lung hemorrhage. Possibly this prevention of liver injury by  $\alpha$ -tocopherol is merely an example of a physiologic role of  $\alpha$ -tocopherol whereby environmental, dietary, and drug stresses are combatted.

Some evidence, both experimental and clinical, points to a sparing effect of  $\alpha$ -tocopherol upon hormone action, particularly insulin and the sex hormones. This is considered a result of  $\alpha$ -tocopherol exerting an antioxidant or sparing action upon the hormone metabolism. Various pathological states in poultry and livestock have been shown to be aspects of vitamin E deficiency and to respond to administration of tocopherols. Among them are "crazy-chick disease," "enlarged hock disease" of turkey poults, "white muscle disease" of calves and colts, "stiff lamb disease," and steatitis or "yellow fat disease" of mink.

**REQUIREMENT.** The need for vitamin E has been established qualitatively for a variety of animal species. However, quantitative requirements, either minimal or optimal, for various animals including man, have not been determined.

Diets of good quality consumed by healthy persons in good economic circumstances average between 10 and 25 mg.  $\alpha$ -tocopherol daily. Reducing diets and some therapeutic-type diets furnish as little as 4 mg. per day. From a curve relating vitamin E requirements for laboratory animals to (body weight)<sup>0.7</sup>, the value for a 70-kg. animal may be extrapolated. An estimated requirement for humans of 30 mg. D- $\alpha$ -tocopherol is thus derived. From a consideration of the results of these two approaches, the human requirement may be estimated as 15–25 mg.  $\alpha$ -tocopherol daily.

**BIOPOTENCY.**  $\alpha$ -Tocopherol and various of its derivatives have different relative potencies depending upon the procedure used for bioassay. Esterified  $\alpha$ -tocopherol is more potent by the rat bioassay (in which sub-optimal amounts are fed) than an equivalent quantity of free  $\alpha$ -tocopherol, probably because of the relative instability of the latter in the intestinal tract (see Table, p. 1270). Tests on human infants and adults with therapeutic doses fail to show this superiority of the ester form. Hence the National Formulary X considers 1 mg. of synthetic  $\alpha$ -tocopheryl acetate

## RELATIVE BIOPOTENCY OF VARIOUS FORMS OF VITAMIN E

| <i>Compound</i>                                              | <i>Molecular Weight</i> | <i>Relative Biopotency*</i> | <i>International Units per Mg.</i> |
|--------------------------------------------------------------|-------------------------|-----------------------------|------------------------------------|

| “ - $\alpha$ -Tocopheryl acetate<br>(International Standard) | 472.8                   | 100                         | 1.00 (by definition)               |

\* Based on feeding equivalent amounts of  $\alpha$ -tocopherol.

equal to 1.0 I.U. and 1 mg. of natural  $\alpha$ -tocopheryl acetate equal to 1.36 I.U. The free  $\alpha$ -tocopherols, on the basis of their molecular weight, have a biopotency of 1.1 I.U. per mg. for the synthetic and of 1.49 I.U. per mg. for the natural form.

**PHYSIOLOGICAL ANTIOXIDANT ACTIVITY.** The fact that protoplasm is an aqueous-lipide emulsion in which metabolic reactions occur at interfaces immediately poses the problem of properly stabilizing the lipide phase.  $\alpha$ -Tocopherol is the only naturally occurring, fat-soluble food antioxidant which accompanies lipide through the intestinal tract and during its transport via blood or lymph to storage depots or metabolic sites. Other antioxidants are eliminated during absorption or in transit, and  $\alpha$ -tocopherol emerges as the only physiological fat-soluble antioxidant.

The amount of  $\alpha$ -tocopherol deposited in the tissues is proportional to the quantity ingested. In certain species—for example, turkeys and pigs—the concentration of  $\alpha$ -tocopherol in tissue lipides is so low that turkey carcass fat and lard oxidize and become rancid even under conditions of low-temperature storage. The cow excretes a proportional amount of ingested or stored  $\alpha$ -tocopherol into her milk, and whenever the level falls below 20–30  $\mu$ g. per g. milk fat, the milk has poor stability and off-flavor develops.

**Chemistry of the Tocopherols.** The four compounds in vegetable oils possessing vitamin E activity have been isolated and their structures proved. They were named *tocopherols* (Greek, “young-bearing”), and found to differ only in the extent of methylation of the chroman nucleus.  $\alpha$ -Tocopherol was synthesized by L. I. Smith and by Karrer, independently, in 1938. The structure of  $\alpha$ -tocopherol is shown on p. 1271 with those carbon atoms marked where asymmetry may occur, thus giving rise to isomers. Natural  $\alpha$ -tocopherol is the D form whereas synthetic vitamin E consists of a mixture of isomers usually designated as racemic DL- $\alpha$ -tocopherol.

The other tocopherols,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherols, have been synthesized and characterized. However, they are considered to be less important, since they are less effective physiologically than  $\alpha$ -tocopherol. The structural differences of the various tocopherols are shown in the follow-

**α-Tocopherol**

\* Points of asymmetry. Natural-occurring α-tocopherol is the D form, whereas synthetic α-tocopherol is a mixture of isomers.

ing scheme. The β form has about one-third the biopotency of α-tocopherol, the γ form about one-twelfth, and the δ form about one-hundredth.

**The Tocopherol Nucleus**

| Name         |                        | Substituents at Positions |                   |                   |
|--------------|------------------------|---------------------------|-------------------|-------------------|
|              |                        | 5                         | 7                 | 8                 |

α-Tocopherol is easily destroyed by oxidation. Esterification with acetic, succinic, phosphoric, and other acids is commonly practiced to stabilize the vitamin. These esters have essentially the same potency as α-tocopherol except that under certain test conditions they bioassay higher than the free tocopherol because of their enhanced stability.

Other changes in the molecule, such as alteration of the side chain, etherification at position 6, or substitution of the ring methyl groups, markedly reduce or completely eliminate vitamin potency. Oxidation of α-tocopherol, which progresses through an epoxide intermediate, a hydroquinone, and a free radical semiquinone to tocopherol quinone, destroys the vitamin E potency for most animal species. However, the epoxide intermediate is physiologically active for the rat, the tocopherol hydroquinone will prevent or cure muscle degeneration in the hamster and the final oxidation product, tocopherol quinone, has vitamin E activity for the rabbit.

**Occurrence and Distribution of Vitamin E.** Vegetable-seed oils, particularly those of wheat, soybean, cotton, and corn, are the richest natural sources of tocopherols (approximately 0.5 to 3.0 mg. per g.). These are used as source materials for the manufacture of vitamin E concentrates and pure natural  $\alpha$ -tocopherol preparations. Margarine made from hydrogenated vegetable oils is one of the best food sources of  $\alpha$ -tocopherol. Dairy products supply relatively low and variable amounts of  $\alpha$ -tocopherol. Colostrum, both human and bovine, contains levels of  $\alpha$ -tocopherol ten times higher than later milk. This is important because the newborn infant or calf has a poor endowment of tocopherol in its tissues. The total amount of tocopherol in the newborn infant is about 20 mg., less than the amount eaten daily by a well-fed adult. Cow's milk is only from one-fourth to one-half as potent as human milk in  $\alpha$ -tocopherol content. This fact should be considered when cow's milk is substituted for human milk in infant feeding. Hydrogenation and refining processes do not completely destroy this vitamin. Other foods of vegetable origin, such as lettuce, celery, and sweet potato, while rich in tocopherol on the basis of their fat content, make relatively minor contributions of vitamin E to the diet.

Foods of animal origin are generally poor sources of  $\alpha$ -tocopherol unless one excepts meat cuts from animals fed rations high in tocopherol just prior to slaughter. Milk, butter, cheese, other dairy products, and eggs are similarly quite low in  $\alpha$ -tocopherol content.

## DETERMINATION OF VITAMIN E

### CHEMICAL METHODS

Analysis of biological materials for  $\alpha$ -tocopherol content is complicated because of the presence of non- $\alpha$ -tocopherols, carotenoids, and many other extraneous materials which possess reducing power and which must be corrected for, or eliminated, prior to colorimetric measurement. Another difficulty is the problem of extracting, saponifying, and concentrating the small quantities of this vitamin present without oxidative destruction and loss.

Analyses of foodstuffs, blood, and other tissues for  $\alpha$ -tocopherol require different steps of extraction, concentration and purification.

The colorimetric measurement of pure tocopherols with ferric chloride-dipyridyl reagent is precise but nonspecific. Any compound capable of reducing ferric to ferrous ions, which then react with dipyridyl to form a red color, would be measured as tocopherol. However, for the determination of tocopherol in purified extracts, or in pure standard solutions of  $\alpha$ -tocopherol, the following procedure may be used:

#### *Ferric Chloride-Dipyridyl Method (Emmerie-Engel Reaction).*

**Procedure.** Prepare a solution in absolute ethanol containing from 10 to 25 mg. tocopherol per 100 ml. Transfer 2 ml. of this solution to an opaque, glass-stoppered flask. Add 1.0 ml. ferric chloride reagent and 1.0 ml. 0.5 per cent dipyridyl in absolute ethanol (redistilled from 0.02 per cent alkaline potassium permanganate). Swirl to mix. Add 21 ml. of absolute ethanol and shake vigorously. After  $9\frac{1}{2}$  minutes from the addition of ferric chloride

reagent (0.1 g. ferric chloride dissolved in 50 ml. absolute ethanol), transfer an aliquot to a spectrophotometer or colorimeter cell. Determine the absorbancy at 520  $m_\mu$  against absolute ethanol as a blank, at exactly 10 minutes after addition of the ferric chloride. Prepare a control sample exactly as described except for the use of 2 ml. absolute ethanol for the 2 ml. tocopherol solution. Again, after 10 minutes determine the absorbancy at 520  $m_\mu$  against absolute ethanol as a blank.

The difference between the absorbancies of the control sample and the test sample is converted to "mg. tocopherol" by reference to a standard curve.

A good alternative procedure consists in using ceric sulfate as the oxidizing reagent and titrating the tocopherol-containing extract using diphenylamine or ferroin as the indicator.

*Saponification (For Extracts Containing Tocopherol Esters or  $\alpha$ -Tocopheryl Acetate Standards).* Weigh a sample containing 150–300 mg. tocopherol ester into a 250-ml. glass-stoppered actinic glass flask. Use of rubber stoppers may introduce interfering reducing substances, and exposure to light causes destruction of tocopherol. Add 50 ml. absolute ethanol, fit with a reflux condenser, and reflux for at least 1 minute to remove all traces of air from the system. Add carefully and slowly through the condenser 1 g. KOH to the refluxing solution. Reflux for 20 minutes. Without cooling, add 2 ml. HCl dropwise. Cool to room temperature and transfer to a 500-ml. separatory funnel, rinsing the flask with 100 ml. water and 100 ml. freshly distilled, peroxide-free ethyl ether. Shake vigorously. Allow the layers to separate. Extract the aqueous layer twice more with 50-ml. portions of ethyl ether. Wash the combined ether extracts with four 100 ml. portions of water. Evaporate the ether solution on a water bath, in vacuum or under streams of nitrogen, to less than 10 ml.; then to dryness without heat. Immediately dissolve the residue in absolute ethanol, transfer to a 250-ml. volumetric flask and dilute to volume.

Alternatively, the labile tocopherol may be protected during the saponification step by using antioxidants, such as pyrogallol or acetyl *p*-aminophenol.

*Analysis of Biological Tissues (Method of Quaife and Dju<sup>427</sup>).* Practically all of the tocopherol in human and animal tissues is  $\alpha$ -tocopherol. A specimen is taken and frozen solid in dry ice. It is pulverized, sieved, sampled, and weighed in the frozen state. The sample is then extracted with hot ethanol for 24 hours, transferred to purified petroleum ether, molecularly distilled, and hydrogenated. The extract is then assayed by the ferric chloride–dipyridyl method.

Blood serum or plasma is easier to analyze for tocopherol content since the molecular distillation step may be omitted.<sup>428</sup>

*Analysis of Foods (Method of Quaife and Harris<sup>429</sup>).* The procedure for foods, particularly vegetable foods, is similar to that used for animal tissues except that a dehydration step is used to effect some concentration of tocopherol, and the ethanol extraction time is only two hours. Final colorimetric

<sup>427</sup> Quaife and Dju: *J. Biol. Chem.*, **180**, 263 (1948).

<sup>428</sup> Quaife and Harris: *J. Biol. Chem.*, **156**, 499 (1944); Quaife and Biehler: *J. Biol. Chem.*, **159**, 663 (1945).

<sup>429</sup> Quaife and Harris: *Anal. Chem.*, **20**, 1221 (1948); Harris, Quaife and Swanson: *J. Nutrition*, **40**, 367 (1950).

estimation of tocopherol with ferric chloride-dipyridyl reagent measures total tocopherols, and some procedure for obtaining only the  $\alpha$ -tocopherol content is required. In foods where the tocopherol concentration is low,  $\gamma$ - +  $\delta$ -tocopherol concentration is measured by diazotization with dianisidine.<sup>430</sup> ( $\beta$ -Tocopherol is not measured, but this form occurs only in wheat products.) The  $\alpha$ -tocopherol content is obtained by subtracting the combined value for  $\gamma$ - +  $\delta$ -tocopherols from the total tocopherol value.

In preparations where at least 0.5 mg. of  $\beta$ - +  $\gamma$ - +  $\delta$ -tocopherols are available, analysis of their total content is preferably done by the nitroso method.<sup>431</sup> This value for the combined amount of all non- $\alpha$ -tocopherols, subtracted from the total tocopherol value determined by the ferric chloride-dipyridyl method, has been used to give a measure of the  $\alpha$ -tocopherol content.

Separation, isolation, and direct measurement of  $\alpha$ -tocopherol in extracts of biological materials has been done semiquantitatively by means of paper chromatography. Brown<sup>432</sup> has reported separation of the tocopherols, using petrolatum-coated paper strips and 75 per cent ethanol as solvent, and has estimated the individual tocopherol content of various animal and vegetable tissues.

## BIOLOGICAL METHODS

*Evans Resorption-Gestation Method, Modified by Mason and Harris.*<sup>433</sup> This bioassay is based upon the ability of  $\alpha$ -tocopherol, administered to vitamin E deficient female rats during the first half of pregnancy, to prevent fetal death and resorption. Female rats with low vitamin E reserves are raised on the following vitamin E low diet:

|                                                                                                                   |             |
|-------------------------------------------------------------------------------------------------------------------|-------------|
| Casein, commercial unextracted                                                                                    | 20 per cent |
| Carbohydrate, starch, or sucrose                                                                                  | 56 "        |
| Fat, lard, or olive oil                                                                                           | 10 "        |
| Salt mixture                                                                                                      | 4 "         |
| Brewer's yeast, dried                                                                                             | 10 "        |
| Vitamins A and D, added to fat component<br>to supply 10 units vitamin A and 1 unit<br>vitamin D per gram of diet |             |

When the females are 150 g. in weight, they are mated with normal males. Vaginal smears are made daily until sperm (sign of positive mating) are observed. The pregnant females are placed in individual cages and assigned at random to control or test groups.

Groups of six to ten rats are set up on four or five levels of both the unknown material being assayed and the standard. (The International Vitamin E Standard is a preparation of DL- $\alpha$ -tocopheryl acetate in olive oil. The biological activity of 1 mg. of this DL- $\alpha$ -tocopheryl acetate = 1 International Unit of vitamin E.)

The vitamin E supplement is fed orally in five daily doses prior to the tenth day of pregnancy. On the twentieth day of pregnancy the rats are killed and autopsied. The uterus is inspected for live, dead, and resorbed fetuses. Only those animals with four or more implantation sites are considered. A "positive" response is recorded for animals with one or more viable fetuses, and a

<sup>430</sup> Quaife: *J. Am. Chem. Soc.*, 66, 308 (1944).

<sup>431</sup> Quaife: *J. Biol. Chem.*, 175, 605 (1948).

<sup>432</sup> Brown: *Biochem. J.*, 52, 523 (1952).

<sup>433</sup> Mason and Harris: *Biol. Symposia*, 12, 459 (1947).

“negative” for those with no living fetus. A dose:response curve is constructed relating dose (logarithm) to response (litter efficiency, i.e., percentage of positive responses expressed as probits<sup>434</sup>) for both the standard and the unknown. These are compared at the 50 per cent end point (the Median Fertility Doses) and the potency of the unknown is expressed in terms of International Units of vitamin E.

**Rose-György Erythrocyte Hemolysis Test.**<sup>435</sup> Adult rats, two to three months old, have red blood cells which are normally resistant to the hemolytic action of dialuric acid, hydrogen peroxide, and similar reagents. Changing the animals to a vitamin E low diet for even a few days causes the red cells to become susceptible to hemolysis. Administering various levels of  $\alpha$ -tocopherol, either prophylactically or curatively, to the rats during the depleting period and measuring the degree of red cell hemolysis under arbitrary standard conditions gives a satisfactory bioassay procedure.

**Procedure.** Rats receiving various levels of pure  $\alpha$ -tocopherol as standard and other groups receiving similar levels of tocopherol in the unknown material, both within the range to furnish 0.1 to 0.4 mg.  $\alpha$ -tocopherol per day, are used. The supplements are fed daily for two weeks and on the fifteenth day blood samples are taken and tested. Obtain blood from tail of rats, 10 to 12 drops in a graduated 15-ml. centrifuge tube containing 2 ml. anticoagulant (equal parts of 0.9 per cent NaCl and 1 per cent sodium citrate solutions). Centrifuge and discard supernatant fluid. Dilute the red cells to a 5 per cent suspension with 0.9 per cent NaCl solution.

Pipet 0.25 ml. erythrocyte suspension into each of three test tubes or colorimeter tubes. To one (control) add 4.75 ml. of saline-buffer solution;<sup>436</sup> to tube 2 add 4.75 ml. H<sub>2</sub>O, which hemolyzes red cells completely; to tube 3 add 4.45 ml. saline-buffer solution<sup>436</sup> and 0.30 ml. dialuric acid solution.<sup>437</sup> Mix and incubate for 30 minutes at 37° C. Allow to stand at room temperature for at least two hours, invert tube, centrifuge, and measure in the colorimeter the red color from the hemolyzed cells.

**CALCULATION.** The reading of the control sample is subtracted from readings of both the test sample and the completely hemolyzed sample. The percentage of hemolysis is calculated as the ratio of the corrected test-sample reading  $\times 100$ , to the corrected hemolyzed-sample reading.

Human infants, especially premature, have red blood cells which are hemolyzed by dilute hydrogen peroxide. Administration of  $\alpha$ -tocopherol, either *in vivo* or *in vitro*, prevents this hemolysis.<sup>438</sup>

Other bioassays have been developed and used to a limited extent. For example, young male rats raised for three months or more on vitamin E deficient diets supplemented with various levels of  $\alpha$ -tocopherol, 0.0 to 1.0 mg. daily, show testis weight proportional to the dose of  $\alpha$ -tocoph-

<sup>434</sup> Converting percentage responses to probits (a mathematical convention), by reference to tables, results in a straight-line dose:response curve instead of a sigmoid-shaped curve. This makes it easier to derive a median value from the data (Bliss: *Ann. Applied Biol.*, **22**, 134, 1935).

<sup>435</sup> Rose and György: *Proc. Soc. Exptl. Biol. Med.*, **74**, 411 (1950).

<sup>436</sup> *Saline Phosphate Buffer*, pH 7.4: 0.2 M KH<sub>2</sub>PO<sub>4</sub>, 50 ml.; 0.2 M NaOH, 39.34 ml.; and water up to 200 ml. Mix with equal volume of 0.9 per cent NaCl.

<sup>437</sup> *Dialuric Acid Solution*. 1 mg./ml. saline phosphate buffer solution (equal parts of phosphate buffer and 0.9 per cent NaCl solution). Since dialuric acid is easily oxidized, the solution should be prepared immediately before use.

<sup>438</sup> György, Cogan, and Rose: *Proc. Soc. Exptl. Biol. Med.*, **81**, 536 (1952).

erol. The severity of testicular degeneration as seen histologically is inversely proportional to the dose of tocopherol.

Rabbits fed a vitamin E deficient diet develop muscle dystrophy in about three weeks which is characterized by creatinuria. In the early and reversible stages of the dystrophy the creatine excretion can be reduced temporarily to normal by single doses of vitamin E. The time elapsed from dosing to the return of the creatinuria to its initial high level is proportional to the dose of tocopherol.

## VITAMIN K

In the late 1920's, Dam<sup>439</sup> observed a hemorrhagic syndrome in chicks raised on a diet low in lipides which failed to respond to rich sources of the known vitamins. The disease is associated with a reduction in clotting power of the blood, hemorrhages occurring especially in regions exposed to trauma. In 1935, Dam advanced the claim that this syndrome was due to deficiency of a new fat-soluble vitamin in green leaves, which he called vitamin K (for Koagulations). Almquist and Stokstad<sup>440</sup> independently announced a similar claim for a factor present in putrefied fish meal. In 1939, the pure vitamin was isolated from alfalfa by Dam and others<sup>441</sup> and from both alfalfa and putrefied fish by MacCorquodale, Binkley, McKee, Thayer, and Doisy.<sup>442</sup> Physical and chemical differences in the vitamins thus isolated led to the designation K<sub>1</sub> for the vitamin from green leaves and K<sub>2</sub> for that formed by bacterial putrefaction. Investigation of the vitamin K molecule has revealed the presence of a quinoid ring structure, 2-methyl-1,4-naphthoquinone, which alone or substituted in various ways possesses all or part of the physiological activity of the vitamin; thus vitamin K has various natural and synthetic vitamers.

**Physiological and Clinical Aspects of Vitamin K.** The specific type of hemorrhagic diathesis observed in vitamin K deficiency is due to a lowering of the prothrombin level of the plasma. (For the role of prothrombin in the coagulation of blood, see p. 477.) Hypoprothrombinemia may, however, result from other causes, such as cirrhosis, chloroform poisoning, or Banti's disease, where liver tissue is damaged. Vitamin K is without value in hemophilia, a condition due to a deficiency of thromboplastin and hence a failure of conversion of prothrombin to thrombin. Vitamin K does not alter the clotting time of hypoprothrombinemic blood when added *in vitro*; its function in the body is to facilitate the synthesis of prothrombin in the liver, but it has not been definitely established whether the role of vitamin K is that of a precursor or a catalyst. Prothrombin synthesis occurs in the liver, and a vitamin K "tolerance test" for normal liver function has been proposed. In cases of prothrombin deficiency administration of vitamin K causes the prolonged prothrombin time to return to normal, provided the impairment of liver function has

not reached an advanced state.<sup>443</sup> The prolonged clotting time associated with hypervitaminosis A responds to vitamin K administration.<sup>444</sup>

Chicks, ducklings, and other birds fed a vitamin K-deficient diet develop severe hemorrhagic lesions both internally and subcutaneously, especially under the wings, on the legs, breast, abdomen, and neck, and in the intestinal tract. The concomitant anemia terminates in death. In the rat, bacterial synthesis of vitamin K<sub>2</sub> in the intestine, especially when coprophagy is possible, usually obscures the effect of a vitamin-K-free diet.

Simple dietary deficiency of vitamin K is rare, not merely because of the presence of the vitamin in foods, but because intestinal microorganisms, especially of the *coli* group, synthesize the vitamin, which is released upon putrefactive disintegration of the bacterial cells. K avitaminosis in humans is more often associated with impaired absorption of fat (and concomitantly of vitamin K) such as is seen in obstructive jaundice and biliary fistulas, as well as in intestinal disorders like celiac disease and ulcerative colitis. In these conditions, or after removal of biliary obstructions, vitamin K is administered parenterally or orally to prevent or relieve the bleeding tendency. When the flow of bile is obstructed, oral dosage of vitamin K must be accompanied by bile salts to insure its absorption; this may be avoided by the use of water-soluble derivatives of the vitamin. Vitamin K preparations are also used to treat hemorrhagic emergencies (hypoprothrombinemia) resulting from the use of anti-prothrombinemic drugs in thromboembolic conditions (e.g., coronary artery thrombosis).

The most common form of vitamin K deficiency is seen in newborn infants, so-called *hemorrhagica neonatorum*. The blood prothrombin level is low at birth; it decreases further during the first few days, rises sharply and then gradually until a normal level is reached between one and two months of age. Whether the initial hypoprothrombinemia is due to poor placental transfer has not been established. It is significant that milk, both human and cow, is a very poor source of vitamin K. The rise in prothrombin after birth is attributed to bacterial synthesis in the intestine. Administration of vitamin K to the mother before parturition results in higher blood prothrombin levels at birth. Direct dosage of the infant with as little as one microgram of the vitamin is also effective.

The minimum daily requirement of vitamin K has not been established. The extremely low prophylactic dose for the infant, and subsequent synthesis in the intestine, indicate that the dietary requirement, if any, is small. One to 2 mg. of the vitamin is capable of correcting most deficiencies, although the therapeutic dose may vary with the severity of the hepatic or intestinal condition. For further discussion of clinical aspects, see p. 1293.

**Storage and Distribution of Vitamin K.** With the possible exception of the liver, the organs and tissues of the body do not store vitamin K to any significant degree. In the hen, even when the ration is rich in this

<sup>443</sup> Unger, Weiner, and Shapiro: *Am. J. Clin. Pathol.*, **18**, 835 (1948).

<sup>444</sup> Walker, Eyleburg, and Moore: *Biochem. J.*, **41**, 575 (1947); Quick and Stefanini: *J. Biol. Chem.*, **175**, 945 (1948).

vitamin, only small concentrations are found in the various organs. Vitamin K is not found in the urine; the high concentration in the feces is due largely to intestinal synthesis.

**Occurrence of Vitamin K.** The principal natural source of vitamin K is the green leaf or other chlorophyll-containing portions of plants; this form of the vitamin ( $K_1$ ) has therefore been named *phylloquinone*. The vitamin is present in high concentration in spinach and alfalfa, while cabbage, cauliflower, seaweed, and carrot tops are good sources. Most seeds, fruits, and roots (including cereals, beans, potatoes, peas) contain little if any vitamin K, although soybean oil, tomatoes, orange peel, and hemp seed are good sources. Milk and eggs are poor sources of vitamin K even when the ration of the cow or hen contains a high level of the vitamin.

**Chemistry of Vitamin K.** Recognition of the quinoid structure of vitamins  $K_1$  and  $K_2$  was due to the work of McKee, *et al.*<sup>445</sup> at Washington University, St. Louis, and of Karrer and Geiger.<sup>446</sup> The former group established that these vitamins were derivatives of 2-methyl-1,4-naphthoquinone with substituent groups in the 3 position,  $K_1$  containing the phytyl group and  $K_2$  a similar but longer (difarnesyl) side chain.

Vitamin  $K_1$  ( $C_{31}H_{46}O_2$ )

2-methyl-3-phytyl-1,4-naphthoquinone

Vitamin  $K_2$  ( $C_{41}H_{56}O_2$ )

2-methyl-3-difarnesyl-1,4-naphthoquinone

Vitamin  $K_1$  is a light yellow, viscid oil, whereas  $K_2$  is a yellow crystalline solid (melting point  $54^\circ$ ). Both are soluble in oil and various fat solvents. The vitamins are sensitive to light and, as would be expected from their quinoid structure, are destroyed by saponification. Vitamins  $K_1$  and  $K_2$  are characterized by ultraviolet absorption maxima at wavelengths of 243, 248, 261, 270, and 328  $m\mu$ . The quinoid ring common to these compounds is responsible for their physiological activity. This is shown by the fact that the synthetic compound 2-methyl-1,4-naphthoquinone, to

<sup>445</sup> McKee, Binkley, MacCorquodale, Thayer, and Doisy: *J. Am. Chem. Soc.*, **61**, 1295 (1939).

<sup>446</sup> Karrer and Geiger: *Helv. Chim. Acta*, **22**, 945 (1939).

which the name *menadione* has been given, is equally as active on a molar basis as the natural vitamers. Menadione has a molecular weight of 172,

**Menadione** ( $C_{11}H_8O_2$ )  
**2-methyl-1,4-naphthoquinone**

whereas the molecular weights of  $K_1$  and  $K_2$  are 450 and 580 respectively. Menadione is a yellow, crystalline compound (melting point  $106^\circ$ ), slightly soluble in water and soluble in alcohol, ether, acetone, and glacial acetic acid and in vegetable oils. It is light-sensitive and, in common with other quinones, has a burning taste and is irritating to mucous membranes. The long substituent side chains of the natural vitamins diminish their solubility in water and, at the same time, their taste.

Many active derivatives and homologs of menadione or the natural vitamins have been prepared but always with a diminution or loss of biological potency. Phthiocol (2-methyl-3-hydroxy-1,4-naphthoquinone), a constituent of the tubercle bacillus, was early recognized to have slight vitamin K activity. Substitution of the 2-methyl group by hydrogen or various alkyl radicals results in marked loss of activity. Substitution in the 3 position does not cause a serious drop in potency, although a double bond in the position shown for the phytol group in vitamin  $K_1$  and a long branched side chain are essential in such substituted compounds.

The hydroquinones of vitamins  $K_1$  and  $K_2$  or of menadione may be converted into diacetates, diphosphates, disulfates, etc., which possess lower activity than the corresponding quinones but are less irritating to the mucosa of the mouth and gastrointestinal tract. Nevertheless, certain of these derivatives which, unlike natural vitamin K, are water-soluble and more stable to light and air have been employed clinically. Important among these is menadione sodium bisulfite, a white crystalline powder containing 49 per cent menadione.

## DETERMINATION OF VITAMIN K

Physical or chemical procedures for the estimation of vitamin K activity are complicated by the presence of interfering substances (including vitamins A and E), the different forms in which vitamin K occurs in nature, and their susceptibility to destruction by light, heat, and air, especially during the saponification and extraction steps. The method of Scudi and Buhs<sup>447</sup> involving reduction of the quinones by catalytic hydrogenation, and subsequent reaction of the hydroquinones with 2,6-dichlorophenol indophenol, appears to offer the best approach to the determination of vitamin K in extracts of natural materials including blood and plasma.

<sup>447</sup> Scudi and Buhs: *J. Biol. Chem.*, **141**, 451 (1941); **143**, 665 (1942); **144**, 599 (1942).

The extent of the reaction is measured in a photoelectric colorimeter. The use of hydrosulfite has been recommended to avoid destruction of the vitamin during saponification.

### ASSAY FOR VITAMIN K

**Biological Method of Almquist:**<sup>448</sup> **Principle.** The assay is based on the relative doses of assay material and of standard menadione required to restore the prothrombin clotting time of the blood of vitamin K depleted chicks.

**Procedure.** One- or two-day-old chicks are placed in heated (90° to 95° F.) battery brooders with wire-mesh floors. To prevent consumption of vitamin K from bacterial synthesis, food and water should be provided through apertures outside the cage, and moist or soiled food should be discarded. The following ration is fed *ad libitum*:

|                                             |       |
|---------------------------------------------|-------|
| Sardine meal (ether extracted).....         | 17.5  |
| Dried brewers' yeast (ether extracted)..... | 7.5   |
| Ground polished rice.....                   | 72.5  |
| Codliver oil.....                           | 1.0   |
| Calcium carbonate.....                      | 0.5   |
| Manganous sulfate.....                      | 0.005 |

After 10 to 14 days, when the clotting time of the blood of 5 per cent of the chicks is 15 minutes or more, divide them into groups of 12. (Determine clotting time as follows: Withdraw a few drops of blood from clean cut of exposed wing vein. Place in small vials and shake in water bath at 38.5° to 39° C. Time from withdrawal of blood to formation of a firm clot.)

Maintain one group on basal ration as negative controls, at least two groups on different dosages of U.S.P. menadione, and at least one on each product to be assayed. Administer doses orally in 0.1 ml. water or ethyl laurate, depending on solubility. Open mouth of chick by applying pressure at the corners so that the dose may be given with a tuberculin syringe (fitted with a blunt-edged needle) well down in the throat. Do not permit access to food or water for one-half hour after dosage. Repeat dosage for four days at 24-hour intervals.

Determine prothrombin clotting time on all chicks 24 hours after administration of last dose, as follows: Place 0.2 ml. of 0.1 M sodium oxalate in short, narrow tubes graduated at 2 ml. Introduce 2 ml. blood from each chick into a tube. (Blood may be obtained by decapitation with scissors and directing flow into tube with fingers.) Shake thoroughly. Pipet 0.1-ml. portions into small flat-bottomed vials (15 × 50 mm.). Add 0.2 ml. of clotting agent<sup>449</sup> and start timing with stopwatch. Place vials in thermostatically controlled water bath at 38.5° to 39° C. so that they are tilted at an angle of 45° in a device to permit moving them to a vertical position once per second. When gelatinous film (clot) covers bottom of vial, stop watch and record

<sup>448</sup> Almquist: *J. Assoc. Off. Agr. Chem.*, **24**, 405 (1941); also *Methods of Analysis of the A.O.A.C.*, 6th ed. Washington, D.C., 1945. See also Almquist: *Biological Symposia*, **12**, 508 (1947).

<sup>449</sup> *Preparation of Clotting Agent.* Maintain 4 or 5 chicks on a practical ration containing at least 5 per cent dried alfalfa. (Avoid contamination of vitamin K deficient ration.) Kill one bird by bleeding. Excise 10 g. of breast muscle and grind with sand and 10 ml. of 0.85 per cent NaCl. Centrifuge and filter through coarse paper. Store in refrigerator no more than a few days. Dilute to 200 ml. with 0.85 per cent NaCl and mix with 200 ml. 0.025 M CaCl<sub>2</sub>. This clotting agent should clot blood of normal chicks in 20 to 30 seconds. If it does not, modify concentration until prothrombin time falls within this range.

**“prothrombin time.” Duplicate test on each blood sample until results agree within 2 seconds.**

CALCULATION. Plot the mean prothrombin time (M.P.T.) against log micrograms of menadione for reference groups and draw best-fitting straight line. Interpolate equivalent dosage of assay material. (1  $\mu$ g. menadione = 1 A.O.A.C. unit of vitamin K activity.)

## THE PHYSIOLOGICAL AVAILABILITY OF THE VITAMINS

The vitamin content of a food, or of the diet as a whole, as determined by chemical or microbiological assay, does not always constitute a reliable indication of the actual amount of utilizable vitamin consumed. Failure of foods to be completely digested and absorbed from the intestinal tract, *in vivo* destruction due to oxidation or incompatibilities among the dietary constituents, abnormal pH conditions due to gastric hypoacidity or the use of antacids—these are among the many factors which influence the physiological availability of the vitamins. Vitamins often exist in nature in firm union with protein or other compounds, necessitating hydrolysis prior to chemical or microbiological assay to a degree not duplicated in the gastrointestinal tract. Animal assays are a better measure of physiologically available vitamins, although they do not always simulate conditions in man. For example, assay materials sometimes have to be subdivided or dissolved in order to feed the small doses required by animals; moreover, purified basal rations deviate considerably from the diet of man.

These factors emphasize the desirability of a human assay technique for determining physiologically available vitamins in foods and other sources and for determining the effect of various conditions which influence their availability. A highly reproducible procedure developed by Melnick, Hochberg, and Oser,<sup>450</sup> is based on the fact that normal human subjects subsisting on a complete diet excrete the water-soluble vitamins in the urine in direct proportion to the quantity consumed above the adequate basal level. These vitamins may be excreted either unchanged or as derivatives. The linear relationship of excretion to dosage is established for a group of experimental subjects by feeding the vitamins in pure solution, the form in which they are most completely available. Fig. 292 illustrates a series of such urinary excretion studies for thiamine, riboflavin, niacinamide, and ascorbic acid. To determine the physiologically available vitamin content of an unknown material, the experiment is repeated, feeding an amount of the test food furnishing (according to chemical or microbiological analysis) a critical dose of the vitamin in question. The relation between the extra urinary excretion of the vitamin in the test dose and in the pure solution constitutes the index of physiological availability. For example, if under the test conditions three-quarters as much extra thiamine (i.e., above the basal excretion level) is found in the 24-hour urine following the ingestion of a given food as was excreted following the ingestion of an equivalent amount of thiamine in the form of the pure solution, the physiological availability of the thiamine in the test food is said to be 75 per cent.

<sup>450</sup> Melnick, Hochberg, and Oser: *J. Nutrition*, **30**, 67 (1945).

The illustrations of the application of this technique which follow are taken from the work of Melnick, Hochberg, and Oser.<sup>450</sup> The method may be applied only to those vitamins normally excreted via the urinary tract, which of course excludes the fat-soluble vitamins.

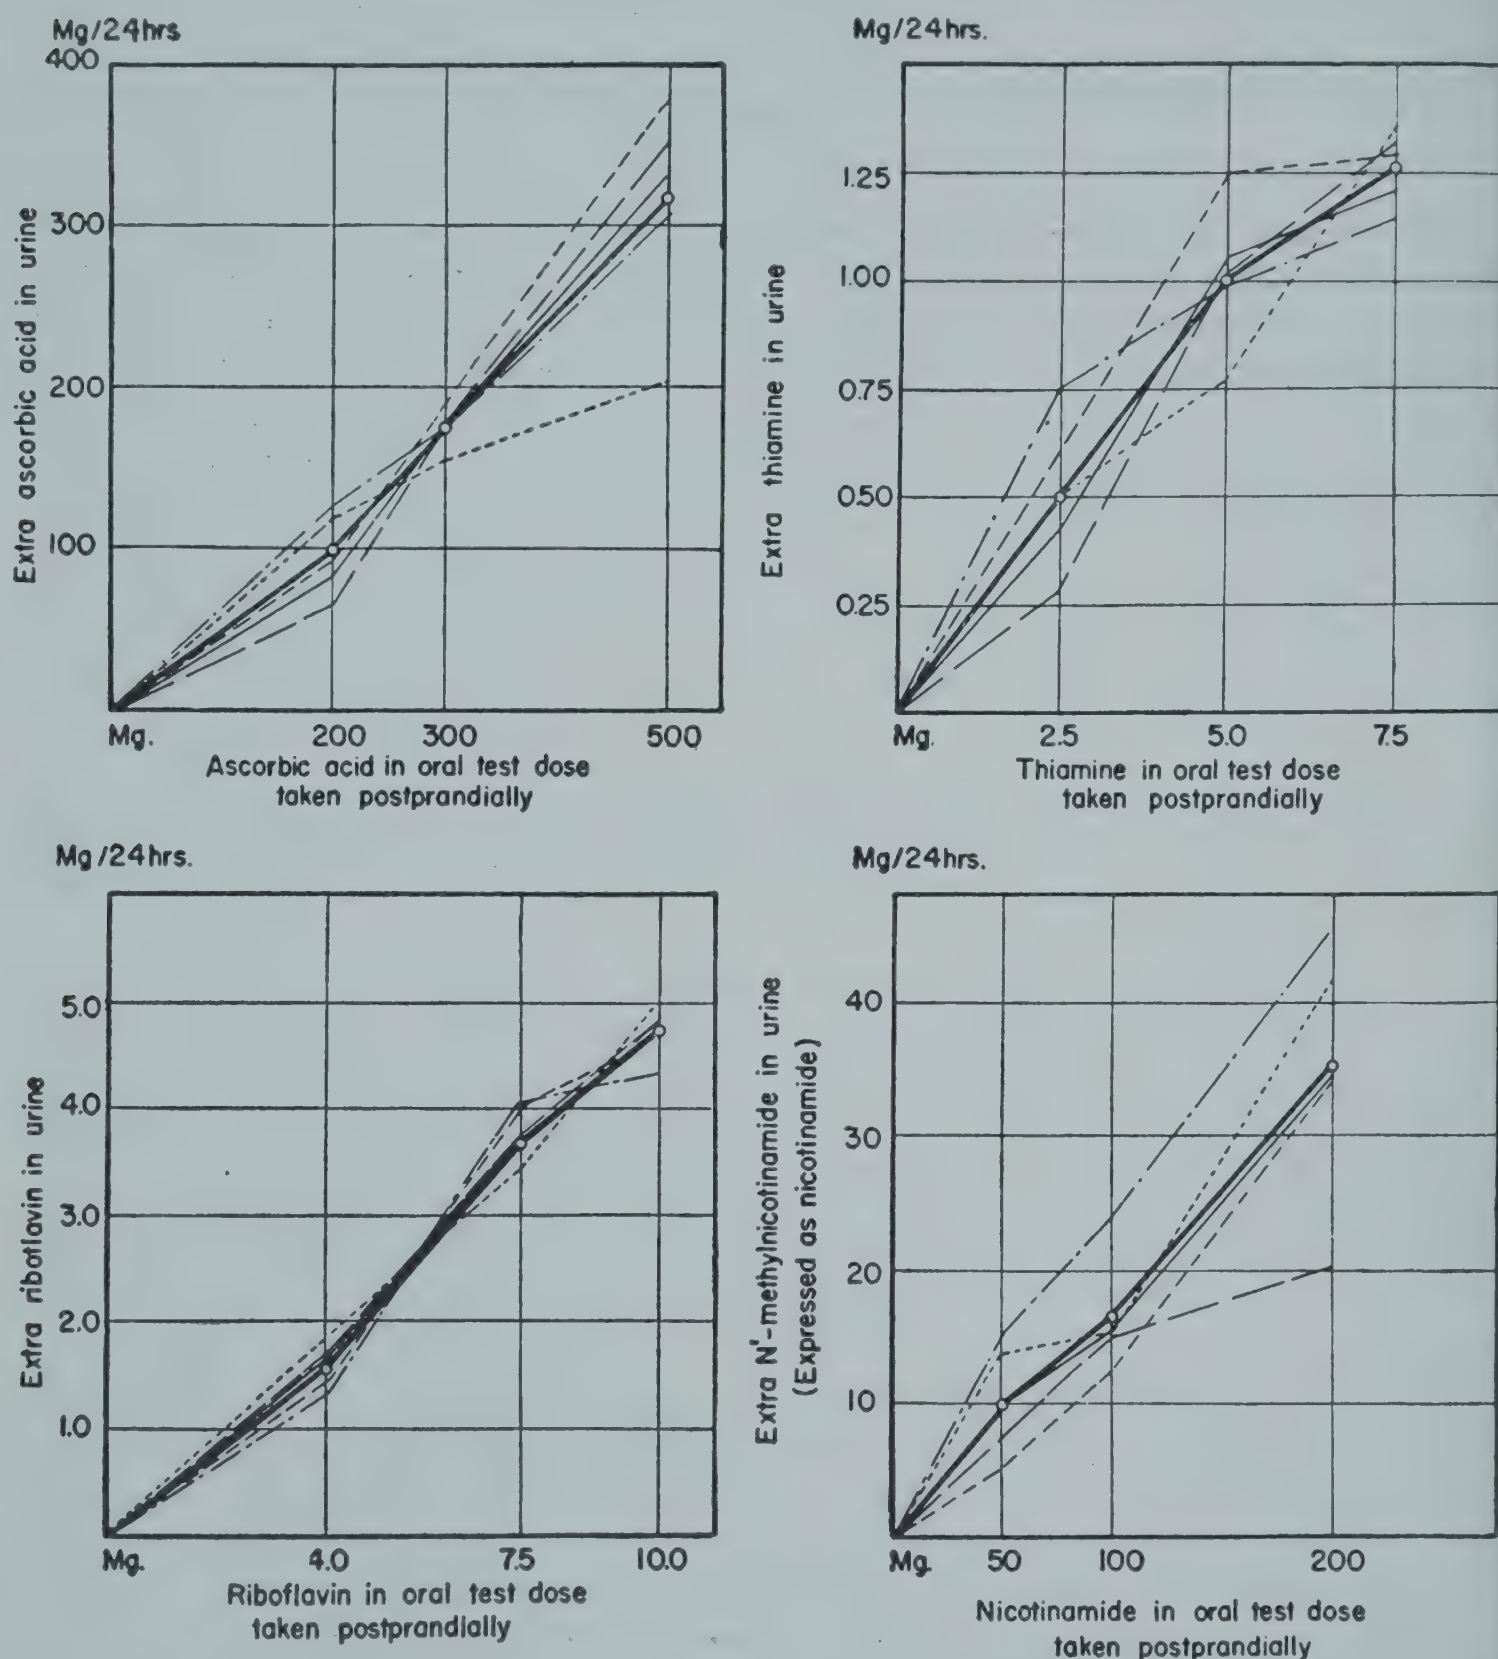

FIG. 292. THE LINEAR RELATIONSHIP BETWEEN DOSAGE WITH THE WATER-SOLUBLE VITAMINS ASCORBIC ACID, THIAMINE, RIBOFLAVIN, AND NICOTINAMIDE, AND THE EXTRA URINARY EXCRETION OF THE VITAMINS (OR DERIVATIVE).

The test doses in aqueous solution (pH 3.0) were taken orally immediately after dinner. The fine lines represent the responses of the individual subjects, whereas the heavy line indicates the average responses.

Any suitable method may be employed for the analysis of the urine for the vitamin and its metabolites. It is worth noting that thiamine is excreted in the urine as the free, unphosphorylated vitamin; ascorbic acid is largely, but not entirely, in the reduced state, so that reduction of the dehydro form is necessary; nicotinic acid is excreted principally as the metabolite N<sup>1</sup>-methylnicotinamide, and vitamin B<sub>6</sub> chiefly as pyridoxic acid.

Determinations of the physiological availability of the vitamins employing this procedure have been reported for pharmaceutical tablets in which the vitamin ingredients are protectively coated to insure their stability; for the thiamine in live yeast cells; for ascorbic acid as influenced by the presence of copper or ascorbic acid oxidase; for thiamine as influenced by the presence of the antithiamine factor in raw fish such as clams; and for the B vitamins in the presence of adsorbing agents.

**Determination of the Physiological Availability of Thiamine in Live Yeast Cakes: Principle.** Unless yeast cells are destroyed by autolysis or heat, they yield only a small proportion of their thiamine content in the human gastrointestinal tract. Subjects in whom nutritional equilibrium has been established each receive, on a control day, 6 mg. of thiamine in pure solution and in divided doses after each meal. After an intervening period has elapsed, the same subjects receive 6 mg. of thiamine (determined by chemical analysis) in the form of live yeast cakes, similarly divided, after meals. The ratio of extra thiamine excretion in the test and control days is the measure of physiological availability of thiamine in the yeast product.

<sup>451</sup> Expressed in terms of total food consumed in the three meals.

**Procedure.** A group of five subjects in good nutritional status, but not unduly saturated with respect to thiamine, is assigned for four days to a complete diet (as illustrated in the table above). The dietary schedule is as follows: a basal day followed immediately by a control (standard dose) day; then, after an interval of one to two weeks another basal day followed immediately by a test (assay dose) day. Just before the largest (noonday) meal of each basal day, the urine is voided and discarded. The urine collection is then begun (in a 2-liter brown glass bottle containing 20 ml. 10 per cent sulfuric acid as a preservative) this marking the beginning of the control (or test) period. On the control day, 2 mg. thiamine, dissolved in water or milk, is taken after each meal. The 24-hour urine is collected as described above. At least one week (preferably two) should elapse to provide for complete flushing of this control dose, during which no remaining collections are made and the subjects are free to eat adequate diets of their own selection.<sup>452</sup> The basal diet is then resumed and the urine collected for a 24-hour period. On the succeeding (test) day the same diet is consumed, but in place of the thiamine supplement of the control period each meal is supplemented with a suspension of yeast cake in milk or water furnishing the equivalent of 2 mg. of thiamine. (It is necessary, of course, to establish the thiamine content of the yeast under test by actual analysis rather than to assume the quantity stated to be present on the label.)

Analyses of the 24-hour urine collections made on the basal, control, and test days are performed according to the colorimetric method described on p. 1144.

**CALCULATION.** From the thiamine excretion of both the control and test days, subtract that of the preceding basal days. If the absolute increment of thiamine intake is not identical on the control and test days, express the increment in thiamine excretion as percentages of the respective supplementary doses. The extra excretion of thiamine following yeast dosage divided by that following dosage in the form of pure solution, multiplied by 100, gives the percentage physiological availability of the thiamine contained in the yeast.

The experiment may be so extended that each test period is allowed to run for 48 instead of 24 hours. In experiments reported by the authors of this method,<sup>453</sup> this was done in order to eliminate the possibility of a delayed rate of absorption of thiamine from live yeast cells as compared with pure solutions. That this does not occur is illustrated by the data in the table on p. 1285.

**Effect of Dietary Thiaminase in Fish Products.**<sup>454</sup> Chastek paralysis, an acute dietary disease of foxes, is caused by including 10 per cent or more of certain species of uncooked fish in the diet and may be cured or prevented by giving adequate amounts of thiamine.<sup>455</sup> Thiamine deficiency has been observed in cats fed a diet consisting exclusively of salt-water herring.<sup>456</sup> The enzymic nature of the antithiamine factor was suggested by the fact that concentrates possessed protein characteristics and reacted like a typical enzyme toward inhibitor substances.<sup>457</sup> The over-all reaction has been demonstrated to be the hydrolytic cleavage of the vitamin between the pyrimidine and thiazole rings.<sup>458</sup>

The antithiamine factor has been found in 15 out of 31 species of fresh-water fish

---

<sup>452</sup> Pork meats and pharmaceutical vitamin preparations especially should be avoided.

| E.M.    | 0.20            | 1.67                                                  | 0.64        | 0.28            | 0.37                                    | 0.29        |
| J.C.    | 0.26            | 1.78                                                  | 0.57        | 0.23            | 0.70                                    | 0.40        |
| H.H.    | 0.17            | 1.48                                                  | 0.45        | 0.21            | 0.30                                    | 0.22        |
| Average | 0.21            | 1.63                                                  | 0.56        | 0.24            | 0.47                                    | 0.31        |

$$\frac{0.47 - 0.24}{1.63 - 0.21} \times 100 = 16.2 \text{ per cent availability}$$
  
(as measured by first 24 hrs.' excretion).

$$\frac{(0.47 + 0.31) - 2(0.24)}{(1.63 + 0.56) - 2(0.21)} \times 100 = 17.0 \text{ per cent availability}$$
  
(as measured by 48 hrs.' excretion).

tested,<sup>461</sup> in clams,<sup>462</sup> in the Atlantic herring, in whiting, and in the Pacific mackerel; oysters are among the fish not containing this factor. In many parts of the world, fish are eaten raw or only slightly heated (e.g., smoked). The following experiment demonstrates the effect of the thiaminase in raw clams in subjects receiving thiamine as a dietary supplement, and the inhibition of this effect by heat-inactivation of the destructive enzyme. This experiment may be performed with certain other edible raw or lightly smoked fish.

**Procedure.** Whip 100 g. raw clams in 400 ml. water in a Waring Blendor. Adjust 100 ml. of this suspension to pH 4.5, and boil under reflux for 20 minutes. Cool and readjust to original pH. Prepare an aqueous thiamine solution containing 250 μg. per ml. Set up three 100-ml. centrifuge tubes as follows: (1) 50 ml. water plus 1 ml. thiamine solution, (2) 50 ml. unheated clam suspension plus 1 ml. thiamine solution, (3) 50 ml. heated clam suspension plus 1 ml. thiamine solution.

Store the suspensions for 6 hours at 37° C. with frequent agitation. Centrifuge. To 10 ml. of the clear supernatants, add 10 ml. of phenol-alcohol reagent and complete the colorimetric test for thiamine described on p. 1145.

For the *in vivo* availability study, choose five normal subjects with good dietary histories. Feed the basal diet shown on p. 1283, starting at noon, and collect 24-hour urine samples in 2-liter bottles containing 20 ml. 10 per cent

<sup>459</sup> Taken as three 1.92-mg. doses of thiamine in milk, one after each meal.  
<sup>460</sup> Containing 5.75 mg. of thiamine. Two cakes, containing 1.92 mg., suspended in milk and taken after each meal.  
<sup>461</sup> Deutsch and Hasler: *Proc. Soc. Exptl. Biol. Med.*, 53, 63 (1943).  
<sup>462</sup> Woolley: Personal communication (1943).

sulfuric acid. On the second day, just after the midday meal, feed 5 mg. thiamine in 30 ml. aqueous solution and collect the second 24-hour samples.

Before starting the test period, allow two weeks to intervene during which the subjects return to their usual, adequate diets. The test period comprises four days. On the first three, feed the subjects the basal diet, but at the end of each meal, add a fresh, raw clam weighing approximately 35 g. (without the shell) which may be swallowed whole. At the beginning of the fourth day (after the midday meal) the subjects ingest 5 mg. thiamine in 30 ml. water followed by a clam. Continue the experiment till the end of the fourth day, feeding a clam with each meal as before. Collect 24-hour urine samples on all four days.

Analyze the urine samples for thiamine as described on p. 1144. Note the prompt and marked decrease in basal urinary excretion values when clams are ingested. Note also the effect of the clams on the test dose of the vitamin.

## VI. STUDENT EXERCISES

1. *Demonstrations of Vitamins A, B<sub>1</sub>, D, and G.* Divide at least six rats 21 to 28 days old into two groups so that there are twice as many rats in one group as in the other. Keep the rats in individual cages and follow the instructions for their care outlined on p. 1364 ff. Feed *ad lib.* one of the following diets to the larger group (experimental) and to the other group (preventive controls) feed the same diet plus one of the indicated supplements daily (except Sundays).

(a) *Vitamin A Deficient Diet (see p. 1262): Supplements.* One drop U.S.P. codliver oil daily; or one  $\mu\text{g.}$  of  $\beta$ -carotene in 0.1 ml. of cottonseed oil; or 3 drops of butterfat.

Weigh rats semiweekly and note changes in growth, vaginal smears (usually during the fourth week), condition of the eyes, and appearance of the fur. Compare the experimental group with the control group. Allow half of the experimental group to continue on the basal diet until they die, at which time perform autopsies, noting the presence of localized infections in the respiratory tract, tongue abscesses, renal calculi, etc. When growth has definitely ceased on the basal diet, begin to feed the remainder of the experimental group one drop of codliver oil (or other source of vitamin A). Record your observations.

(b) *Thiamine Deficient Diet (see p. 1147): Supplements.* 0.5 g. dried yeast; 3.0 g. whole wheat flour; 5  $\mu\text{g.}$  of crystalline thiamine diluted in 100 mg. confectioners' sugar-cornstarch mixture (1:1).

Weigh rats semiweekly. Beginning with the third week note signs of polyneuritis. Spin the rats by rolling the tail between the hands. Convulsive seizures following this treatment are evidence of polyneuritis. When this is observed for two or three consecutive days, begin to feed half of the experimental group a thiamine-containing supplement. Allow the remainder of the experimental group to continue on the basal diet until death. Plot growth curves and compare with curative and preventive control groups.

(c) *Vitamin D Deficiency (see p. 1261): Supplements.* One drop of U.S.P. codliver oil; or 0.1 g. of irradiated yeast,<sup>463</sup> or one hour's exposure to sunlight (if the weather is sufficiently warm); or 15 minutes' exposure at a distance

---

<sup>463</sup> Irradiated yeast may be prepared by exposing a thin layer ( $\frac{1}{8}$  inch) of dried brewers' yeast at a distance of 18 inches from a quartz mercury vapor or carbon arc lamp for 20 minutes, raking over the surface every 5 minutes.

of 30 inches from a source of ultraviolet radiation. Feed the experimental and preventive control groups either of the rachitogenic diets described on p. 1261.

Record body weights at semiweekly intervals, and after three weeks examine each rat for evidence of rickets. Note posture, gait, paralysis of hind legs, enlargement of knee joint, etc. Sacrifice one rat from each group, perform autopsy (note beading of rib cartilage) and line test of the tibia as described on p. 1265. If possible, take roentgenograms of at least one rat in each group (cf. Fig. 289). After definite, gross signs of rickets are observed in the experimental group (between three and four weeks), add a vitamin D supplement to the diet of half the group for a two-week curative period. Repeat above examinations for rickets. Compare all animals at autopsy. Dissect tibiae free from connective tissue, wrap in marked filter paper, extract for 24 hours with acetone in a Soxhlet extractor, dry in oven, and determine bone ash on "dry fat-free basis."

(d) *Riboflavin Deficient Diet* (see pp. 1163-4): *Supplements*. 3 ml. whole milk; or, 0.2 g. dried brewers' yeast; or, 10  $\mu$ g. crystalline riboflavin.

Weigh rats semiweekly. When growth ceases in the experimental group, continue half of the group on the basal diet and add to the diet of the other half the same supplement fed the preventive control group. Plot growth curves over a total period of six to eight weeks. Note any signs of alopecia or dermatitis.

2. *Demonstration of Vitamin C Deficiency (Scurvy)*. Divide six guinea pigs weighing about 280 to 300 g. into an experimental group of four, and a preventive control group of two. Feed both groups *ad lib.* one of the scorbutogenic diets described on p. 1239, supplementing the diet of the preventive controls daily with one of the following: 1.5 ml. of fresh orange juice; or, a fresh carrot or small potato; or, 0.5 ml. freshly prepared 0.1 per cent ascorbic acid. Liquid supplements should be pipetted directly into the mouth; the ascorbic acid solution may be sweetened with cane sugar.

Weigh guinea pigs semiweekly; beginning with the fourteenth day examine daily for signs of scurvy (see p. 1240) in the experimental group, particularly, sensitive joints, hemorrhagic gums, loose teeth, and characteristic posture. These should become pronounced during the fourth or fifth weeks. However, when definite symptoms are noted and growth has stopped, begin to feed half the experimental group the same antiscorbutic supplement which the preventive controls receive. Terminate the experiment after a six weeks' curative period. Autopsy each guinea pig either at death or at termination, comparing the negative controls with the preventive and curative groups. Examine especially for enlarged joints in ribs (beading) and leg bones, subcutaneous and intramuscular hemorrhages, loose, fragile teeth and soft hemorrhagic gums.

3. *Demonstration of Vitamin E*. Place two male (A and B) and two female (C and D) rats at weaning, on the vitamin E deficient diet described on p. 1274 and two males (E and F) and one female (G) on the same diet supplemented with a daily allotment of 3 drops of nonrancid wheat germ oil. At the age of about three months, mate these rats in the following sequence (removing the supplement-fed rats from the cage for their daily dose of wheat germ oil):

I. Male E with females C and D.

Allow mating to continue until each female shows a typical resorption.

(The first impregnation may result in the birth of a litter.) (See IV.)

**II. Male F with female G.**

Allow mating to continue until two live litters are born and carried through the lactation period.

**III. Males A and B with female G.**

After one month, during which no pregnancy should result, kill male A, weigh the testicles and examine histologically. Compare with normal male E, of the same age.

**IV. Begin feeding male B and female C, 3 drops of wheat germ oil daily at conclusion of previous matings. Mate F with C and D. Only C should produce a live litter while D should show resorption.****V. Male B with female G.**

No live litter should result in spite of the proved fertility of female G. Record your observations and draw conclusions as to the effect of vitamin E deficiency on male and female fertility.

**4. Studies on the Planning of Experimental Diets.** With the aid of the data given in the various tables on pp. 1335 to 1363, and of other available reference books from which the calorific value, nitrogen content, vitamin content, etc., may be obtained, plan experimental diets as described below, using the following dietary constituents: Casein, egg albumin, gelatin, gluten, whole wheat, lean beef heart, dried milk, dried liver, starch, sugar, agar, lard, hydrogenated vegetable oil, butter, butterfat, codliver oil, dried yeast, orange juice, tomato juice, salt mixtures (see pp. 1262, 1374, and 1375) etc.

Plan diets which may be predicted to have the following effects, and hand in a report to your instructor explaining the reasons for your selections. Include in this report the calorific value, the protein content, and any other properties of the diet your instructor may suggest.

1. A diet that will *produce ophthalmia*.
2. A diet that will *promote growth but cause rickets*.
3. A diet that will *cure or prevent rickets*.
4. A diet that will *prevent growth but not cause rickets*.
5. A diet that will *restore growth following Diet 4*.
6. A diet that will *prevent normal reproduction*.
7. A diet that will *cause scurvy*.
8. A diet that will *cure or prevent scurvy*.
9. A diet that will *cause ketonuria*.
10. A diet that will *correct this ketonuria*.
11. A diet that will *cause polyneuritis*.
12. A diet that will *cure polyneuritis*.
13. A diet that will be *conducive to longevity and the birth and rearing of sturdy offspring*.
14. A diet that will *produce a dermatitis in rats*.
15. A diet that will *cure this dermatitis*.
16. A diet that will *cause anemia in rats*.
17. A diet that will *correct this anemia*.

## CLINICAL VITAMIN DEFICIENCIES

### SYLLABUS OF "STIGMAS, SYMPTOMS AND THERAPY" OF THE COUNCIL ON FOODS AND NUTRITION OF THE AMERICAN MEDICAL ASSOCIATION<sup>464</sup>

The stigmas and symptoms associated with deficiency of vitamin A, thiamine, riboflavin, niacin, ascorbic acid, vitamin D and vitamin K are listed in this syllabus together with a statement concerning treatment of each deficiency. Deficiencies of several vitamins, notably biotin, pyridoxine, pantothenic acid, and vitamin E, are not accompanied by stigmas which can be recognized at present.<sup>465</sup> The subject is in a stage of fluidity and development which probably will necessitate early revision or amplification. Particularly is this true of the diagnosis and treatment of deficiency of folic acid. This vitamin has been prepared in isolated form so recently that its consideration here is omitted. Not many of the stigmas listed are diagnostic of a vitamin deficiency in themselves, but the occurrence of several of these stigmas in association is at least presumptive evidence of some nutritional failure. Vitamin deficiencies commonly encountered in clinical practice are multiple. Scrutiny of the dietary history is indicated in cases in which several of the stigmas listed are present. Due attention should be paid to the well known fact that stresses such as pregnancy, exposure or disease may occasion the development of deficiency states when the diet otherwise might be considered adequate.

Treatment for a deficiency involves administration orally or, if need be, parenterally of large enough doses of the vitamin to be of therapeutic value and continuation of this treatment for long enough periods to assure a satisfactory therapeutic trial. However, since the diagnosis is necessarily presumptive in many instances, exclusive dependence on specific therapy is justified only infrequently, and basic to good treatment in all cases is a diet planned to be adequate nutritionally and assurance that the diet is eaten.<sup>466</sup> The diet is important for the education of the patient and as a means of dispensing factors heretofore not isolated which will be contained in the foods of such a diet. Likewise helpful in treatment because of its content of factors not as yet identified is some good source of the vitamin B complex as a whole. Products such as brewers' yeast or an extract of such yeast, wheat germ, extracts of cereal grasses or of rice bran, crude extract of liver or desiccated liver represent such sources. For a patient who cannot take foods or drugs orally or in whom absorption is poor, crude liver extract may be given intramuscularly or even on occasion it may be diluted with sterile isotonic solution of sodium chloride or dextrose and administered by vein.

### Stigmas Suggesting Deficiency of Vitamin A

#### *Xerosis of the conjunctiva:*

Thickening with loss of transparency, so that only the more superficial vessels of the bulbar conjunctiva are clearly seen, associated with more or less yellow pigmentation, especially along the horizontal meridian of the eyeball; infrequently associated with small foamlike plaques called Bitot's spots.

#### *Papular eruptions of pilosebaceous follicles:*

A grater-like feel, which in early stages resembles gooseflesh but, when more fully developed, presents the picture of keratosis pilaris. The extensor surfaces of the arms and thighs and the flexor surfaces of the legs are primarily affected.

#### *Xerosis or asteatosis of the skin:*

Dryness, scaliness and crinkling, in extreme cases resembling alligator skin. In early stages the condition is associated with keratosis pilaris but it persists and extends after follicles have disappeared, the body hairs being broken and later lost. All parts of the body are involved, but the skin of the extremities, particularly of the legs, is more severely affected than the skin of the head and the trunk.

#### *Follicular conjunctivitis:*

Hypertrophy of the follicles, particularly of the lower eyelids.

#### *Night blindness:*

Conspicuous only in cases of advanced, severe deficiency.

#### *Keratomalacia:*

Thickening with subsequent ulceration and necrosis of the cornea: present only in most severe and advanced forms of deficiency.

### Stigmas Suggesting Deficiency of Thiamine

*Loss of strength of the quadriceps:* disproportionate to loss of general strength, evidenced by difficulty in rising from the squatting position.

*Loss of vibration sense:* first of the toes and later of the malleoli and tibias.

*Tenderness of the calves and hyperesthesia of the feet.*

*Diminution and loss of the achilles tendon and patellar reflexes first.* Other tendon reflexes are lost in the later stages of the polyneuritis of "dry beriberi."

*Edema of the shins, ankles and knee joints:* found in "wet beriberi."

### Treatment of Vitamin A Deficiency

#### *Early deficiency state:*

25,000 U.S.P. units of vitamin A twice daily for two months or longer.

#### *More chronic states:*

25,000 U.S.P. units of vitamin A two to three times daily for a prolonged period.

### Treatment of Thiamine Deficiency

#### *Acute deficiency state:*

10 to 20 mg. or more of thiamine twice daily until relief of symptoms; this may be days or weeks.

#### *Chronic deficiency state:*

5 to 10 mg. or more of thiamine twice daily for a prolonged period.

*Enlarged heart with dependent edema* and elevated venous pressure: Poor response to rest and administration of digitalis unless thiamine is given. This is a late manifestation of severe deficiency (beriberi heart).

*Papillary edema with retinal hemorrhages*: associated with ophthalmoplegia and polyneuritis. The condition is a late manifestation of severe deficiency.

### Stigmas Suggesting Deficiency of Riboflavin

#### *Congestion of the limbic plexus:*

Visible with a small hand lens or the +20 lens of the ophthalmoscope; invasion of the cornea by capillaries arising from this plexus (vascularization) requires a biomicroscope and slit lamp for detection.

#### *Cheilosis:*

Represented in chronic deficiency by excessive and irregular wrinkling, in acute deficiency by swelling and erasure of the normal wrinkling of the lips. Reddening, thinning, scaling, chapping of epithelium are associated.

#### *Angular stomatitis:*

Various combinations of erythema and open fissuring in the angles of the mouth with or without a white, moist maceration (perlèche); scars of healed fissures.

#### *Dyssebacia:*

An erythema overlaid with somewhat greasy, flaky accumulations resembling hoar frost, noted mostly in the alae nasi, canthi, pinnae, and other folds of the skin, accompanied in some cases by coarsening and elevation of the sebaceous follicles of the nose and cheeks, the latter also seen with deficiency of vitamin A.

#### *Magenta tongue:*

A purplish red coloring with moderate edema and flattening of filiform papillae; observed in more advanced deficiency.

### Stigmas Suggesting Deficiency of Niacin

#### *Edema of the tongue:*

Shown by dental indentations.

#### *Increased redness of the tongue:*

Beefy red in chronic states; scarlet red in severe acute deficiency.

#### *Congestion and hypertrophy of the papillae of the tongue, followed by fusion and atrophy:*

In early stages the fungiform papillae are congested and hypertrophied. This is followed by

### *Treatment of Riboflavin Deficiency*

#### *Acute deficiency state:*

5 mg. of riboflavin three times daily for weeks.

#### *Chronic deficiency state:*

3 to 5 mg. of riboflavin three times daily for a prolonged period.

### *Treatment of Niacin Deficiency*

#### *Acute deficiency state:*

100 mg. or more of niacinamide twice daily for weeks:

#### *Chronic state:*

100 mg. of niacinamide twice daily over a prolonged period.

hypertrophy of the filiform papillae and later by their flattening. As they atrophy they fuse or mat together with multiple fissuring to give a cobblestone appearance and finally baldness. Vincent's infection of tongue and fauces, ulceration and pseudomembrane formation may or may not accompany these changes in the more advanced stages of this deficiency.

*Dermatitis:*

Erythema, rough scaling, with ulceration and formation of bullae, affecting primarily areas of the skin exposed to light; namely, wrists, ankles, neck, and face; observed only in severe deficiency (pellagra) and then frequently associated with diarrhea and dementia.

*Encephalopathy:*

Clouding of consciousness, cogwheel rigidity, and grasping, sucking reflexes observed in acute, severe deficiency.

### **Stigmas Suggesting Deficiency of Ascorbic Acid**

*Redness, edema, tenderness, and bleeding on pressure of the gums:*

Observed in acute or subacute deficiency of moderate severity, sometimes with, but usually without, other signs of ascorbic acid deficiency.

*Thickening and increased firmness of the gums:*

With recession and exposure of the base of the teeth, including recession of interdental papillae; observed in chronic deficiency.

*Retraction of the gums:*

Leaving pockets between gum and tooth, secondary infection and resulting pyorrhea; observed in chronic deficiency.

*Loosening and shedding of the teeth.*

*Increased capillary fragility:*

Manifested by petechial hemorrhages of the skin, especially in the tourniquet test; observed in more severe acute and subacute deficiency. Easy bruising, spontaneous ecchymosis of the skin, idiopathic hemorrhage into joints and slow healing of wounds, observed in severe acute and subacute deficiency.

### **Stigmas Suggesting Deficiency of Vitamin D**

*Deformities of the skeleton:*

Bowed legs, malformation of the chest (funnel breast) and defects of the teeth may be residues of early rickets which is usually no longer active or susceptible to treatment; enlargement of the wrists, elbows, knees, ankles and costochondral

### **Treatment of Ascorbic Acid Deficiency**

*Acute or subacute deficiency state:*

100 mg. or more of ascorbic acid daily for weeks.

*Chronic deficiency state:*

100 mg. of ascorbic acid three times daily over a prolonged period.

### **Treatment of Vitamin D Deficiency**

*In infants:*

1,500 to 2,500 U.S.P. units of vitamin D daily, continued for several months (double this amount for premature infants).

junctions (beading, rachitic rosary) and bulging forehead (cranial bosses) which respond to treatment are found in infancy and in the rare example of late rickets.

### Stigmas Suggesting Deficiency of Vitamin K

#### *A tendency to bleeding:*

Particularly from minor wounds, related to abnormal lengthening of the prothrombin time, developing spontaneously in newborn infants; observed in adults after treatment with dicoumarol or large doses of salicylates; in advanced disease of the liver with poor excretion of bile, and in disease of the intestine, such as sprue in which vitamin absorption is disturbed.

### *Treatment of Vitamin K Deficiency*

#### *In adults:*

1 mg. of vitamin K two to three times daily with or without bile (1 g. of desiccated bile or bile salts).

#### *In newborn babies:*

1 mg. of synthetic vitamin K intramuscularly daily in oil solution for several days.

### Deficiency Symptoms

A diagnosis of vitamin deficiency only rarely can be based on symptoms or less significant abnormalities than those which have been listed thus far. However, such symptoms and abnormalities frequently accompany the more specific lesions of deficiency.

Symptoms commonly observed with deficiency of thiamine, also less conspicuously in deficiency of other vitamins, include apathy, lethargy, increased emotional irritability, hypersensitivity to noise and painful stimuli, headache, vague fears, confusion of thought, uncertainty of memory, asthenia, loss of manual dexterity, insomnia, heart consciousness, paresthesia, anorexia, nausea, flatulence, epigastric pain, constipation.

Photophobia, burning of the eyes, lacrimation and eyestrain not relieved by glasses are encountered in deficiency of riboflavin.

Other abnormalities unrelated to deficiency of any single vitamin but commonly observed in persons who are malnourished are dry, brittle, lack-luster, rebellious, so-called staring head hair, a loss of sleekness analogous to the rough coat of malnourished animals, blepharitis, spider-like telangiectasis of the face, seborrhea of the face, patchy pigmentation of the face, especially suborbital and circumoral, sinus arrhythmia, bradycardia, tachycardia, low blood pressure, loss of tone of muscles and anemia.

## Metabolic Antagonists and Antibiotics

Few, if any, enzymes or enzyme systems have absolute specificity for a single substrate. For example, the hippuricase of Taka-diastase will not only catalyze the hydrolysis of hippuric acid, but also that of *m*- and *p*-chloro-, bromo-, iodo-, nitro-, and methyl-hippuric acids. The corresponding ortho substituted acids unite with the enzyme, but hydrolysis of the peptide linkage does not occur and the enzyme is rendered inactive.<sup>1</sup> There are many similar instances in which compounds other than the usual substrate will combine with an enzyme, but do not react further. Such blocking compounds are usually structurally similar to the normal substrate. The enzyme so blocked is unable to combine with its usual substrate, and the reaction catalyzed by the enzyme is slowed or stopped according to the proportion of total enzyme molecules thus blocked.

Perhaps the simplest example of inhibition related to structural analogy is found in the case of the enzyme succinic dehydrogenase. This enzyme catalyzes the oxidation of succinic acid to fumaric acid in the presence of a hydrogen acceptor (see p. 318). The action of succinic dehydrogenase on succinic acid is almost completely inhibited by the presence of malonic acid.<sup>2</sup> The relation between these two compounds is evident from a comparison of their structures:

The inhibition by malonic acid is reversible, that is, it may be overcome by the addition of a sufficient amount of succinic acid, in which case the enzyme behaves as though no inhibitor were present. This reversible relation between succinic and malonic acids, together with the obvious fact that these two substances cannot react with each other, implies that both types of molecule are competing for a reactive group on the enzyme molecule itself. This is therefore an example of *competitive inhibition*. Since the rate of formation of a particular enzyme-substrate complex depends upon the frequency of collisions of substrate molecules with the enzyme surface, which in turn depends upon the concentration of substrate, the extent to which malonic acid will inactivate succinic dehy-

<sup>1</sup> Ellis and Walker: *J. Biol. Chem.*, **142**, 291 (1942).

<sup>2</sup> Quastel and Wooldridge: *Biochem. J.*, **21**, 1224 (1927).

drogenase depends upon the *relative* concentrations of succinic and malonic acids. This relationship defines competitive as opposed to non-competitive inhibition. In any competitive inhibition—

where  $E$  is the enzyme involved,  $S$  is its normal substrate,  $I$  is the competitive inhibitor, usually a structural analog, and  $P$  is the product. By the mass-action law, the dissociation constant of the enzyme-substrate complex is  $K_s$

$$K_s = \frac{[E][S]}{[ES]}$$

and the dissociation constant of the enzyme-inhibitor complex is  $K_i$ .

$$K_i = \frac{[E][I]}{[EI]}$$

Dividing  $K_i$  by  $K_s$ , we can get an inhibition constant,  $K$ .

$$K = \frac{[I][ES]}{[S][EI]}$$

At 50 per cent inhibition

$$[ES] = [EI]$$

and

$$K = \frac{[I]}{[S]}$$

Thus, the effectiveness of a competitive inhibitor depends upon the *ratio* of concentrations of inhibitor and normal substrate, and not upon their absolute amounts. The relationship of competition applies to a number of well-known enzyme inhibitions, including the inhibition of saccharase by fructose, and of xanthine oxidase by adenine.

In considering enzymes which have several substrates (e.g. amine oxidase) it is not always possible to make a sharp distinction between substrates and competitive inhibitors. One substrate may be considered to be competing with the other substrates.

Another example of what is believed by many to be an instance of competitive inhibition is found in the action of the sulfonamides on bacteria. In studying the action of sulfanilamide on certain bacteria, Woods<sup>3</sup> found that the growth-inhibiting effect of this compound could be reversed by a substance present in yeast extracts. This substance was believed to be structurally similar to sulfanilamide, so a number of structural analogs were tested for their antisulfanilamide activity. Of these, *p*-aminobenzoic acid (PABA) proved to be remarkably effective; the struc-

<sup>3</sup> Woods: *Brit. J. Exptl. Path.*, **21**, 74 (1940).

tural similarity of this compound to sulfanilamide is evident from a comparison of their structures:

On the basis of his results, Woods suggested that *p*-aminobenzoic acid should prove to be an essential growth factor for bacteria, and this was later shown to be the case.

Lampen and Jones<sup>4</sup> related the need of certain organisms for *p*-aminobenzoic acid to its utilization in the formation of folic acid (see p. 1195). Sulfonamides competitively inhibit enzymatic reactions whereby *p*-aminobenzoic acid is built into the folic acid molecule. Most organisms, probably all organisms, require folic acid. Organisms that require their folic acid ready-made are not hampered by sulfonamides, which interfere with folic acid formation; but growth of such organisms is inhibited by certain structural analogs of folic acid itself, such as aminopterin.<sup>5</sup> Those organisms which require *p*-aminobenzoic acid for the synthesis of folic acid within the organism are subject to sulfonamide inhibition, which can be released competitively by *p*-aminobenzoic acid or non-competitively by folic acid. If enough folic acid is present to meet the growth requirement, no inhibition of growth of *Streptococcus faecalis* will be brought about by sulfonamides. Still other organisms exist, including many common pathogens, which are sensitive to sulfonamides, but are not released from growth inhibition by folic acid. In such instances the essential substance synthesized from *p*-aminobenzoic acid may be a derivative of folic acid (such as the citrovorum factor, p. 1201), and folic acid itself may not be an intermediate in the formation of the essential substance. Alternatively, in some organisms *p*-aminobenzoic acid may have important functions other than folic acid synthesis. Each microbial species must be evaluated for its requirement of folic acid and related substances. As an example of a notable difference, *Streptococcus faecalis* requires folic acid and synthesizes it from *p*-aminobenzoic acid, whereas *Lactobacillus arabinosus* breaks down added folic acid and utilizes the components.<sup>6</sup>

Fluoroacetate<sup>7</sup> is a metabolic analog of acetate. Like acetate, fluoroacetate can form an active 2-carbon fragment which proceeds to form a fluorotricarboxylic acid. This product appears to be the actual anti-

<sup>4</sup> Lampen and Jones: *J. Biol. Chem.*, **166**, 435 (1946).

<sup>5</sup> Aminopterin (4-aminopteroylglutamic acid) is the structural analog most antagonistic to folic acid and diminishes the utilization of formate in purine and pyrimidine synthesis. Aminopterin and other folic acid antagonists have been used in the treatment of leukemia. For a full discussion of folic acid antagonists, see Petering: *Physiol. Revs.*, **32**, 197 (1952).

<sup>6</sup> Koft, Sevag, and Steers: *J. Biol. Chem.*, **185**, 9 (1950).

<sup>7</sup> Peters: *Brit. Med. J.*, Nov. 29, 1952, 1165. Do not confuse fluoroacetate with iodoacetate which is not an antimetabolite. Iodoacetate is a nonspecific inactivator of sulfhydryl groups, the integrity of which is necessary for the action of numerous enzymes.

metabolite, which blocks the normal conversion of the acids of the citric series into  $\alpha$ -ketoglutaric acid. The result is accumulation of citrate.

There is another type of inhibition of biological systems and its reversal which has not always been recognized as being somewhat different from the type described here. This is the condition in which an inhibition of enzymatic or cellular activity by one substance is reversed—i.e., the activity is restored—by the addition of a second substance which is capable of reacting directly with the inhibitor. For example, many compounds are known which react with the sulfhydryl group ( $-\text{SH}$ ). Certain of these compounds will inactivate biological systems, and the activity may be regenerated by adding an excess of a second substance which contains sulfhydryl groups, such as cysteine or mercaptoacetic acid. It is to be noted, however, that the substance which overcomes the inhibition is not necessarily a constituent of the biological system being acted upon by the inhibitor, and the reversal of inhibition is essentially one of neutralizing the activity of the inhibitor by reacting directly with it. While this type of study may suggest the kind of compounds or active groups which function in biological systems, it is clearly different from metabolic antagonism as described here.

In the following pages examples are given of what appears to be metabolic antagonism between structurally related compounds. It must be recognized that in practically all instances the precise mode of action of even the normal metabolite is relatively unknown; the action of the antagonist, therefore, can only be a subject for speculation. There is, nevertheless, a fundamental similarity in action among all of the substances to be described, in that their inclusion in a normally functioning biological system leads to signs of a deficiency which resembles that produced by a lack of the normal metabolite concerned, and which can be overcome by the presence of sufficient amount of the latter. The substances to be discussed include structural analogs of the naturally occurring amino acids, vitamins, and hormones.

### ANALOGS OF AMINO ACIDS

**Methionine and Ethionine.** In 1938 Dyer<sup>8</sup> reported that the S-ethyl analog of methionine, called ethionine, appeared to be toxic to rats on a low-cystine, low-methionine diet, whereas in the presence of sufficient methionine loss of weight and death did not occur.

<sup>8</sup> Dyer: *J. Biol. Chem.*, **124**, 519 (1938).

Subsequent work has shown that ethionine blocks several vital functions of methionine: (a) transmethylation, (b) incorporation of methionine and other amino acids into protein, (c) formation of cystine, and (d) lipotropic action. The antibacterial action of sulfonamides is partially antagonized by methionine, but is augmented by ethionine. The sulfonamides compete with *p*-aminobenzoic acid in its function as part of a coenzyme related to the methylation of homocysteine.

The experimental results of Dyer represent probably the first authentic demonstration of metabolic antagonism involving amino acids, in terms of the concept as it has been presented in the preceding pages.

Another example of an antimetabolite to methionine is found in the compound known as methionine sulfoximine:

**Methionine sulfoximine**

This substance was first isolated from the hydrolyzate of the protein of wheat flour which had been oxidized (matured) by means of nitrogen trichloride (Agene). Such flour is toxic to dogs, producing the disease known as canine hysteria or running fits. The toxic principle was isolated with the aid of chromatographic techniques and was proved to be a derivative of the amino acid methionine, produced by the action of the nitrogen trichloride on the methionine of the wheat-flour protein. The compound has been synthesized and given the name methionine sulfoximine because of its structure. The compound shows a high degree of species specificity, being much more toxic to dogs than to other laboratory animals, but investigations have revealed no evidence of any effect of the treated flour on human beings. However, nitrogen trichloride is no longer permitted in the United States for maturing flour.

The toxic effect of methionine sulfoximine on dogs can be readily overcome by the addition of methionine to the diet. The growth of certain microorganisms can be inhibited by low concentrations of methionine sulfoximine, and this effect is reversed by methionine, glutamine, and to some extent by methionine sulfoxide (but not by methionine sulfone or glutamic acid). Thus methionine sulfoximine appears to be a true anti-metabolite but the mechanism of this action is still obscure.

**Phenylalanine and Thienylalanine.** The synthetic compound  $\beta$ -2-thienylalanine is similar in structure to the amino acid phenylalanine except that a  $-\text{CH}=\text{CH}-$  group in the benzene ring of phenylalanine is replaced by  $-\text{S}-$  in thienylalanine:

**Phenylalanine** **$\beta$ -2-Thienylalanine**

The growth of certain yeasts and bacteria is inhibited by thienylalanine and the inhibition is overcome by phenylalanine. The growth inhibition of *E. coli* caused by 100 parts of thienylalanine was 50 per cent nullified by 5 parts of phenylalanine, but tryptophan was almost as effective as phenylalanine. Inhibition of yeast growth by thienylalanine was overcome by certain other amino acids in 10 to 30 times the concentration of phenylalanine required. The tubercle bacillus, which is resistant to most growth inhibitors, is susceptible to thienylalanine, as is vaccinia virus, although in the latter case action on the host cell can not be ruled out. Studies with  $\beta$ -3-thienylalanine have indicated that it is a somewhat more effective phenylalanine antagonist than its  $\beta$ -2 isomer, whereas  $\beta$ -2-furylalanine is less effective. Inhibition of weight gain in young or protein-depleted rats can be produced by phenylalanine antagonists, and reversed by phenylalanine but not by tyrosine. Halogenated phenylalanines and phenylserine have been shown to be competitive antagonists to phenylalanine in several microbial species. A very important non-competitive antagonist to phenylalanine is chloramphenicol, one of the broad-spectrum antibiotics (see p. 1317).

The enzymes which catalyze the oxidation of phenylalanine to tyrosine, and through further steps to melanin, may be blocked by certain analogs. Thienylalanine will block the first step in *E. coli*; the oxidation of tyrosine by bacterial and mammalian tyrosinases is blocked by *N*-acetyl-, *N*-formyl-, or 3-fluorotyrosine. Epinephrine and norepinephrine are inactivated in the body by several enzymatic mechanisms. One of these, amine oxidase, is competitively blocked by *ephedrine*, *amphetamine*, and other related compounds. This blockage of epinephrine inactivation is not a complete explanation of the pharmacological actions of these sympathicomimetic drugs.

**Epinephrine****Ephedrine****Amphetamine**

Isonicotinic acid hydrazide is inhibitory to amine oxidase, and 1-isonicotinyl-2-isopropylhydrazine is about 10 times as effective.

These two compounds, like other basic antitubercular drugs and antibiotics, inhibit the diamine oxidase of mycobacteria.<sup>9</sup> Against mammalian diamine oxidase, the antibiotics streptomycin and neomycin have little effect, but the two hydrazides inhibit both the bacterial and the mammalian enzyme.

**Other Amino Acids.** The amino acid L-canavanine, which occurs in jack beans, is a competitive antagonist to arginine and inhibits growth of *E. coli*, of certain strains of *Neurospora*, and of lactic acid bacteria. Arginase, however, will split urea from canavanine. Citrulline and ornithine will release organisms capable of utilizing these substances from canavanine inhibition.

One general method of modifying amino acids consists in replacing the carboxyl group by the sulfonic acid group, as in the case of sulfanilamide and *p*-aminobenzoic acid (p. 1299). These aminosulfonic acids prove to be growth-inhibitory to microorganisms but the inhibition is apparently nonspecific, since it may be reversed by aminocarboxylic acids not structurally related to the inhibiting compound. McIlwain<sup>10</sup> interprets this as indicating that structural analogy alone is not the sole consideration in

<sup>9</sup> Owen, Karlson, and Zeller: *J. Bact.*, **62**, 53 (1951).

<sup>10</sup> McIlwain: *Brit. J. Exptl. Path.*, **22**, 148 (1941).

explaining the action of metabolic antagonists. Indoleacrylic acid, the deaminated  $\alpha$ ,  $\beta$  unsaturated analog of tryptophan, has been reported to inhibit the growth of *E. coli*, and this inhibition is overcome by tryptophan, but apparently not competitively.

The D and L forms of an amino acid would appear to be competitive analogs in those instances where only one of the two forms is metabolized by an organism. While there are numerous instances demonstrating the lack of availability of one of the two enantiomorphs of an amino acid for growth, there are relatively few examples where competitive inhibition has been demonstrated.

There are numerous instances in which naturally occurring amino acids compete with each other; for example, arginine competes with lysine in a mutant strain of *Neurospora*. This and other examples have been tabulated by Martin. The possibility that competition between naturally occurring substances plays a part in regulating metabolic processes can not be overlooked. Martin postulates, as the "relativity theory" of the biological world, that natural metabolite antagonisms are fundamental to life by virtue of stabilizing relative concentrations of available nutrilites. In pharmacology and therapeutics, numerous applications are made of the theory of metabolite antagonism. In relatively few instances can competitive relationship be demonstrated; more often, the action is noncompetitive or irreversible.

## ANALOGS OF VITAMINS

**Thiamine and Pyrithiamine.** Pyrithiamine is the pyridine analog of thiamine, obtained by replacing the —S— group in the thiazole ring of thiamine by —CH=CH—; the structural relationship is thus similar to that between thienylalanine and phenylalanine.

Pyrithiamine was found by Robbins<sup>11</sup> to be inhibitory to the growth of certain microorganisms which required an exogenous supply of thiamine for growth, and Woolley and White<sup>12</sup> showed that the feeding of pyrithiamine to mice produced a severe deficiency which resembled that of thiamine deficiency and which could be overcome by the administration of thiamine; one molecule of thiamine was required for approximately 40 molecules of pyrithiamine. This is one of the earliest instances of a deficiency disease produced in animals by the administration of a structural analog of a vitamin.

<sup>11</sup> Robbins: *Proc. Nat. Acad. Sci.*, **27**, 419 (1941).

<sup>12</sup> Woolley and White: *J. Biol. Chem.*, **149**, 285 (1943).

Studies on the inhibition of growth of microorganisms by pyrithiamine have revealed that the substance is inhibitory only in those instances where the organism requires an external supply of thiamine. If the organism is capable of synthesizing thiamine from the constituents of the medium, pyrithiamine is not inhibitory to growth. This emphasizes the point already made that structural analogy per se is not necessarily the sole factor in determining whether competitive inhibition will occur, particularly in the complex metabolic processes of living protoplasm. One interesting example has been presented of a strain of yeast which became resistant to the inhibitory effect of pyrithiamine apparently by the development of a system which permitted liberation of the pyrimidine portion of the molecule and its subsequent utilization in the synthesis of thiamine itself.<sup>13</sup>

Certain other structural analogs of thiamine have likewise been shown to be antagonistic to thiamine; for example, oxythiamine, in which the  $\text{NH}_2$  of thiamine is replaced by  $\text{OH}$ . The thiamine molecule is particularly susceptible to such chemical modification, consisting as it does of two reactive portions, the pyrimidine moiety and the thiazole portion.

**Pantothenic Acid and Pantoyltaurine.** The replacement of the carboxyl group of pantothenic acid by the sulfonic acid group<sup>14</sup> produces a substance known as pantoyltaurine (or thiopanic acid):

**Pantoyltaurine**

This substance and related compounds, e.g. the amide, have been shown to be antagonistic to pantothenic acid for a variety of microorganisms; growth inhibition caused by pantoyltaurine can be overcome in most instances by pantothenic acid, and the inhibition appears to be truly competitive in nature. As with thiamine and pyrithiamine, pantoyltaurine is not inhibitory to the growth of those microorganisms which can synthesize the pantothenic acid they need.

Pantoyltaurine has not as yet been shown to produce unequivocal signs of a pantothenic acid deficiency in animals, probably because of the relatively large amounts which would be required to compete successfully with the pantothenic acid present in animal tissues. Some success has been obtained in the use of pantoyltaurine as a chemotherapeutic agent in rats infected with an organism susceptible to inhibition by pantoyltaurine, but here again the doses required were so large as to indicate little practical application of this fact. The possibility remains open, however, that further studies along these lines may produce more effective substances. As with thiamine, the presence of two chemically distinct portions in the pantothenic acid molecule has permitted the synthesis of a

<sup>13</sup> Woolley: *Proc. Soc. Exptl. Biol. Med.*, **55**, 179 (1944).

<sup>14</sup> Snell: *J. Biol. Chem.*, **139**, 975 (1944).

variety of structural analogs other than pantooyltaurine, and certain of these appear to be effective in inhibiting the growth of microorganisms in a manner similar to that described for pantooyltaurine.

**Riboflavin and Analogs.** Various structural analogs of riboflavin have been synthesized which appear to be metabolic antagonists of the naturally occurring vitamin. One of these is isoriboflavin, in which the two methyl groups are in the 5,6 positions instead of in the 6,7 positions as in the naturally occurring vitamin:

5,6-Dimethyl-9-(D-1'-ribityl)-isoalloxazine  
(Isoriboflavin)

The onset of the symptoms of riboflavin deficiency can be hastened in rats already on a suboptimal diet by the feeding of isoriboflavin, but this substance does not function as a riboflavin antagonist in any bacterial species so far studied. Antagonists similarly effective in animal experiments have been prepared by substituting sugars other than ribose in the 9-position. Effective both in animals and bacteria is 2,4-diamino-7,8-dimethyl-10-ribityl-5,10-dihydrophenazine:

Large doses of isoriboflavin or D-galactoflavin render mice refractory to implants of lymphosarcoma.

**Pyridoxine and Analogs.** Deoxypyridoxine produces acrodynia in the mouse and has produced glossitis, cheilosis, and seborrhea in human

subjects, corrected promptly by pyridoxine. Methoxypyridoxine is an effective antagonist to pyridoxine in chicks but is much less active in rats and is inactive in the mouse, which can form pyridoxine from methoxypyridoxine. A number of other analogs are antagonistic to pyridoxine when tested with yeast.

Deoxypyridoxine

Methoxypyridoxine

**Nicotinic Acid and Analogs.** Analogs of nicotinic acid which appear to act as competitive antagonists of the latter have been obtained by replacing the carboxyl group of nicotinic acid with either the sulfonic acid group or the acetyl group:

Nicotinic acid

Pyridine-3-sulfonic acid

3-Acetylpyridine

The analogous amides have also been studied. The sulfonic acid analog produces inhibition of growth of certain microorganisms which can be overcome by nicotinic acid, but is apparently without effect on animals. As with certain other inhibitors already discussed, pyridine sulfonic acid is without effect on those species of microorganisms which can synthesize nicotinic acid, again suggesting that cell penetration or local concentration may be as important as simple structural analogy in explaining the action of metabolic antagonists. The acetylpyridine analog of nicotinic acid brings about reversible signs of nicotinic acid deficiency in mice and dogs, but is without effect on those microorganisms which have been studied.

**Ascorbic Acid and Glucoascorbic Acid.** It was shown by Woolley and Krampitz<sup>15</sup> in 1943 that a synthetic compound called glucoascorbic acid produced scurvylike symptoms when fed to mice on a highly purified diet. These symptoms could not be cured when ascorbic acid was also included in the diet, but disappeared when the glucoascorbic acid was omitted. It will be recalled that mice do not require ascorbic acid in the diet, apparently being capable of synthesizing the amount they need. In the case of the guinea pig, however, which develops scurvy on diets free from ascorbic acid, Woolley has reported that a disease which is not exactly like scurvy but which has some similarities to it is produced on diets containing glucoascorbic acid, and ascorbic acid counteracts this

<sup>15</sup> Woolley and Krampitz: *J. Exptl. Med.*, 78, 333 (1943).

effect. The structural relationship between ascorbic acid and glucoascorbic acid is evident from the following:

It appears likely that the relation between ascorbic acid and glucoascorbic acid is one of metabolic antagonism, although the evidence is more limited than for most other examples of this phenomenon.

**Vitamin K and Analogs.** A hemorrhagic disease occurs in cattle from eating spoiled sweet-clover hay. The substance responsible is *dicoumarol* (see formula), which is an antagonist of the K vitamins, interfering with their utilization in the synthesis of prothrombin. Dicoumarol and several related compounds have been used extensively for the prevention of thrombosis. Derivatives of 1,3-indandione have been investigated for anticoagulant activity, and successful clinical use has been reported for the phenyl and the diphenylacetyl derivatives.

Vitamin K<sub>1</sub>

1,3-Indandione

3,3'-methylene-bis(4-hydroxycoumarin)  
(Dicoumarol)

**Biotin and Analogs.** The structural relation to biotin of some analogs or biotin which have been shown by Dittmer and du Vigneaud<sup>16</sup> to have antibiotin activity is as follows:

<sup>16</sup> Dittmer and du Vigneaud: *Science*, **100**, 129 (1944).

**Biotin****Dethiobiotin****Biotin sulfone****Imidazolidone caproic acid**

Evidence for competition between biotin and its structural analogs has been obtained largely by the use of yeast and bacteria. Inhibition of growth of microorganisms by the three structural analogs whose formulas are given is overcome in each case by the presence of an excess of biotin, but the three differ among themselves in antibiotin potency and likewise show some differences with different microorganisms. Dethiobiotin for example inhibits the growth of *L. casei* but for yeast is a growth stimulant, i.e., it replaces biotin. It is probable that this is due to the ability of the yeast cell to convert dethiobiotin into biotin. Biotin sulfone is inhibitory to the growth of both yeast and *L. casei*, as is imidazolidone caproic acid, and this inhibition is reversed by biotin. It is interesting to note that all of the antibiotins mentioned combine with avidin.

Another group of synthetic structural analogs of biotin has been described by English, *et al.*<sup>17</sup> The most potent in the group, in terms of the inhibition of growth of *L. casei*, has the following structure:

**γ-3,4-Ureylene-cyclohexyl-butyric acid**

<sup>17</sup> English, Clapp, Cole, Halverstadt, Lampen, and Roblin: *J. Am. Chem. Soc.*, **67**, 295 (1945).

Other members of the series differ from the structure shown in the type of main ring system and the length of the side chain. Practically all of the compounds described act as antibiotins against either yeast or *L. casei*, but with varying effectiveness, and in every case the inhibition of growth is overcome by the presence of sufficient biotin.

### ANALOGS OF HORMONES

Relatively little is known concerning the existence of structural antagonism among the various hormones of known structure. The various protein hormones are of course out of consideration in this connection because their structures are not known; the concept of an "antihormone" for a protein hormone has an immunological connotation rather than one of structural analogy. Among the hormones of known structure, it has been pointed out by Woolley that the naturally occurring estrogens and androgens are structural analogs of each other, and it is suggested that the known instances of biological antagonism between these two groups of compounds may be related to structural similarity and competitive properties. Woolley has also cited as an instance of structural antagonism the interesting findings of Kuhn<sup>18</sup> in connection with the sex hormones of algae. Kuhn showed that the two sex hormones were not different compounds but *cis* and *trans* modifications of the same compound. The factor determining sex was the ratio between these two forms.

It appears likely, therefore, that as further knowledge is gained in the field of hormone chemistry and physiology, the existence of competitive inhibition and modification of biological action by structural differences may become as firmly established for some of the hormones as it now is for vitamins and specific amino acids.

### ANALOGS OF OTHER METABOLITES

In addition to the specific examples which have been cited of metabolic antagonism between naturally occurring metabolites and synthetic structural analogs, the concept has been applied to other classes of compounds of biological importance, such as purines, porphyrins, choline and related compounds, amines, etc. A detailed consideration of these appears unprofitable at this time; references to certain of them will be found in the reviews by Welch and by Woolley cited in the Bibliography and in Martin's monograph.

Successful antidotes for poisonous substances must be able to compete with the receptors in the body which are damaged by the poison. Examples are the counteraction of arsenic poisoning by 2,3-dimercaptopropanol (BAL), and the prevention or reversal of cyanide poisoning by vitamin B<sub>12a</sub>. This substance (hydroxocobalamin) reacts irreversibly in the animal body to form vitamin B<sub>12</sub> (cyanocobalamin).<sup>19</sup>

### ANTIBIOTICS

The terms *antibiosis* and *antibiotic powers* were coined by Paul Vuillemin in 1889 and were used by him in a broad sense, referring to all in-

<sup>18</sup> Kuhn: *Angew. Chem.*, **53**, 1 (1940).

<sup>19</sup> Mushett, Kelley, Boxer, and Rickards: *Proc. Soc. Exptl. Biol. Med.*, **81**, 234 (1952).

stances where one species destroys the life of another to preserve or maintain its own. One example of antibiosis cited by Vuillemin fits exactly, however, the current and more restricted concept. He mentioned the observation that products secreted by the blue pus microbe would hold the anthrax bacillus in check. He went on to predict that by an understanding of symbiotic and antibiotic powers man would learn to dominate disease. Present-day definitions characterize antibiotics as organic chemical substances which are produced by microorganisms and have the capacity in dilute solutions to inhibit the growth of other microorganisms and in some situations to destroy them. Opinion is divided whether or not to classify as antibiotics antibacterial substances of animal or vegetable origin.

The blue pus microbe, *Pseudomonas aeruginosa*, the first microorganism in which the property of antibiosis was clearly recognized, actually produces several definitely identified<sup>20</sup> compounds with antibacterial activity. The crude mixture had been tried half a century ago against anthrax infections and had been found too toxic to the host to be of any value in treatment. It was not until 1939, when Dubos reported on tyrothricin (see p. 1314), that interest in antibiotics was again accentuated.

Unlike the common disinfectants and antiseptics, which usually act by irreversibly denaturing or precipitating protein, or by inactivating functional groups (sulfhydryl, iron, etc.) within the cell, the action of antibiotics must be much more subtle since they are apparently harmless in the organisms which produce them but inhibitory or toxic in the susceptible organism. Most antibiotics are primarily bacteriostatic in their action; that is, they do not appear to inhibit the metabolic processes of treated microorganisms except where subdivision and growth are concerned. In some instances, however, substrate utilization may be affected. Some antibiotics are bactericidal, irreversibly destroying the metabolic processes of the susceptible cell. In some cases concentration may determine whether the action is bacteriostatic or bactericidal.

Antibiotics differ considerably in their relative effectiveness against various species of microorganisms, and even against different strains of the same species. In some instances susceptibility to an antibiotic may be considerably modified by variations in the conditions of culture.

The differential susceptibility of various species of microorganisms to a given antibiotic permits the construction of a bacterial "spectrum" for the antibiotic, in which the relative effectiveness is determined for a standardized series of test organisms. Such a spectrum may be useful in comparing two supposedly identical or dissimilar antibiotics and in comparing synthetic compounds or derivatives with the naturally occurring antibiotic.

Antibiotics also differ considerably in their relative toxicity to animals and in their effectiveness *in vivo* as compared with *in vitro*. Effectiveness *in vitro* may be modified by the presence in the host of means for metabolizing or destroying the antibiotic.

---

<sup>20</sup> Wells: *J. Biol. Chem.*, **196**, 331 (1952).

**The Penicillins.** In 1929 Fleming reported<sup>21</sup> that a certain species of mold, later recognized to be a strain of *Penicillium notatum* and first encountered as an accidental contaminant of bacteriological plate cultures, produced a soluble diffusible substance which inhibited the growth of the common *Staphylococcus aureus* and certain (but not all) other microorganisms in culture media. Fleming was able to concentrate this substance from cultures of the mold, and called the material penicillin. It is now known that the original penicillin was a mixture of several similar substances which are called as a class the penicillins.

Fleming showed that his penicillin preparation could be used for the differential separation of resistant and nonresistant species of microorganisms in culture media, and that it was nontoxic to animals. He suggested its possible use in the treatment of infections due to penicillin-sensitive organisms.

These observations however attracted little further attention until about ten years later, when Dubos<sup>22</sup> published his striking results on the antibacterial properties of tyrothricin (see p. 1314). It is probable that these results contributed significantly to a reawakening of interest in the antibacterial possibilities of penicillin. In 1940 Chain, Florey, *et al.*,<sup>23</sup> reported the preparation of penicillin in impure form, with some studies on its toxicity to animals and therapeutic value in experimental infections in mice. This was followed by a more extensive study on methods for large-scale production, partial purification, and assay, and further studies on toxicity and therapeutic value in animals and man. Similar studies on the chemotherapeutic value of penicillin were reported by Dawson, Hobby, Meyer, and Chaffee<sup>24</sup> at about the same time. Developments since then have made penicillin by far the most widely used and important of all the antibiotics thus far known.

Of the various known penicillins, the most important at the present time is the one named penicillin-G (penicillin-II in Britain). The structure of penicillin-G is as follows:

As a class, the penicillins all have the composition represented by  $R\text{—CO—NH—C}_7\text{H}_9\text{OSN—COOH}$ , where R varies. In penicillin-G for example,  $R = \text{C}_6\text{H}_5\text{CH}_2\text{—}$  (the benzyl group); the relationship among various natural penicillins is indicated in the table on page 1313.

It has been suggested that the various penicillins be designated by

<sup>21</sup> Fleming: *Brit. J. Exptl. Path.*, **10**, 226 (1929).

<sup>22</sup> Dubos: *J. Exptl. Med.*, **70**, 1 (1939); Dubos and Cattaneo: *J. Exptl. Med.*, **70**, 249 (1939).

<sup>23</sup> Chain, Florey, Gardner, Jennings, Orr-Ewing, Sanders, and Heatley: *Lancet*, **2**, 226 (1940); Abraham, Chain, Fletcher, Gardner, Heatley, Jennings, and Florey: *Lancet*, **2**, 177 (1941).

<sup>24</sup> Dawson, Hobby, Meyer, and Chaffee: *J. Clin. Invest.*, **20**, 434 (1941).

names which include the name of the major differentiating group (the R group in the table below). According to this suggestion, penicillin-G becomes benzylpenicillin, penicillin-X is *p*-hydroxybenzylpenicillin, etc.

As a class the penicillins are moderately strong monobasic organic acids, soluble in water and in organic solvents such as alcohol, ether, amyl acetate, etc. The sodium salt, which is quite soluble in water and alcohol, is the usual commercial form. Neutral aqueous solutions of the sodium salt will retain their activity for several days if stored in the cold; acid, alkaline, and alcoholic solutions rapidly become inactive.

THE NATURAL PENICILLINS

| Name                     | Type Structure: R—CO—NH—C <sub>7</sub> H <sub>9</sub> OSN—COOH                                                          |                          |
|--------------------------|-------------------------------------------------------------------------------------------------------------------------|--------------------------|
|                          | R                                                                                                                       | Name of R                |
| Penicillin-F.....        | CH <sub>3</sub> ·CH <sub>2</sub> ·CH=CH·CH <sub>2</sub> —                                                               | Δ <sup>2</sup> -pentenyl |
| Dihydropenicillin-F..... | CH <sub>3</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> —                                   | <i>n</i> -amyl           |
| Penicillin-G.....        | C <sub>6</sub> H <sub>5</sub> CH <sub>2</sub> —                                                                         | benzyl                   |
| Penicillin-K.....        | CH <sub>3</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> ·CH <sub>2</sub> — | <i>n</i> -heptyl         |
| Penicillin-X.....        | HO·C <sub>6</sub> H <sub>4</sub> ·CH <sub>2</sub> —                                                                     | <i>p</i> -hydroxybenzyl  |

All of the penicillin available commercially is obtained from natural sources, i.e., from cultures of mold, of which special strains of *P. notatum* and *P. chrysogenum* have been most commonly employed. About 30 other variants of penicillin have been produced biosynthetically by the growth of *Penicillium* in the presence of specific organic acid or amide precursors.<sup>25</sup> These penicillins are all antibacterial *in vitro*, and some of them have been used therapeutically, with particular value in patients who have developed sensitivity to benzylpenicillin.

Penicillins inhibit and in higher concentrations kill actively growing cells of susceptible strains. Inhibitory or lethal action on resting or non-multiplying cells is insignificant. By the use of radioactive penicillin, fixation of penicillin by a susceptible organism (*Micrococcus pyogenes* var. *aureus*) was demonstrated to be chiefly in the bacterial cell wall.<sup>26</sup> Penicillin does not enter yeast cells, which are unaffected by its antibiotic activity. Staphylococci can be grown in high concentrations of penicillin, provided these concentrations are low in proportion to bacterial mass. Under these cultural conditions, the conversion of amino acids to bacterial protein was inhibited.<sup>27</sup> Instead, extracellular polypeptides were produced in approximately equivalent amounts. Penicillins also block the uptake of glutamic acid by susceptible staphylococcal strains during active growth. The formation of a precursor of pentose nucleic acid is also delayed. None of these effects has been clearly established as an example of antagonism to a specific metabolite. The structural similarity

<sup>25</sup> Behrens, Corse, Edwards, Garrison, Jones, Soper, Abeele, and Whitehead: *J. Biol. Chem.*, **175**, 793 (1948); Volini, Shlaes, and Felsenfeld: *J. Am. Med. Assoc.*, **143**, 794 (1950).

<sup>26</sup> Few, Cooper, and Rowley: *Nature*, **169**, 283 (1952).

<sup>27</sup> Hotchkiss: *J. Exp. Med.*, **91**, 351 (1950).

of benzylpenicillin to glutathione has been noted,<sup>28</sup> but the evidence that penicillin may act as a glutathione antagonist is scant and inconsistent.

Penicillin may be administered orally or by injection, usually intramuscularly. Questions of dosage, form of administration, and choice of penicillin as compared with other therapeutic agents will not be considered here. The monograph of Welch and Lewis gives the bacterial "spectra" and the details of therapeutic application of penicillin and other antibiotics. Penicillins are nontoxic to animal tissues in any except very large doses; for example, in ordinary concentrations they have no demonstrable effect on the metabolic characteristics of those isolated animal tissues which have been thus far investigated. They differ among themselves, however, in their action on microorganisms; penicillin-G, for example, is most effective clinically, while penicillin-K is much less useful. Lack of recognition of this fact led to some confusion concerning the therapeutic effectiveness of commercial penicillin preparations during the early stages of their clinical application. A wide variety of organisms, mostly Gram-positive but including some Gram-negative, are susceptible to the action of penicillin.

**Gramicidin and Tyrocidine.** The antibiotic preparation obtained by Dubos from cultures of *B. brevis* and called tyrothricin proved on further study to consist of two separate compounds, called gramicidin and tyrocidine. They may be separated from tyrothricin by treatment with acetone-ether mixture, in which gramicidin is soluble but tyrocidine is insoluble. Gramicidin may be recrystallized from acetone, and tyrocidine hydrochloride from acidified alcohol. Both of these substances are polypeptides of fairly low molecular weight but as yet unknown structure. They are resistant to the action of proteolytic enzymes. On hydrolysis they yield mixtures of amino acids, all of which have presumably been identified (see below). It is interesting to note that certain of these amino-acids are of the D configuration, in contrast with the hydrolytic products of animal proteins, where the L configuration prevails.

Gramicidin is insoluble in water, slightly soluble in ether, and readily soluble in acetone and alcohol. Estimates of its molecular weight vary; on the basis of the amino acid composition a value of approximately 2800 has been proposed. On hydrolysis, gramicidin yields five known amino acids and the basic compound ethanolamine. These components of the gramicidin molecule, and their estimated molecular ratios, are as follows: D-leucine, 6; L-tryptophan, 6; DL-valine, 5; L-alanine, 3; glycine, 2; ethanolamine, 2; making a minimum of 24 residues present. The valine was probably racemized during the hydrolysis; if it were all present in the D form, the leucine and valine would account for the approximately 45 per cent of D-amino acids found present in gramicidin by the use of the enzyme D-deaminase (D-amino acid oxidase).<sup>29</sup> There are no free carboxyl or amino groups, so that a cyclic structure is probable.

Gramicidin is inhibitory to all Gram-positive organisms except acid-fast bacilli, but is entirely inactive against Gram-negative bacilli. It does not destroy the respiration of susceptible cells; in particular instances it

<sup>28</sup> Grevenstuk: *Science*, **114**, 74 (1951).

<sup>29</sup> Lipmann, Dubos, and Hotchkiss: *J. Biol. Chem.*, **141**, 163 (1941).

may be highly bacteriostatic but not at all bactericidal, thus indicating that it acts rather as a metabolic inhibitor than as a protoplasmic poison. The therapeutic value of gramicidin is limited by its relative toxicity to animals and its low solubility in water, penicillin for example being much superior in both respects. It has, however, found some application in the topical treatment of infected wounds.

Tyrocidine is a polypeptide containing free amino groups (probably the  $\delta$ -amino group of the ornithine present, see below) and forms a crystalline hydrochloride, which is insoluble in water, acetone, and ether but soluble in alcohol, from which it may be crystallized. On hydrolysis it yields the amino acids phenylalanine, leucine, proline, valine, tyrosine, ornithine, glutamic acid, aspartic acid, and tryptophan. Of these, the phenylalanine has the D configuration while all the rest (with the possible exception of tryptophan) have the common L configuration. It is interesting to note that the amino acid valine occurs in one configuration in tyrocidine and in the opposite configuration in gramicidin. The proof of the existence of ornithine in the tyrocidine molecule is probably the first instance of the discovery of this amino acid as a primary constituent of polypeptide chains in nature.

Tyrocidine is strongly bactericidal for various Gram-positive and some Gram-negative organisms *in vitro*. It is inactivated *in vivo* by blood plasma and body fluids in general, and so contributes little to the clinical value of tyrothricin. The importance of tyrothricin in medicine is indicated by its inclusion in the United States Pharmacopeia XIV. Its clinical applications are limited, however, by its toxicity, which prevents systemic use. The chief method of administration is by local application or by instillation into body cavities.

**Streptomycin.** This antibiotic, obtained from cultures of the actinomycete *Streptomyces griseus*, was first characterized by Schatz, Bugie, and Waksman in 1944. Its discovery was the result of a systematic study of organisms antagonistic to Gram-negative bacteria.

Streptomycin is a water-soluble, crystallizable, organic base, with the structure shown in the formula on page 1316. Its solutions are administered by injection, since absorption from the gastrointestinal tract is minimal.

Although streptomycin was originally introduced as a therapeutic agent against infection with Gram-negative organisms in general, the so-called broad-spectrum antibiotics (which will be considered later) have replaced many of its earlier uses. Against the tubercle bacillus, however, streptomycin remains the most useful of the antibiotics. Both streptomycin and a derivative, *dihydrostreptomycin*, are toxic, affecting the eighth cranial nerve. Streptomycin tends to cause damage to vestibular function and dihydrostreptomycin to auditory function. Use of a mixture of the two has minimized damage.

Concerning the effect of streptomycin on bacterial metabolism, observations with *E. coli* show that the antibiotic inhibits a condensation between oxalacetic and pyruvic acids which precedes their oxidation by a path differing from the usual citric acid cycle. Certain variants of *E. coli* which have been made resistant to (or dependent upon) streptomycin

do not utilize these metabolites appreciably, but depend upon other metabolic reactions.<sup>30</sup> Numerous other possible mechanisms of antibacterial action have been noted.

**Neomycin**, from *Streptomyces fradiae*, is a mixture of water-soluble basic substances, effective against the tubercle bacillus along with a wide variety of Gram-positive and Gram-negative organisms. Its clinical use is limited by a toxic action leading to focal necrosis in the renal tubules.

**Bacitracin**, from *Bacillus licheniformis* (closely related to *B. subtilis*) is a polypeptide, comparable in a general way with certain other polypeptides of microbial origin—polymyxin, subtilin, and eumycin—which also are antibiotics. Bacitracin has had wide application in the treatment of skin infections, one of its advantages being that it seldom induces allergic reactions. All of the antibiotic polypeptides show some degree of toxicity to the kidney, which limits their systemic use.

**Broad-spectrum antibiotics.** This group of antibiotics is characterized by activity against a great number of different pathogenic microorganisms, including certain rickettsiae and large viruses. *Chlortetracycline* (Aureomycin) and *oxytetracycline* (Terramycin), from *Streptomyces aureofaciens* and *rimosus*, respectively, are quite similar in structure. Both are relatively nontoxic and are commonly given by mouth, although intravenous use is possible.

<sup>30</sup> Umbreit, Smith, and Oginsky: *J. Bact.*, **61**, 595 (1951); Umbreit: *Trans. N. Y. Acad. Sci.*, Ser. II, **15**, 12 (1952).

**Chlortetracycline**  
(Aureomycin)

**Oxytetracycline**  
(Terramycin)

*Chloramphenicol* was originally identified as a naturally occurring antibiotic, elaborated by a species of *Streptomyces*. It is now produced synthetically. Chloramphenicol is the first nitrobenzene compound to be found in living cells.

**Chloramphenicol**

It is a noncompetitive antagonist of phenylalanine. Woolley<sup>31</sup> has emphasized that noncompetitive antimetabolites are more effective antibiotics, since their activity is not canceled by a simple increase in concentration of the specific metabolite. Chloramphenicol may be given orally or intravenously, and is of particular therapeutic value in typhoid fever and against certain rickettsiae, spirochetes, and viruses. Some degree of calculated risk is involved in its use, since depression of bone marrow function has been reported in a small fraction of cases treated with this agent.

<sup>31</sup> Woolley: *J. Biol. Chem.*, **185**, 293 (1950).

All three of the broad-spectrum antibiotics have the property in common of inhibiting the synthesis of protein in susceptible bacterial cells. Chlortetracycline will dissociate phosphorylation from oxidation in animal tissue or mitochondrial preparations, and at higher concentration will inhibit both processes. At similar concentrations, terramycin shows these actions only minimally.<sup>32</sup>

**Antibiotics in Feeds.** The crude residues of *Streptomyces aureofaciens* and of other organisms grown for the production of antibiotics were introduced into the rations of poultry and pigs as a source of vitamin B<sub>12</sub>. The growth-promoting effect of these antibiotic residues was found to be greater than could be accounted for by their B<sub>12</sub> content. A similar impetus to growth of pigs, chicks, and poults could be observed on the addition of penicillin, streptomycin, chlortetracycline, or oxytetracycline to a diet adequate by all recognized standards. The hypothesis that these antibiotics are themselves essential growth factors is unlikely on account of the diversity of their chemical structure, and because a similar effect can be observed upon administration of sulfonamides, phenylarsonic acid and other nonbiological antibacterial agents. It is now understood that the growth stimulus depends upon the more or less selective antibacterial action of these substances, which permits the multiplication of certain bacteria which produce B vitamins and possibly other growth factors, meanwhile suppressing other organisms which would compete with these beneficial organisms or even destroy the growth factors produced by them. In some instances actual infections, previously unrecognized, have been shown to be suppressed by the antibiotics included in the rations.

## DETERMINATION OF PENICILLIN

**1. Method of Vincent and Vincent:<sup>33</sup> Principle.** A disk of filter paper is saturated with the solution to be analyzed, which has been diluted if necessary so as to contain approximately 1 unit per ml. The disk is placed on a nutrient agar culture plate impregnated with the test organisms and incubated at 37° C. If the solution contains penicillin, after incubation a clear zone of inhibition of colony formation surrounds the disk. The diameter of this zone is measured and the penicillin content determined by reference to a calibration curve showing the relation between inhibition zone diameters and known amounts of penicillin.

**Procedure.** The test organism (*Staphylococcus aureus* H is recommended) is transferred from an agar slant twice through peptone broth for 24-hour periods at 37° C. The second transfer is held at 5° for 16 to 18 hours.

Pipet 10 ml. of nutrient agar into uniform flat-bottomed petri dishes and incubate at 37° C. for 16 to 18 hours. Transfer to a refrigerator for at least one hour. When the plates are ready, flood each one with 1 ml. of the refrigerated culture of test organisms. Remove the excess with a capillary pipet. Place the plates at 37° C. for one hour to dry. At this point it is necessary to use wooden racks which support the top half of the petri dish above the bottom half so that there is about ½ inch clearance. When the plates are dry, store in an inverted position in the refrigerator for at least one hour.

<sup>32</sup> Regna: *Trans. N. Y. Acad. Sci.*, Ser. II. 15, 12 (1952).

<sup>33</sup> Vincent and Vincent: *Proc. Soc. Exp. Biol. Med.*, 55, 162 (1944). Similar methods were described almost simultaneously by Epstein, Foley, Perrine and Lee: *J. Lab. Clin. Med.*, 29, 319 (1944), and by Sherwood, Falco, and de Beer: *Science*, 99, 247 (1944).

Sterilize the filter-paper disks<sup>34</sup> by dry heat and immerse them for 30 seconds in the solution to be tested. Remove each disk from the fluid with sterile forceps, shake off excess fluid, and place flat on the seeded agar plate. Three disks, evenly spaced, may be placed on a plate, and it is suggested that the plates be run in triplicate for greater accuracy. One of the disks on a plate may serve as a standard penicillin control.

Incubate the prepared plates (not inverted) at 37° C. for 14 hours. The plates should be placed on a wooden block in the incubator to prevent excess condensation. After the incubation period, measure to the nearest mm. the diameter of the zone of inhibition around each disk.<sup>35</sup> Average the results for each unknown.

**CALCULATION.** The penicillin content of the sample is equal to that of a standard solution of penicillin which gives the same diameter of inhibition zone under comparable conditions. This is best established by reference to a previously prepared calibration curve relating known amounts of penicillin to zone diameters. To prepare such a curve, set up a series of solutions of penicillin in amounts ranging from 4 to 0.1 units per ml., and carry out the procedure as described for the unknown on each of these solutions. Plot a curve with zone diameters in mm. on the *y* axis against units of penicillin per ml. on the *x* axis. A curve similar to that shown in Fig. 293 should be obtained. It is advisable to check this curve at intervals with standard penicillin solutions, and to reconstruct it if necessary.

FIG. 293. TYPE OF CALIBRATION CURVE OBTAINED IN PENICILLIN DETERMINATION BY METHOD OF VINCENT AND VINCENT.

**Interpretation.** This method is a slight modification of the original method of Chain, Florey, *et al.* (*loc. cit.*) developed at Oxford in England and called the "Oxford cup" method, in which the solution to be tested is placed in small glass cylinders partially immersed in the seeded agar; this solution then diffuses out beneath the cup rim into the agar to produce a zone of inhibition similar to that described here. A unit of penicillin (formerly called the Oxford unit and now known as the Florey unit) was defined as that amount which produced a zone of inhibition 24 mm. across under the conditions of the cup assay. Such a unit is clearly subject to variation from laboratory to laboratory and even in the same laboratory unless assay procedures are rigorously controlled. With the availability of pure crystalline sodium penicillin-G, it is possible to define a penicillin unit in terms of this substance. The Federal Food and Drug Administration of the United States has adopted the following relationship: 1 mg. of pure sodium penicillin-G is equivalent to 1667 units of penicillin. Thus 1 unit equals 0.6  $\mu$ g. of the sodium salt.

The disk method described here has been found to give satisfactory

<sup>34</sup> Schleicher and Schull No. 470,  $\frac{1}{2}$  inch in diameter.

<sup>35</sup> A bacteriological "colony counter," equipped with a magnifying glass and a built-in millimeter scale, is very satisfactory for this measurement.

results on blood serum, spinal fluid, urine, and other solutions whose penicillin activity is to be established. For greatest accuracy the solution to be tested should contain between 0.1 and 4 units per ml.

**2. Other Methods.** Rammelkamp<sup>36</sup> has described a procedure for penicillin assay in which the fluid to be analyzed is incubated at various dilutions with a standard inoculum of hemolytic streptococci in the presence of erythrocytes. Dilutions of a standard penicillin solution are treated in the same way. From the relative dilutions of sample and standard required to inhibit the hemolytic action of the test organisms, the penicillin content is obtained. This method, although not so accurate as the one described above, has given satisfactory results on whole blood, erythrocytes, urine, spinal fluid, exudates, and joint fluid. Hiscox<sup>37</sup> has described a colorimetric procedure, applicable to benzylpenicillin only, for the assay of batches of commercial penicillin. This method involves nitration of the benzene ring, reduction, diazotization, and coupling with a color reagent. A turbidimetric method has been reported<sup>38</sup> which is applicable to the measurement of any of the commonly used antibiotics in blood or body fluids.

For techniques of streptomycin assay, and of tests of organisms for sensitivity to antibiotics, consult the *Diagnostic Procedures and Reagents* of the American Public Health Association. Sensitivity tablets and disks impregnated with varying concentrations of different antibiotics are available from biological supply houses, and each manufacturer recommends procedures and media for use with his product.

## I. REAGENTS AND SOLUTIONS

REAGENTS FOR PARTICULAR METHODS ARE DESCRIBED IN THE TEXT AND FOOTNOTES FOR THESE METHODS.

SEE INDEX

**Acid Digestion Mixture.** To 50 ml. 5 per cent copper sulfate solution add 300 ml. 85 per cent phosphoric acid and mix. Add 100 ml. concentrated sulfuric acid ( $\text{NH}_3$ -free) and mix. Keep in a glass-stoppered bottle, protected against the absorption of ammonia from laboratory atmosphere.

**Alcohol-Ether Mixture.** Mix three volumes 95 per cent redistilled alcohol and 1 volume redistilled ether.

**Alizarin.** A 1 per cent solution of alizarin monosodium sulfonate in water.

**Alkaline Pyrogallate Reagent.** Prepare a solution of potassium hydroxide by dissolving 160 g. in 130 ml. water. In 200 ml. of this solution dissolve 10.0 g. pyrogalllic acid.

**Almén's Reagent.** Prepare by dissolving 5 g. tannic acid in 240 ml. 50 per cent alcohol and adding 10 ml. 25 per cent acetic acid.

**Aluminum Hydroxide Cream.** To a 1 per cent solution of ammonium alum at room temperature add a slight excess of a 1 per cent solution of ammonium hydroxide. Wash by decantation until the wash water shows only the faintest trace of residue on evaporation. For the preparation of other forms of alumina see p. 329.

***o*-Aminobenzaldehyde Reagent.** Mix 3 g. crystalline *o*-nitrobenzaldehyde with 50 g. crystalline ferrous sulfate. Add 75 ml. concentrated ammonia. Heat on a steam bath for one hour. Distil off the *o*-aminobenzaldehyde with steam. The mixture before distillation will keep for two weeks.

**Ammoniacal Silver Solution.** Dissolve 26 g. silver nitrate in about 500 ml. water, add enough ammonium hydroxide to redissolve the precipitate which forms upon the first addition of the ammonium hydroxide, and make the volume of the mixture up to 1 liter with water.

**Ammonium Molybdate Solution.** See Molybdate Solution, p. 1328.

**Ammonium Thiocyanate Solution.** This solution is made of such a strength that 1 ml. of it is equal to 1 ml. of the standard silver nitrate solution mentioned below. To prepare the solution dissolve 12.9 g. ammonium thiocyanate,  $\text{NH}_4\text{SCN}$ , in a little less than a liter of water. In a small flask place 20 ml. of the standard silver nitrate solution, 5 ml. of a cold saturated solution of ferric alum, and 4 ml. nitric acid (sp. gr. 1.2), add water to make the total volume 100 ml., and thoroughly mix the contents of the flask. Now run in the ammonium thiocyanate solution from a buret until a permanent *red-brown* tinge is produced. This is the end reaction and indicates that the last trace of silver nitrate has been precipitated. Take the buret reading and calculate the amount

of water necessary to use in diluting the ammonium thiocyanate in order that 10 ml. of this solution may be exactly equal to 10 ml. of the silver nitrate solution. Make the dilution and titrate again to be certain that the solution is of the proper strength.

**Antifoaming Oil Mixture** (Use like caprylic alcohol). To 1 volume crude fuel oil add about 10 volumes toluene.

**Asbestos for Suction Filters.** The asbestos is shredded, placed in a wide-mouth flask, and covered with 10 per cent HCl. Heat on a water bath for five hours. Filter on a Buchner funnel, wash free from acid, return to the flask, cover with 5 per cent NaOH, and heat on a water bath for three hours. Filter, wash free from alkali, then with dilute acid and finally with water until free from acid. Suspend in a large volume of water, allowing it to settle for five minutes. Pour off the upper two-thirds and discard. Repeat the washing of the desired coarse portion several times until the supernatant liquid remains nearly clear.

**Barfoed's Solution.** Dissolve 13.3 g. neutral, crystallized copper acetate in 200 ml. water, filter if necessary, and add 1.8 ml. glacial acetic acid.

**Barfoed's Solution (Tauber-Kleiner Modification).** Dissolve 24 g. copper acetate (Merck, normal, c.p.) in 450 ml. boiling water. If a precipitate forms, do not filter. Immediately add 25 ml. 8.5 per cent lactic acid (Mallinckrodt, U.S.P., 85 per cent) to the hot solution. Shake; nearly all the precipitate will dissolve. Cool, dilute to 500 ml., and after sedimentation filter off the impurities.

**Baryta Mixture.** A mixture consisting of 1 volume of a saturated solution of barium nitrate and 2 volumes of a saturated solution of barium hydroxide.

**Basic Lead Acetate Solution.** This solution possesses the following formula:

|                              |         |
|------------------------------|---------|
| Lead acetate.....            | 180 g.  |
| Lead oxide (litharge).....   | 110 g.  |
| Distilled water to make..... | 1000 g. |

Dissolve the lead acetate in about 700 ml. distilled water, with boiling. Add this hot solution to the finely powdered lead oxide and boil for one-half hour with occasional stirring. Cool, filter, and add sufficient distilled water to the filtrate to make the weight 1 kg.

**Benedict's Solution.** Benedict's modification of the Fehling solution is stable even upon long standing. It has the following composition:

|                              |          |
|------------------------------|----------|
| Copper sulfate.....          | 17.3 g.  |
| Sodium citrate.....          | 173.0 g. |
| Sodium carbonate.....        | 100.0 g. |
| Distilled water to make..... | 1 liter  |

With the aid of heat dissolve the sodium citrate and carbonate in about 800 ml. water. Pour (through a folded filter paper if necessary) into a glass graduate and make up to 850 ml. Dissolve the copper sulfate in about 100 ml. water. Pour the carbonate-citrate solution into a large beaker or casserole, and add the copper sulfate solution slowly, with constant stirring, and make up to 1 liter. The mixed solution is ready for use and does not deteriorate upon long standing.

**Benedict's Quantitative Sugar Reagent.**

|                                                                                             |            |
|---------------------------------------------------------------------------------------------|------------|
| Copper sulfate (crystallized).....                                                          | 18.0 g.    |
| Sodium carbonate (crystallized, one-half the weight of the anhydrous salt may be used)..... | 200.0 g.   |
| Sodium or potassium citrate.....                                                            | 200.0 g.   |
| Potassium thiocyanate.....                                                                  | 125.0 g.   |
| Potassium ferrocyanide (5 per cent solution).....                                           | 5.0 ml.    |
| Distilled water to make a total volume of.....                                              | 1000.0 ml. |

With the aid of heat dissolve the carbonate, citrate, and thiocyanate in enough water to make about 800 ml. of the mixture and filter if necessary.

Dissolve the copper sulfate separately in about 100 ml. water and pour the solution slowly into the other liquid, with constant stirring. Add the ferrocyanide solution, cool, and dilute to exactly 1 liter. Of the various constituents, the copper salt only need be weighed with exactness. Twenty-five ml. of the reagent are reduced by 50 mg. of glucose.

**Benedict's Sulfur Reagent.**

|                                                                          |          |
|--------------------------------------------------------------------------|----------|
| Crystallized copper nitrate, sulfur-free or of known sulfur content..... | 200 g.   |
| Sodium or potassium chlorate.....                                        | 50 g.    |
| Distilled water to.....                                                  | 1000 ml. |

**Benzidine Solution.** Place 4.33 ml. glacial acetic acid in a small Erlenmeyer flask, warm to 50° C., and add 0.5 g. of benzidine. Heat the flask for eight to ten minutes in water at 50°. To the resultant solution add 19 ml. of distilled water. This solution may be kept for several days without deterioration.

**Bial's Reagent.**

|                                    |             |
|------------------------------------|-------------|
| Orcinol.....                       | 1.5 g.      |
| Concentrated HCl.....              | 500 ml.     |
| Ferric chloride (10 per cent)..... | 20-30 drops |

**$\alpha$ ,  $\alpha'$ -Bipyridine Solution.** Dissolve 0.2 g.  $\alpha$ ,  $\alpha'$ -bipyridine (Edwal Laboratories, 732 Federal St., Chicago) in 100 ml. 10 per cent acetic acid.

**Biuret Paper (Kantor and Gies).** Immerse filter paper in Gies' Biuret Reagent (below), then dry and cut into strips.

**Biuret Reagent (Gies).** This reagent consists of 10 per cent KOH solution to which 25 ml. 3 per cent  $\text{CuSO}_4$  solution per liter has been added. This imparts a slight though distinct color to the clear liquid.

**Biuret Reagent (Welker).** Add 1 per cent copper sulfate solution, drop by drop, with constant stirring, to some 40 per cent sodium hydroxide solution until the mixture assumes a deep blue color.

**Black's Reagent.** Make by dissolving 5 g. ferric chloride and 0.4 g. ferrous chloride in 100 ml. water.

**Boneblack, Purification of.** Treat 250 g. commercial boneblack with 1500 ml. 1:4 HCl solution. Boil for half an hour. Filter the boneblack from the acid solution by means of a Buchner funnel and aspirating pump. Wash with hot water until the washings are neutral to litmus paper. Dry and powder.

**Bromine Water.** Add a few drops of liquid bromine (*Caution: Very corrosive!*) to about 100 ml.  $\text{H}_2\text{O}$ , and shake. Prepare fresh when reagent becomes colorless.

**Buffer Solutions, Standard.** See pp. 35 to 37.

**Carmine-fibrin.** Run fibrin through a meat chopper, wash carefully, and place in a 0.5 per cent ammoniacal carmine solution (1 g. carmine dissolved in 1 ml. ammonia and diluted to 200 ml.) for 24 hours or until the maximum coloration of the fibrin (a dark red) is obtained. The fibrin is then washed in water and water acidified with acetic acid. It is preserved under glycerol.

**Cleaning Solution.** To a few grams of sodium bichromate crystals dissolved in a minimum quantity of water, add about 500 ml. concentrated sulfuric acid (technical grade is satisfactory).

**Cochineal Solution.** A saturated solution of cochineal in 30 per cent alcohol.

**Congo Red.** Dissolve 0.5 g. Congo red in 90 ml. water and add 10 ml. 95 per cent alcohol.

**Congo Red-Fibrin.** This may be prepared by placing fibrin in faintly alkaline Congo red solution and heating to  $80^\circ \text{C}$ . The fibrin is then washed and preserved under glycerol.

#### **Copper Sulfate Solutions for Specific Gravity Determination.**

A. SATURATED COPPER SULFATE SOLUTION. Place 4 lb. "fine crystals," or pulverized  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , in a 4-liter bottle, and add about 2.5 liters distilled water. Stopper and shake vigorously for five minutes. Immediately at the close of the shaking period, insert a thermometer into the solution and record the temperature to the nearest half degree Centigrade. When this has been done, immediately decant the supernatant solution from the excess solid, then clarify by filtration through cotton or a dry filter paper into a clean dry bottle. This solution, which has been saturated with copper sulfate at a known temperature and is therefore of known composition, is used at once to make up a stock copper sulfate solution of sp. gr. 1.100.

B. STOCK COPPER SULFATE SOLUTION OF SP. GR. 1.100. From the table (p. 1325) determine the volume of saturated copper sulfate solution which is to be diluted to 1 liter to prepare a solution of sp. gr. 1.100. Measure out the indicated volume of saturated copper sulfate solution into a 500-ml. graduated cylinder. Pour the cylinder contents into a 1-liter volumetric flask, allowing the cylinder to drain for 30 seconds. Dilute the flask contents to the mark with distilled water, stopper, and mix well by inversion. Because of a contraction in volume, the meniscus of the solution will now be somewhat below the mark. Allow to stand for one minute for drainage, then add enough distilled water to bring the meniscus again to the mark, stopper, and again mix well by inversion. Pour into a clean dry 4-liter bottle. Rinse the flask with distilled water, discarding the rinsings, and repeat the above preparation three more times, thus preparing 4 liters stock copper sulfate solution of sp. gr. 1.100.

This stock solution, used for the preparation of the standards described below, should be labeled with its temperature at the time of preparation, since it may be used indefinitely provided the temperature at the time of use is within  $5^\circ \text{C}$ . of the temperature at the time of preparation.

VOLUME OF SATURATED COPPER SULFATE SOLUTION TO DILUTE TO 1 LITER TO PREPARE STOCK SOLUTION OF  $D_{25}^{25} = 1.1000$

| Temperature of the Saturated Solution at the Time of Saturation |      | Volume of Solution to Dilute to 1 Liter | Temperature of the Saturated Solution at the Time of Saturation |      | Volume of Solution to Dilute to 1 Liter | Temperature of the Saturated Solution at the Time of Saturation |       | Volume of Solution to Dilute to 1 Liter |
|-----------------------------------------------------------------|------|-----------------------------------------|-----------------------------------------------------------------|------|-----------------------------------------|-----------------------------------------------------------------|-------|-----------------------------------------|
| ° C.                                                            | ° F. | Ml.                                     | ° C.                                                            | ° F. | Ml.                                     | ° C.                                                            | ° F.  | Ml.                                     |
| 10.0                                                            | 50.0 | 587                                     | 20.0                                                            | 68.0 | 489                                     | 30.0                                                            | 86.0  | 424                                     |
| 10.5                                                            | 50.9 | 581                                     | 20.5                                                            | 68.9 | 485                                     | 30.5                                                            | 86.9  | 421                                     |
| 11.0                                                            | 51.8 | 575                                     | 21.0                                                            | 69.8 | 481                                     | 31.0                                                            | 87.8  | 418                                     |
| 11.5                                                            | 52.7 | 569                                     | 21.5                                                            | 70.7 | 477                                     | 31.5                                                            | 88.7  | 415                                     |
| 12.0                                                            | 53.6 | 563                                     | 22.0                                                            | 71.6 | 474                                     | 32.0                                                            | 89.6  | 412                                     |
| 12.5                                                            | 54.5 | 557                                     | 22.5                                                            | 72.5 | 470                                     | 32.5                                                            | 90.5  | 410                                     |

C. STANDARD COPPER SULFATE SOLUTIONS OF KNOWN SPECIFIC GRAVITY. A 100-ml. portion of copper sulfate solution of any desired sp. gr. between 1.008 and 1.075, accurate to  $\pm 0.0003$ , may be prepared from the stock solution of sp. gr. 1.100 as follows: measure from a buret into a 100-ml. volumetric flask a volume of stock solution *less by 1 ml.* than the value represented by the second and third decimal places of the desired sp. gr. (For instance, if the desired sp. gr. is 1.055, 54 ml. of stock solution are taken; for a sp. gr. of 1.017, 16 ml. are taken and so on.) After measuring out the stock solution, dilute the contents of the 100-ml. flask to the mark with distilled water and mix well. This solution may be used at any temperature within 15° to 20° C. of the temperature at preparation. Smaller portions than 100 ml. may be prepared by using proportionately reduced volumes.

**Cross and Bevan's Reagent.** Prepare by combining 2 parts of concentrated hydrochloric acid and 1 part of zinc chloride, by weight.

**Digitonin Solution.** Dissolve 1 g. digitonin (Hoffmann-La Roche, Inc., Nutley, N. J.) in 1 liter of distilled water and place in a refrigerator for 24 hours. Filter. Concentrate the entire filtrate and make up to ex-

actly 500 ml. (To hasten evaporation draw a rapid stream of air, filtered through cotton, over the surface of the solution in a tared flask, which is immersed in a boiling water bath until the desired weight is reached.)

**Duponol C.** (E. I. du Pont de Nemours and Co., Wilmington, Delaware). Sodium salt of a sulfuric ester of lauryl alcohol.

**Ehrlich's Aldehyde Reagent.** A solution of *p*-dimethylamino-benzaldehyde acidified with HCl.

**Ehrlich's Diazo Reagent.** Two separate solutions should be prepared and mixed in definite proportions when needed for use.

(a) 5 g. sodium nitrite dissolved in 1 liter distilled water.

(b) 5 g. sulfanilic acid and 50 ml. hydrochloric acid in 1 liter distilled water.

Solutions (a) and (b) should be preserved in well-stoppered vessels and mixed in the proportion 1:50 when required. It is said that greater delicacy is secured by mixing the solutions in the proportion 1:100. A satisfactory modification of this reagent, containing less acid, is described on p. 593. The sodium nitrite deteriorates upon standing and becomes unfit for use in the course of a few weeks.

**Esbach's Reagent.** Dissolve 10 g. picric acid and 20 g. citric acid in 1 liter water.

**Exton's Reagent.** Dissolve 200 g.  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$  in 800 ml. water. Cool to 35° C. and add 50 g. sulfosalicylic acid. Dissolve and dilute to 1 liter.

**Fehling's Solution.** Fehling's solution is a mixture of copper sulfate solution and alkaline tartrate solution, prepared as follows:

*Copper sulfate solution* = 34.65 g. copper sulfate dissolved in water and made up to 500 ml. *Alkaline tartrate solution* = 125 g. potassium hydroxide and 173 g. Rochelle salt dissolved in water and made up to 500 ml.

These solutions should be preserved separately in rubber-stoppered bottles and mixed in equal volumes when needed for use. This is done to prevent deterioration.

**Ferric Hydroxide (Oxide) Suspension.** Dissolve 100 g. ferric ammonium sulfate in 200 ml. water. Pour all at once with vigorous stirring into 800 ml. of a mixture containing 10.8 g. ammonia and 27.5 g. ammonium sulfate. Stir vigorously for one-half hour. Make to 4 liters with water. Let settle and decant. Repeat washing about 12 times, adding a few ml. of concentrated ammonia to first two wash waters.

**Folin-McEllroy Reagent.** Dissolve 100 g. sodium pyrophosphate, 30 g. disodium phosphate and 50 g. dry sodium carbonate in approximately 1 liter of water by the aid of a little heat. Dissolve separately 13 g. copper sulfate in about 200 ml. water. Pour the copper sulfate solution into the phosphate-carbonate solution and shake.

**Furfural Solution.** Add 1 ml. furfural to 1000 ml. distilled water.

**Fusion Mixture.** 20 g. sodium carbonate plus 10 g. potassium nitrate.

**Guaiac Solution.** Dissolve 0.5 g. guaiac resin in 30 ml. 95 per cent alcohol.

**Gum Ghatti Solution.** Fill a liter cylinder with cold water. Just below the surface suspend a wire screen on which are placed 20 g. soluble gum ghatti. Let stand 18 to 24 hours. Remove the screen and filter, or strain through clean cloth.

**Günzberg's Reagent.** Dissolve 2 g. phloroglucinol and 1 g. vanillin in 100 ml. 95 per cent alcohol.

**Haines' Solution.** This solution may be prepared by dissolving 8.314 g. copper sulfate in 400 ml. water, adding 40 ml. glycerol and 500 ml. 5 per cent potassium hydroxide solution.

**Hopkins-Cole Reagent.** To 1 liter of a saturated solution of oxalic acid add 60 g. sodium amalgam and allow the mixture to stand until the evolution of gas ceases. Filter and dilute with 2 to 3 volumes of water.

**Hopkins-Cole Reagent (Benedict's Modification).** Place 10 g. powdered magnesium in a large Erlenmeyer flask and shake up with enough distilled water to liberally cover the magnesium. Now slowly add 250 ml. of a cold, saturated solution of oxalic acid. The reaction proceeds very rapidly and with the liberation of much heat, so that the flask should be cooled under running water during the addition of the acid. The contents of the flask are shaken after the addition of the last portion of the acid and then poured upon a filter, to remove the insoluble magnesium oxalate. A little wash water is poured through the filter, the filtrate acidified with acetic acid to prevent the partial precipitation of the magnesium on long standing, and made up to a liter with distilled water. This solution contains only the magnesium salt of glyoxylic acid.

**Hübl's Iodine Solution.** A solution of iodine and mercuric chloride used to determine iodine numbers of unsaturated compounds. (See Iodine Solution, Wijs.)

**Hydrochloric Acid Standard (0.1 N) Solution.** See p. 868.

**Hypobromite Solution.** The ingredients of this solution should be prepared in the form of *two* separate solutions which may be united as needed.

(a) Dissolve 125 g. sodium bromide in water, add 125 g. bromine, and make the total volume of the solution 1 liter.

(b) A solution of sodium hydroxide having a specific gravity of 1.25. This is approximately a 22.5 per cent solution.

Preserve both solutions in rubber-stoppered bottles and when needed for use mix 1 volume of solution (a), 1 volume of solution (b), and 3 volumes of water.

**Iodine Solution.** Prepare a 2 per cent solution of potassium iodide and add sufficient iodine to color it a deep yellow.

**Iodine Solution (0.1 N).** Weigh 12.685 g. pure resublimed iodine into a small weighing bottle using a porcelain spatula. Dissolve 18 g. pure KI in about 150 ml. water. Transfer the iodine to a liter flask, washing out the last traces with some of the KI solution, which is then poured into the flask. Stopper and shake occasionally until dissolved. If necessary, a few more crystals of KI may be added to aid solution. Dilute to the mark and mix well. Keep in a glass-stoppered bottle in a cool dark place. Standardize at once against 0.1 N sodium thiosulfate solution. Measure out accurately 25 ml. of the iodine solution into an Erlenmeyer flask, run in sodium thiosulfate until the color is pale yellow, then add a few ml. of a 1 per cent solution of starch (preferably soluble starch) and titrate to disappearance of blue color. Care should be taken near the end point.

**Iodine Solution (Wijs).** Weigh into a 300-ml. flask 9.4 g. iodine trichloride. Add about 200 ml. glacial acetic acid. Stopper with a cork

carrying a  $\text{CaCl}_2$  tube and heat on the water bath until solution is complete. Rub 7.2 g. iodine to a fine powder in a mortar, wash with glacial acetic acid into a second flask, and heat this in the same way to dissolve the iodine. Pour the contents of both flasks into a liter volumetric flask. Add glacial acetic acid. Measure 10 ml. of the solution into a 500-ml. Erlenmeyer flask. Add 10 ml. 10 per cent KI and about 200 ml. water. Titrate with standard sodium thiosulfate solution and determine the iodine equivalent of 1 ml. of the solution.

**Iodine-Zinc Chloride Reagent.** Dissolve 20 g.  $\text{ZnCl}_2$  in 8.5 ml. water and, when cool, introduce the iodine solution (3 g. KI and 1.5 g. I in 60 ml. water) drop by drop until iodine begins to precipitate.

**Kraut's Reagent.** Dissolve 272 g. KI in water and add 80 g. bismuth subnitrate dissolved in 200 g.  $\text{HNO}_3$  (sp. gr. 1.18). Permit the  $\text{KNO}_3$  to crystallize out; then filter it off and make the filtrate up to 1 liter with water.

**Lead Acetate, Basic.** (See Basic Lead Acetate.)

**Lime Water.** Shake up an excess of calcium oxide or hydroxide with distilled water and leave well-stoppered over night. Decant clear supernatant solution and keep free from  $\text{CO}_2$  of air.

**Litmus-Milk Powder.** Add 1 part powdered litmus to 50 parts dried milk powder. To make a litmus milk *solution*, add 1 part of this powder to 9 parts water.

**Lohmann's Reagent.** Add 25 ml. concentrated nitric acid to 100 g. mercuric nitrate octahydrate, followed by 25 ml. water. Warm to dissolve.

**Lugol's Solution.** Dissolve 5 g. iodine and 10 g. potassium iodide in 100 ml. distilled water.

**Magnesia Mixture.** Dissolve 175 g. magnesium sulfate and 350 g. ammonium chloride in 1400 ml. distilled water. Add 700 g. concentrated ammonium hydroxide, mix thoroughly, and preserve the mixture in a glass-stoppered bottle.

**Magnesium Nitrate Solution for Ignition.** Dissolve 320 g. calcined magnesia in nitric acid, avoiding an excess of the latter; then add a little calcined magnesia in excess, boil, filter from the excess of magnesia, ferric oxide, etc., and dilute with water to 2 liters.

**Methyl Orange.** Dissolve 0.1 g. methyl orange in 100 ml. distilled water.

**Methyl Red.** Saturated solution in 50 per cent alcohol.

**Milk of Lime.** A 1.5 per cent suspension of  $\text{CaO}$  in water. To be labeled: "Shake before using."

**Millon's Reagent.** Digest 1 part (by weight) mercury with 2 parts (by weight) nitric acid (sp. gr. 1.42) and dilute the resulting solution with 2 volumes water.

**Molisch's Reagent.** A 5 per cent alcoholic solution of  $\alpha$ -naphthol.

**Molybdate Solution.** Dissolve 100 g. molybdic acid in 144 ml. ammonium hydroxide (sp. gr. 0.90) and 271 ml. water; slowly and with constant stirring pour the solution thus obtained into 489 ml. nitric acid (sp. gr. 1.42) and 1148 ml. water. Keep the mixture in a warm place for several days, or until a portion heated to  $40^\circ \text{C}$ . deposits no yellow precipitate of ammonium phosphomolybdate. Decant the solution from any sediment and preserve in glass-stoppered bottles.

**Mörner's Reagent.** Prepare by thoroughly mixing 1 volume formalin, 45 volumes distilled water, and 55 volumes concentrated sulfuric acid.

**$\alpha$ -Naphthol Solution.** Dissolve 1 g.  $\alpha$ -naphthol in 100 ml. 95 per cent alcohol.

**Nessler's Reagent:** (A) FORMULA OF FOLIN AND WU. Nessler's solution is an alkaline solution of the double iodide of mercury and potassium ( $\text{HgI}_2 \cdot 2\text{KI}$ ). Into a 500-ml. Florence flask introduce 150 g. potassium iodide and 100 g. iodine; add 100 ml. water and an excess of metallic mercury, 140 to 150 g. Shake the flask continuously and vigorously for 7 to 15 minutes or until the dissolved iodine has nearly all disappeared. The solution becomes quite hot. When the red iodine solution begins to become visibly pale, though still red, cool in running water and continue the shaking until the reddish color of the iodine has been replaced by the greenish color of the double iodide. The whole operation does not usually take more than 15 minutes. Decant the solution, washing mercury and flask with liberal quantities of distilled water. Dilute the solution and washings to 2 liters. If the cooling was begun in time, the resulting reagent is clear enough for immediate dilution with 10 per cent alkali and water and the finished solution can be used at once for nesslerization.

From this stock solution of potassium mercuric iodide prepare final Nessler's solution as follows: Into a flask of at least 5 liters capacity introduce 3500 ml. 10 per cent sodium hydroxide solution, add 750 ml. of the double iodide solution and 750 ml. distilled water, making 5 liters of solution. The 10 per cent NaOH should be made from a saturated solution (containing about 75 g. per 100 ml.) which has been allowed to stand until the carbonate has settled, the clear solution being decanted and used. This solution should have been standardized with an accuracy of at least 5 per cent. Nessler's reagent should be used in the ratio of 10 ml. per 100 ml. of solution to be nesslerized, except where excessive amounts of acids are present, as in direct nesslerization procedures.

The alkalinity of the Nessler's reagent is important and may be checked by titrating with it 20 ml. portions of N HCl. A good end point with phenolphthalein should be obtained at 11 to 11.5 ml. If as little as 9.5 ml. is required, the solution is too alkaline. One ml. of the dilute (1:1) acid digestion mixture should also require 9 to 9.3 ml. Nessler's solution to neutralize it.

(B) FORMULA OF KOCH AND McMEEKIN. Dissolve 22.5 g. iodine in 20 ml. water containing 30 g. potassium iodide. After the solution is complete, add 30 g. pure metallic mercury, and shake the mixture well, keeping it from becoming hot by immersing it in tap water from time to time. Continue this until the supernatant liquid has lost all of the yellow color due to iodine. Decant the supernatant aqueous solution and test a portion by adding a few drops thereof to 1 ml. of a 1 per cent soluble starch solution. Unless the starch test for iodine is obtained, the solution may contain mercurous compounds. To the remaining solution add a few drops of an iodine solution of the same concentration as employed above, until a faint excess of free iodine can be detected by adding a few drops thereof to 1 ml. of the starch solution. Dilute to 200 ml. and mix well. To 975 ml. of an accurately prepared 10 per cent sodium hydroxide solution now add the entire solution of potassium mercuric iodide prepared above. Mix thoroughly and allow to clear by standing.

(C) FORMULA OF BOCK AND BENEDICT. Place 100 g. mercuric iodide and 70 g. potassium iodide in a liter volumetric flask and add about 400 ml. water. Rotate until solution is complete. Now dissolve 100 g.

NaOH in about 500 ml. water, cool thoroughly and add with constant shaking to the mixture in the flask; then make up with water to the liter mark. This usually becomes perfectly clear. When the small amount of brownish-red precipitate which forms settles out, the supernatant fluid is ready to be poured off and used.

**Neutral Olive Oil.** Shake ordinary olive oil with a 10 per cent solution of sodium carbonate, extract the mixture with ether, and remove the ether by evaporation. The residue is *neutral* olive oil.

**Neutral Red.** A 1 per cent solution in 50 per cent alcohol.

***p*-Nitrophenol.** A 1 per cent solution in 50 per cent alcohol.

**Nylander's Reagent.** Digest 2 g. bismuth subnitrate and 4 g. Rochelle salt in 100 ml. of a 10 per cent solution of potassium hydroxide. The reagent should then be cooled and filtered.

**Obermayer's Reagent.** Add 2 to 4 g. of ferric chloride to a liter of hydrochloric acid (sp. gr. 1.19).

**Oxalic Acid Standard (0.1 N) Solution.** See p. 867.

**Permutit.** A synthetic aluminum silicate obtained from the Permutit Company, New York. Only such preparations as pass through a 60-mesh sieve but not through an 80-mesh sieve should be used. It should give off very little dust or turbid material to water and settle in a few seconds. It may be used more than once by washing first with water, then with 2 per cent acetic acid and finally with water again.

**Phenol Reagent (Folin and Ciocalteu).** See p. 939.

**Phenolphthalein.** Dissolve 1 g. phenolphthalein in 100 ml. 95 per cent alcohol.

**Phenylhydrazine Acetate Solution.** This solution is prepared by mixing 1 volume glacial acetic acid, 1 volume water, and 2 volumes phenylhydrazine (the base).

**Phenylhydrazine Mixture.** This mixture is prepared by combining 2 parts phenylhydrazine hydrochloride and 3 parts sodium acetate *by weight*. These are thoroughly mixed in a mortar. A mixture of better keeping quality may be made by mixing equal weights of the hydrochloride and *anhydrous* sodium acetate.

**Phosphomolybdic Acid.** Saturate some sodium carbonate solution with pure molybdic acid. Add 1 part crystalline disodium phosphate to 5 parts acid and evaporate to dryness. Fuse in a porcelain dish at a dull red heat. Dissolve the sodium phosphomolybdate in 10 parts water and add nitric acid until the solution turns a golden yellow color.

**Phosphotungstic Acid.** Dissolve 100 g. sodium tungstate and 60 to 80 g. disodium phosphate in 500 ml. water. Add nitric acid to an acid reaction.

**Picric Acid, Pure.** Picric acid as purchased contains 10 per cent of added water. By exposure to the air between large filter papers (best in a warm place) the water disappears by evaporation. Dry picric acid may be prepared in this way. If the alkaline picrate formed from this acid gives too deep a color, it may be purified as follows:

A. RECRYSTALLIZATION OF PICRIC ACID FROM ACETIC ACID. Dissolve 100 g. picric acid (previously thoroughly dried at 80 to 90° C.) with the aid of heat in 150 ml. glacial acetic acid in an Erlenmeyer flask and continue the heating on an electric plate until the mixture boils. Pour the hot solution upon a fluted filter contained in a dry funnel which has been previously heated, and collect the filtrate in a dry beaker. Cover with a

watch glass and let stand over night at room temperature. If crystallization fails to occur, seed with a small crystal of pure picric acid. At the end of two hours, filter with suction on a hardened filter, and wash with about 35 ml. cold glacial acetic acid. Suck as free from acetic acid as possible and dry at about 80° to 90° C., with occasional stirring, until there is no odor of acetic acid. Conduct operations in a good current of air.

**B. SODIUM PICRATE METHOD OF FOLIN.** Transfer 500 g. moist picric acid to a Florence flask of 1500 ml. capacity. Add 500 ml. acetone. Shake, with a little warming under hot tap water, until all the crystals have dissolved. Add 20 g. active charcoal ("Norit"). Shake, and filter into another flask. During this filtration keep the funnel closed with a watch glass to prevent evaporation.

Dissolve 250 g. anhydrous sodium carbonate and 100 g. sodium chloride in 2500 ml. warm water in a 4-liter beaker. While stirring with an agate-ware spoon, add the acetone solution gradually to the alkaline salt solution. When the reaction ( $\text{CO}_2$  evolution) is finished, let stand, preferably in cold water, for about 30 minutes, and filter on a large Buchner funnel (diam. 20 cm.). Wash with about 2 liters sodium chloride solution (7 per cent) and suck as dry as possible.

If the original picric acid is of good quality, the sodium picrate on the Buchner funnel will be pure, but it is a little safer to recrystallize it once as follows:

Return the precipitate to the 4-liter beaker and add 2 liters boiling water and 20 g. sodium carbonate. To the resulting hot solution add gradually, with stirring, 150 g. sodium chloride, cool, filter, and wash as before with 7 per cent sodium chloride solution. Then wash once or twice with a more dilute sodium chloride solution (2 per cent) and finally wash once with methyl alcohol to remove most of the remaining chloride and water. Dry, either at room temperature or over a radiator.

**TEST FOR THE PURITY OF SODIUM PICRATE.** Make 100 ml. of a 3 per cent solution. Transfer 5 ml. and 10 ml. to test tubes graduated at 25 ml. Dilute each to about 22 ml., add 2 ml. 5 per cent sodium hydroxide, dilute to volume, mix, and let stand for 10 minutes. Then add 4 g. powdered potassium chloride, mix by inversion for about 1 minute, filter on a 9-cm. quantitative filter paper, and compare the two filtrates in the colorimeter. If the picrate is pure, the two filtrates will have the same color.

**PICRIC ACID.** The process for the preparation of pure picric acid is exactly the same as described above, up to the final washing with methyl alcohol, except that hardened filter paper should be used on the Buchner funnel.

One simply converts the purified sodium picrate in the Buchner funnel into picric acid by treating it with dilute hydrochloric acid.

Prepare at least 2 liters of such acid (1 volume conc. acid to 4 volumes water). Disconnect the filtering flask from the suction pump. Pour the acid over the picrate. Stir up the precipitate with a porcelain or glass spoon, so as to make sure that the acid has acted on it all. Use plenty of the acid. Unchanged picrate can be distinguished by its darker color. When no more picrate is visible, connect again with the suction pump, and filter to dryness. Then wash five or six times with cold distilled water and suck as dry as possible. Temperatures up to 90° C. can safely be used for the drying of picric acid.

**Picric Acid, Saturated Solution.** This may be prepared either by allowing distilled water to stand in contact with an excess of picric acid with occasional shaking, or by making a 1.2 per cent solution.

**Potassium Mercuric Iodide.** Dissolve 6.775 g. dry crystalline mercuric chloride and 25 g. potassium iodide separately in water. Mix. Dilute to 1000 ml.

**Potassium Permanganate Standard (0.1 N) Solution.** Dissolve 3.162 g. pure potassium permanganate in a liter of distilled water, allow to stand a few days, and filter through glass wool. Standardize against 0.1 N oxalic acid solution or against pure dry sodium or potassium oxalate. One ml. 0.1 N permanganate is equivalent to 6.7 mg. sodium oxalate. (See also footnote 250, p. 645.)

**Potassium Persulfate Solution (Saturated).** Add 100 ml. distilled water to 7 g. pure potassium persulfate in a glass-stoppered bottle. Undissolved excess settles and compensates for loss by decomposition.

**Ringer's Solution.** To 960 ml. 0.154 M NaCl solution add 20 ml. 0.154 M KCl solution and 20 ml. 0.11 M  $\text{CaCl}_2$  solution.

**Roberts' Reagent.** Mix 1 volume concentrated nitric acid and 5 volumes saturated solution of magnesium sulfate.

**Rosenheim's Iodo-potassium Iodide Solution.** Dissolve 2 g. iodine and 6 g. potassium iodide in 100 ml. water. (This is different from Lugol's solution in which the proportion of iodine to potassium iodide is 1:2.)

**Sahli's Reagent.** This reagent consists of a mixture of equal parts of 48 per cent solution of potassium iodide and 8 per cent solution of potassium iodate.

**Schweitzer's Reagent.** To 10 parts ammonium hydroxide (sp. gr. 0.90), add 3 parts distilled water. To this mixture, add a slight excess of copper carbonate, shake vigorously and allow to stand over night. Siphon off the clear, supernatant liquid.

**Selivanoff's Reagent.** Dissolve 0.05 g. resorcinol in 100 ml. dilute (1:2) hydrochloric acid.

**Sodium Acetate Solution.** Dissolve 100 g. sodium acetate in 800 ml. distilled water, add 100 ml. 30 per cent acetic acid to the solution, and make the volume of the mixture up to 1 liter with distilled water.

**Sodium Alcoholate (0.1 N) Solution.** The sodium alcoholate is made by dissolving 2.3 g. cleaned metallic sodium in 1 liter absolute alcohol. It may be standardized against pure benzoic acid in washed chloroform, or against 0.1 N HCl provided the alcoholate solution contains not more than traces of carbonate.

**Sodium Alizarin Sulfonate.** Dissolve 1 g. sodium alizarin sulfonate in 100 ml. water.

**Sodium Cobaltinitrite Solution.** Prepare according to Kramer and Tisdall as follows:

**SOLUTION A.** 25 g. cobalt nitrate crystals are dissolved in 50 ml. water and to this solution is added 12.5 ml. glacial acetic acid.

**SOLUTION B.** 120 g. sodium nitrite (potassium-free, Merck) is dissolved in 180 ml. water. This gives a total volume of about 220 ml. To all of Solution A is added 210 ml. of Solution B. An evolution of nitric oxide gas occurs at once. Air is drawn through the solution until

the gas has passed off. The reagent is placed in the ice chest and filtered each time before using. It will keep at least one month.

To 20 ml. of this sodium cobaltinitrite solution add 2 ml. 40 per cent silver nitrate solution. Shake vigorously and filter to remove trace of insoluble precipitate.

**Sodium Hydroxide (Saturated Solution).** Shake up about 110 g. of best quality NaOH with 100 ml. distilled water in a 300-ml. Erlenmeyer flask ("Pyrex"). Stopper and allow to stand for a couple of days or until the sodium carbonate settles to the bottom leaving a clear solution of NaOH practically free from carbonate, and containing about 75 g. NaOH per 100 ml.

**Sodium Hydroxide Standard (0.1 N) Solution.** See pp. 867 and 868.

**Sodium Thiosulfate Standard (0.1 N) Solution.** Weigh out 25 g. ordinary c.p. sodium thiosulfate or 24.83 g. of the pure dry recrystallized salt. Dissolve in water and dilute to a liter. Boiled distilled water must be used. Keep in a bottle with a siphon arrangement and carrying a soda-lime tube to exclude  $\text{CO}_2$ . It is best standardized against acid potassium iodate  $\text{KH}(\text{IO}_3)_2$ . Weigh out accurately 0.3249 g. acid potassium iodate. Dissolve in 50 ml. water, heating gently if necessary. Transfer the solution to a 100-ml. flask, rinsing the beaker carefully and make to mark with water. This solution is exactly decinormal. Pipet 25 ml. into an Erlenmeyer flask, add 1 g. potassium iodide dissolved in a little water, and a few cubic centimeters of dilute hydrochloric acid. Titrate immediately with the thiosulfate solution. When the solution becomes pale yellow add a few ml. 1 per cent solution of soluble starch and titrate to loss of blue color.

**Sodium Tungstate Solution.** A 10 per cent solution of sodium tungstate in water. The c.p. sodium tungstate made by the J. T. Baker Chemical Co., Phillipsburg, N. J., or by the Mallinckrodt Chemical Co., St. Louis, Mo., is satisfactory. (See also p. 561.) If not easily soluble, prepare a hot 10 per cent solution, cool, and titrate 25 ml., with 10 per cent NaOH and phenolphthalein, to a pink color which lasts for 3 minutes. Add a proportional amount of NaOH to the main solution.

**Soluble Starch.** Suspend 3 g. raw potato starch in 100 ml. redistilled 95 per cent alcohol, add 0.75 ml. concentrated HCl, and heat on a boiling water bath with a reflux condenser for exactly 10 minutes. Add at once an amount of normal sodium bicarbonate solution just sufficient to neutralize 0.75 ml. of the acid, using methyl orange as indicator. Decant through a filter and wash with several portions of alcohol. Dry at room temperature, sieve and preserve.

**Soluble Starch Solution.** A solution of soluble starch suitable for most iodometric titrations and with good keeping qualities is made according to Pincussen by dissolving 1 g. soluble starch in 10 ml. boiling water and adding to 90 ml. saturated NaCl solution.

**Starch-Iodic Acid Test Paper.** This test paper is prepared as follows: Saturate a good quality of filter paper with 0.5 per cent starch paste to which has been added sufficient iodic acid to make a 1 per cent solution of iodic acid and allow the paper to dry in the air. Cut it in strips of suitable size and preserve for use.

**Starch Paste.** Grind 2 g. starch powder in a mortar with a small amount of water. Bring 200 ml. water to the boiling point and add the starch mixture from the mortar with continuous stirring. Bring again to the boiling point and allow it to cool. This makes an approximate 1 per cent starch paste which is a very satisfactory strength for general use.

**Stoke's Reagent.** A solution containing 2 per cent ferrous sulfate and 3 per cent tartaric acid. When needed for use a small amount should be placed in a test tube and ammonium hydroxide added until the precipitate which forms on the first addition of the hydroxide has entirely dissolved. This produces *ammonium ferrotartrate*, which is a reducing agent.

**Sulfuric Acid, N/12.** Add 2.5 ml. concentrated sulfuric acid to a liter of distilled water. Standardize against alkali of known strength. (See p. 544.)

**Sulfuric Acid, Two-thirds Normal.** Add 35 g. concentrated c.p. sulfuric acid to a liter of distilled water. Standardize against alkali of known strength.

**Takayama's Solution.** A mixture of 3 ml. 10 per cent NaOH, 3 ml. pyridine, 3 ml. saturated solution of glucose and 7 ml. water. The solution works rapidly in the cold if at least 24 hours old. With a fresh solution, warming or more time is necessary. It keeps for one to two months.

**Tannic Acid.** A freshly prepared 5 per cent aqueous solution.

**Tanret's Reagent.** Dissolve 1.35 g. mercuric chloride in 25 ml. water, add to this solution 3.32 g. potassium iodide dissolved in 25 ml. water, then make the total solution up to 60 ml. with distilled water and add 20 ml. glacial acetic acid to the mixture.

**Tincture of Iodine.** Dissolve 70 g. iodine and 50 g. potassium iodide in 50 ml. distilled water. Dilute to 1000 ml. with 95 per cent alcohol.

**Töpfer's Reagent.** Dissolve 0.5 g. dimethylaminoazobenzene in 100 ml. 95 per cent alcohol.

**Tropeolin 00.** Dissolve 0.05 g. tropeolin 00 in 100 ml. 50 per cent alcohol.

**Tungstate-Molybdate Reagent.** To 10 g. pure,  $\text{NH}_3$ -free, molybdic acid in a flask add 50 ml. N sodium hydroxide and boil gently for 3 to 5 minutes. Add about 150 ml. water. Filter the hot solution and add to the filtrate a solution of 80 g. sodium tungstate dissolved in about 600 ml. water. Dilute to 1000 ml.

**Uranium Acetate Solution.** Dissolve about 35.0 g. uranium acetate in 1 liter water with the aid of heat and 3 to 4 ml. glacial acetic acid. Let stand a few days and filter. Standardize against a phosphate solution containing 0.005 g.  $\text{P}_2\text{O}_5$  per ml. For this purpose dissolve 14.721 g. pure air-dry sodium ammonium phosphate ( $\text{NaNH}_4\text{HPO}_4 + 4\text{H}_2\text{O}$ ) in water to make a liter. To 20 ml. of this phosphate solution in a 200-ml. beaker add 30 ml. water and 5 ml. sodium acetate solution (see p. 1332) and titrate with the uranium solution to the correct end reaction as indicated in the method proper, p. 952. If exactly 20 ml. uranium solution are required, 1 ml. of the solution is equivalent to 0.005 g.  $\text{P}_2\text{O}_5$ . If stronger than this, dilute accordingly and check again by titration.

**Winkler's Reagent.** Cuprous chloride 40 g., ammonium chloride 50 g., distilled water to 150 ml. For use mix this solution with ammonium hydroxide (sp. gr. 0.9) in the proportion of 3:1.

### III. TABLE OF COMPOSITION OF FOODS\*—RAW, PROCESSED, PREPARED

#### SIGNS AND SYMBOLS USED

An asterisk in the table stub indicates an item for which the composition has been calculated from a recipe.

Parentheses denote imputed values for which little or no experimental evidence was available, for which there was relatively little basis for imputing a value from another form of the food, or for which reported data were not considered suitable. A *zero* in parenthesis is used where actual data were lacking and the amount of a constituent present was regarded as *none or probably too little to measure*.

Dashes show that no basis could be found for imputing a value although there was some reason to believe that a measurable amount of the constituent might be present.

The word "Trace" is used to indicate vitamin values that would round to zero with the number of decimal places carried in these tables. For other components that would round to zero, a zero is used. A zero followed by a decimal point indicates that there may be up to 0.5 of the unit present but bases for showing the amount were inadequate. Numbers with or without decimal points indicate that the average has been rounded to the nearest whole number or in the case of vitamin A to the nearest multiple of ten.

---

\* Abridged from Watt, Merrill, Orr, Wu, and Pecot: Agriculture Handbook No. 8, Washington, D.C., U.S. Department of Agriculture, 1950.

In preparing this abridgment the following items have been omitted: Raw foods not commonly eaten; certain canned foods when values for corresponding cooked items are included; frozen foods and prepared infant foods similar in composition to forms included; condensed soups; lean or fat meats when medium-fat meats are listed; cross references. Numbers missing from first column represent omitted items.

<sup>6</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in standards of identity proposed by the Federal Security Agency and published in the Federal Register, August 3, 1943.

<sup>7</sup> When the amount of nonfat milk solids in commercial bread is unknown, use bread with 4 per cent nonfat milk solids, item 135 for unenriched bread and 139 for enriched.

<sup>8</sup> Year-round average.

<sup>9</sup> If the fat used in the recipe is butter or fortified margarine, the vitamin A value per 100 g. would be 540 I.U. in foundation cake; 430 I.U. in foundation cake, iced; 410 I.U. in dark fruit cake; 370 I.U. in plain cake, iced; 990 I.U. in pound cake; 830 I.U. in rich cake; and 690 I.U. in rich cake, iced.

<sup>10</sup> If the calcium contributed by chocolate is considered unavailable, the value would be 38 mg. per 100 g.

<sup>11</sup> Vitamin A based on deeply colored varieties.

<sup>12</sup> Based on products ranging from 2.5 to 6.6 mg. per 100 g. cereal. The niacin value of some products is as high as 23.0 mg.

<sup>13</sup> Calcium may not be available because of presence of oxalic acid.

<sup>14</sup> 460 mg. if the added emulsifying agent does not contain phosphorus.

<sup>15</sup> Vitamin values are based on muscle meat only.

<sup>16</sup> Not less than 60 per cent meat, not more than 8 per cent cereals, seasonings.

<sup>17</sup> Approximately one-third of this total amount of carbohydrate calculated by difference is starch and sugar. The remaining portion is made up of materials thought to be utilized only poorly if at all by the body.

<sup>18</sup> Calcium may not be available because of presence of oxalic acid.

<sup>19</sup> Vitamin A based on yellow corn; white corn contains only a trace.

<sup>20</sup> Based on recipe using white corn meal; if yellow corn meal is used the vitamin A value is 330 I.U.

<sup>21</sup> Based on recipe using white corn meal; if yellow corn meal is used the vitamin A value is 250 I.U.

<sup>22</sup> Vitamin A based on yellow corn flour; white corn flour contains only a trace.

<sup>23</sup> Vitamin A based on yellow corn grits; white corn grits contain only a trace.

<sup>24</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in standards of identity promulgated under the Food, Drug, and Cosmetic Act.

<sup>25</sup> Vitamin A based on yellow corn meal; white corn meal contains only a trace.

<sup>26</sup> Based on pared cucumbers; unpared contain about 1.2 mg. iron and 260 I.U. vitamin A per 100 g.  
<sup>27</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum levels of enrichment specified in standards of identity promulgated under the Food, Drug, and Cos-  
metic Act.  
<sup>28</sup> Values for raw items are from the medium fat wholesale cuts considered to be nearest approximations for indicated retail items.

<sup>29</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity promulgated under the Food, Drug, and Cosmetic Act.

<sup>30</sup> The vitamin values are based on the drained solids.

<sup>31</sup> Based on the average vitamin A content of fortified margarine. Most of the margarines manufactured for use in the United States have 15,000 I.U. of vitamin A added per pound. The minimum Federal specifications for fortified margarine require the addition of 9,000 I.U. of vitamin A per pound.

<sup>32</sup> Based on unfortified products.

<sup>33</sup> Total sugars.

<sup>34</sup> Sulfated ash. This overestimates the ash in the range of 8 to 20 per cent.

<sup>35</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity promulgated under the Food, Drug, and Cosmetic Act.

<sup>36</sup> Calcium may not be available because of presence of oxalic acid.

<sup>37</sup> The proximate constituents, calcium, phosphorus, and vitamin A are calculated from a recipe.

<sup>38</sup> The vitamin A values range from about 10 I.U. per 100 g. of white-fleshed plantains to 1,200 I.U. per 100 g. of deeper-yellow-fleshed varieties.

<sup>39</sup> Values for raw items are from the medium-fat wholesale cuts considered to be nearest approximations for indicated retail items.

<sup>40</sup> Year round average. Recently dug potatoes contain about 24 mg. ascorbic acid per 100 g. The value is only half as high after three months of storage and about one-third as high when potatoes have been stored as long as six months.

<sup>41</sup> Calcium may not be available because of presence of oxalic acid.

<sup>42</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity of breads proposed by the Federal Security Agency and published in the Federal Register, August 3, 1943.

<sup>43</sup> Minerals and vitamins are calculated from a recipe.

<sup>44</sup> If bones are discarded, calcium content would be much lower. Bones equal about 2 per cent of total contents of can.

<sup>45</sup> All the ready-to-serve soups are calculated from equal weights of the condensed soup and water except cream soup which was based on equal weights of the condenses soup and milk.

<sup>46</sup> Navy bean meal with farinaceous flour up to 15 per cent.

<sup>47</sup> Pea meal with farinaceous flour up to 15 per cent.

<sup>48</sup> Approximately 40 per cent of this total amount of carbohydrate calculated by difference is sugar, starch, and dextrin. The remaining portion is made up of materials thought to be utilized only poorly, if at all, by the body.

<sup>49</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity promulgated under the Food, Drug, and Cosmetic Act.

<sup>50</sup> Calcium may not be available because of presence of oxalic acid.

<sup>51</sup> Calcium and phosphorus are based on dark brown sugar; values would be lower for light brown sugar.

<sup>52</sup> If very pale varieties only were used, the vitamin A value would be very much lower.

<sup>53</sup> Vitamin A value of tortillas made from yellow corn; tortillas made from white corn have no vitamin A value.

<sup>54</sup> Values for raw items are from the medium fat wholesale cuts considered to be nearest approximations for indicated retail items.

<sup>55</sup> Data assume cut to be prepared by braising or pot-roasting. Use of proportionate quantity of drippings would add approximately 50 per cent more thiamine and niacin and 25 per cent more riboflavin.

<sup>56</sup> Use of proportionate quantity of liquid would double amount of thiamine and niacin and add one-third more riboflavin.

<sup>57</sup> Figures for moisture are based on product as it reaches the mill prior to tempering; other proximate constituents are adjusted to this basis.

<sup>58</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity promulgated under the Food, Drug, and Cosmetic Act. Calcium is based on the level usually found in self-rising flour which is in excess of the minimum (500 mg. per pound) required.

<sup>59</sup> Iron, thiamine, riboflavin, and niacin are based on the minimum level of enrichment specified in the standards of identity promulgated under the Food, Drug, and Cosmetic Act.

#### IV. AVERAGE PORTIONS OF FOODS

##### Caloric Values and Acid- and Base-Forming Effects

The data presented here are reproduced by permission from the 1946 Nutritional Charts prepared by the H. J. Heinz Co., Pittsburgh, Pa. The alkaline or acid effect is given in terms of ml. of N alkali (+) or acid (—) corresponding to 100 g. or 100 ml. of food (see discussion on p. 1097). The measure of “average portion” as given is based upon the edible portion only and upon articles of average size. The food is calculated as in the raw state. These figures are not offered as exact data but merely as a guide in estimating average portions or servings; naturally there is considerable possible variation in this respect. For precise nutritional studies, all food consumed should be accurately measured. In these tables, T. = table-spoon, t. = teaspoon, c. = cup.

VEGETABLES

\* The infusion has little food value except for added sugar and cream. The analytical figures apply to dried coffee bean and dried tea leaves.

† These foods are alkaline, but because of substances in them which give rise to hippuric acid in the body, they increase the acidity of the urine (see p. 1097).

‡ Ripe olives are soaked in alkali during their manufacture, and the alkaline content is apt to be high.

## V. MAINTENANCE OF ANIMALS FOR NUTRITION EXPERIMENTS

**Introduction.** Laboratory animals should be housed in well-ventilated rooms free from drafts in order to avoid colds or the blowing around of finely divided dietary dust. Rooms should be diffusely lighted during the day and darkened at night, the alternating periods of light and darkness being regular from day to day. Exposure of rats (or chicks) to direct sunlight, even though filtered through window glass, must be avoided in vitamin D assay work. Rats are nocturnal animals and excessive noise or activity during the day interferes with their normal habits.

Air-conditioning of rooms is desirable but not essential except where extreme temperatures would otherwise occur. The optimum environmental temperature for small animals is  $24 \pm 2^\circ \text{C}$ . Provision should be made for screening windows and for frequent washing and flushing of walls and floors, which should be sealed against vermin and wild rodents.

Extermination of insects such as roaches, flies, or bedbugs should be commenced as soon as they are observed. With sufficient attention and use of modern insecticides, infestation can be effectively eradicated.

**FLIES AND ROACHES.** If the room can be cleared of animals, spray<sup>60</sup> thoroughly with a potent commercial insecticide such as those containing pyrethrum,<sup>61</sup> lethane, DDT, methoxychlor, or piperonylbutoxide. Seal room for several hours or overnight. Air thoroughly before returning animals.

If animals cannot be removed from the room, apply the insecticide by means of a soft brush to walls and floors (especially in corners, cracks, and seams), cage racks, and other equipment except the cages themselves.

**BEDBUGS.** Paint walls, crevices and equipment with a 5 per cent solution of DDT in kerosene. One application may suffice to eradicate a severe infestation; if not, repeat after six weeks.

Excreta should be removed at least every other day. Paper rolls or thick layers of newspaper under racks of raised-bottom cages facilitate this operation. Hot tin-dipped galvanized wire cages are preferred. These should be cleaned once every week or two depending upon the number of occupants per cage. Cages should be scraped, scrubbed in hot soap solution or soaked in hot trisodium phosphate solution and finally rinsed thoroughly in hot, then cold water.

**Rats.**<sup>62</sup> Selectively bred albino or piebald rats are the animals *par*

<sup>60</sup> Hand spraying is not nearly as efficient as the use of an electric power spray.

<sup>61</sup> Many insecticidal sprays contain an insufficient concentration of active pyrethrins. A very effective product is Fumol, made by The Fumol Corporation, Long Island City, N. Y.

<sup>62</sup> For handbooks on the care of laboratory animals and their use in experimental work, see Haberland: *Die operative Technik des tierexperimentes*, Berlin, Springer, 1926; Pittenger: *Biologic Assays*, 2d ed., Philadelphia, The Blakiston Company, 1928; Munch: *Bioassays*, Baltimore, The Williams & Wilkins Co., 1931; *Manual of Biological Assaying*, Philadelphia, J. B. Lippincott Co., 1937; Main: *The Care of a Small Rat Colony*, St. Louis, C. V. Mosby Co., 1939; Farris and Griffith: *The Rat in Laboratory Investigation*, 2nd ed., Philadelphia, J. B. Lippincott Co., 1949; Farris: *The Care and Breeding of Laboratory Animals*, New York, J. Wiley & Sons, Inc., 1950.

See also Greenman and Duhring: *The Breeding and Care of the Albino Rat*, Philadelphia, Wistar Institute, 1931. Extensive biometric data may be found in Donaldson: *The Rat*, 2d ed., Philadelphia, Wistar Institute, 1924; Hunt: *A Laboratory Manual of the Anatomy*

*excellence* for nutrition experiments.<sup>63</sup> Black rats are of course more suitable for study of achromotrichia although white rats develop a condition described as "rusting," comparable to graying of black fur. In their dietary habits rats, like man, are omnivorous. Their period of growth (see Fig. 294) extends over approximately 300 days and their life span is about three years. Thus they live through their cycle at about 30 times the rate of the human species; however, compared with other species

FIG. 294. NORMAL GROWTH CURVES OF MALE AND FEMALE ALBINO RATS.<sup>64</sup>

Food Research Laboratories' Breeding Colony.

the rate of prepubertal growth of man is slower. Rats multiply rapidly and the large litters which they produce permit of a high degree of experimental control. They require but little food and are hence economical to use. For studies of certain nutritional deficiencies to which the rat is immune, notably scurvy, other species of animals must be employed. Variation in species requirements (rat *vs.* chick) was partly responsible for the discovery of the multiple nature of vitamin D and of the vitamin B complex.

Rats attain sexual maturity at about 75 days, but should not be mated for breeding purposes until about 100 days of age. One male may be

---

of the Rat, New York, The Macmillan Co., 1925. See also Howell: *Anatomy of the Wood Rat*, Baltimore, The Williams & Wilkins Co., 1926, and especially Greene: *Anatomy of the Rat*, Philadelphia, American Philosophical Society, 1935.

<sup>63</sup> For uniform results in vitamin assay work animals should be bred and reared on stock diets of constant composition, preferably under the direct control of the assayer.

<sup>64</sup> These curves are based on 1946 data. Currently (1954) average weights are 20–30 g. higher from about 16 weeks.

A linear transformation of the normal growth curve can be effected by plotting the log weight *vs.* reciprocal of the age according to the method of Zucker *et al.* (Zucker, Hall, Young and Zucker: *J. Nutrition*, **22**, 123 (1941); Zucker and Zucker: *J. Gen. Physiol.*, **25**, 445 (1942); Gray and Addis: *Am. J. Physiol.*, **153**, 35 (1948)). This procedure facilitates comparison of growth data since it permits expression of the responses in terms of the slope of the line and the extrapolated asymptotic (theoretical maximum) weight.

caged with as many as three females at one time. Pregnant females should be isolated before litters are cast, unless only one female occupies the cage with the male. The gestation period is about 22 days. The young are usually weaned when three to four weeks old. If the number of pups in a litter exceeds 8, it should be reduced to that number to protect the mother and at the same time produce sturdier rats. If litters are cast in wire-mesh cages, the mesh should be less than  $\frac{1}{2}$  inch and shredded paper or cellophane should be furnished for bedding or nesting.

FIG. 295. SCHEME FOR NUMERICAL EARMARKING OF RATS.

FIG. 296. INDIVIDUAL BREEDING CAGE FOR RATS.

With Hendryx water fountains, removable partition, double lid, positive action catch, and sliding tray. The front, bottom, and back are constructed of a continuous sheet of wire mesh.

Constructed to specifications of Food Research Laboratories, Inc., by Norwich Wire Works, Norwich, N. Y.

Rats may be marked by staining the fur with dyes (e.g., methylene blue or picric acid), by means of an ear tattoo-punch,<sup>65</sup> or by earmarking by means of combinations of nine types of cuts (slits, V-shaped notches, or holes) in both ears thus numbering them permanently over a range from 0 to 99. (Fig. 295.)

For breeding and stock purposes in small colonies the cage illustrated in Fig. 296 may be employed; for larger laboratories racks of suspended drawer-type cages are most suitable. These may be equipped to carry outside water bottles and to provide for paper rolls for the collection and removal of excreta (see Fig. 297), although stainless-steel trays and

<sup>65</sup> Keeler: *Science*, 12, 205 (1940).

thick layers of newspaper are in some respects preferable. When they are ready for experiments the rats should be transferred to individual cages of the type illustrated in Fig. 298. These cages are of all-wire construction and have false bottoms to minimize access to excreta.<sup>66</sup> They are easily sterilized.

<sup>66</sup> Cages and accessories may be obtained from the Norwich Wire Works, Norwich, New York; the Geo. H. Wahmann Mfg. Co., Baltimore, Md.; or the A. B. Hendryx Co., New Haven, Connecticut.

SUPPLEMENT:

DOSAGE:

FIG. 306. GROWTH CURVE CHART.

hard plastic cap through which a 30-mm. hole is cut. (See food cup inside cage in Fig. 298.) Dietary supplements may be weighed or measured in small opal glass cups (rouge pots). Oils or liquid supplements are preferably fed directly into the mouth from a tuberculin syringe fitted with a needle (No. 16 or 18) ground to a smooth, blunt tip. For nutritional balance experiments, in which separation and collection of urine and feces are necessary, cages of the type shown in Figs. 299 and 300 may be used. The activity cages (Fig. 301) may be employed as illustrated for studies in voluntary activity, or may be driven by a pulley to produce enforced activity.

Rats may be weighed on a spring balance (Chatillon or Hanson), but for more exact work an Exact Weight or Toledo scale of 250- 500-, or 1000-g. capacity, sensitive to 1 g. should be used. (See Figs. 302 and 303.) These balances are also suitable for weighing food cups. Records are kept of the weekly or semiweekly weighings on form sheets such as are illustrated in Figs. 304 and 305. A modified type of growth chart (Fig. 306) in which the time coordinates (abscissae) are divided into weeks and days has proved very useful.

**Breeding and Stock Diets.** When rats are reared for purposes not requiring careful control of their nutrition, they may be fed a mixed diet consisting of clean table scraps, bread and milk, or dog biscuit<sup>67</sup> supplemented with milk or fresh vegetables such as carrots or lettuce, once or twice a week. Specially prepared rations for rats and other laboratory animals are available on the market and have proved quite satisfactory.<sup>68</sup> Mixed poultry rations (growing mash) or calf meal may also be used. For careful nutritional research it is necessary to use a uniform stock diet whose efficiency has been established through several generations of rats. It is desirable that rats reared for investigations on the fat-soluble vitamins be fed diets which limit or control their reserves of the vitamins in question.

<sup>67</sup> The dog biscuits used should be of known nutritional quality as there is a great variation among them, some being incapable even of supporting normal growth. Certain brands of pet foods are available in the form of unpelleted mixtures or mashes.

<sup>68</sup> Ralston Purina Co., St. Louis, Mo., supplies such rations in the form of compressed "checkers" and meal (Purina Laboratory Chow for rats and mice, and special chows for guinea pigs, rabbits, dogs, etc.). Similar rations are available through Rockland Farms, New City, New York.

<sup>69</sup> Based originally on the Sherman Diet B (*J. Biol. Chem.*, **53**, 49 (1922); **60**, 5 (1924)), this diet has been modified several times to improve breeding results. The present composition brings it into reasonably close agreement with the Department of Agriculture data for U.S. food consumption, particularly with respect to the distribution of the major categories of foods (grains and cereals, meat and meat products, milk and dairy products). (Oser, B. L., and M. Oser: Unpublished data.)

<sup>70</sup> Vitamin B-complex mixture, 1 g. contains:

|                      |         |                        |         |
|----------------------|---------|------------------------|---------|
| Thiamine             | 0.6 mg. | Choline chloride       | 200 mg. |
| Riboflavin           | 1.2 mg. | Liver concentrate 1:20 | 25 mg.  |
| Pyridoxine           | 0.4 mg. | Biotin                 | 1 μg.   |
| Niacin               | 5.0 mg. | Folic acid             | 1 μg.   |
| Calcium pantothenate | 4.0 mg. | Cyanocobalamin         | 1 μg.   |
| p-Aminobenzoic acid  | 2.5 mg. | Cellulose powder q.s.  | 1 g.    |
| Inositol             | 100 mg. |                        |         |

<sup>71</sup> Vitamins in oil, 1 g. contains:

|                     |           |
|---------------------|-----------|
| Vitamin A           | 200 units |
| Vitamin D           | 20 units  |
| α-Tocopherol        | 12 mg.    |
| Menadione           | 100 μg.   |
| Cottonseed oil q.s. | 1 g.      |

2. BILLS' MODIFICATION<sup>72</sup> OF THE  
STEENBOCK STOCK DIET

|                              |     |
|------------------------------|-----|
| Yellow corn . . . . .        | 57  |
| Dried whole milk . . . . .   | 25  |
| Linseed oil meal . . . . .   | 12  |
| Crude casein . . . . .       | 3.7 |
| Alfalfa leaf meal . . . . .  | 1.5 |
| Iodized table salt . . . . . | 0.4 |
| Calcium carbonate . . . . .  | 0.4 |

3. A. D. M. A. BREEDER DIET

|                                        |      |
|----------------------------------------|------|
| Wheat meal (entire kernel) . . . . .   | 33.0 |
| Yellow corn meal (entire kernel) . .   | 34.0 |
| Whole milk powder . . . . .            | 21.0 |
| Old process linseed oil meal . . . . . | 7.0  |
| Alfalfa leaf flour (green) . . . . .   | 2.0  |

|                                     |                  |
|-------------------------------------|------------------|
| Pork liver (vacuum dried) . . . . . | 2.0              |
| Calcium carbonate . . . . .         | 0.5              |
| Sodium chloride . . . . .           | 0.5              |
| Lettuce or spinach . . . . .        | about 5 g. daily |

4. F. R. L. VITAMIN-RESTRICTED DIET<sup>73</sup>

|                                           |      |
|-------------------------------------------|------|
| Wheat meal (entire kernel) . . . . .      | 37.0 |
| Yellow corn meal (entire kernel) . .      | 37.0 |
| Whole milk powder <sup>74</sup> . . . . . | 22.0 |
| Dried yeast <sup>74</sup> . . . . .       | 1.0  |
| Dried pork liver . . . . .                | 0.2  |
| Dried alfalfa . . . . .                   | 2.0  |
| Calcium carbonate . . . . .               | 0.5  |
| Sodium chloride . . . . .                 | 0.5  |

| Liver concentrate (Wilson 1:20) . .       | 0.1  |

FIG. 307. EXACT WEIGHT SCALE FOR PREP-  
ARATION OF EXPERIMENTAL DIETS.  
Courtesy, Underwood and Underwood, Inc.

Typical diets which have proved successful are shown on p. 1373-4. These may be prepared by means of scales of the type illustrated in Fig. 307.

**Salt Mixtures.** Synthetic diet mixtures used in nutritional research on rats include special combinations of inorganic salts whose composition

<sup>72</sup> Bills, Honeywell, Wirick, and Nussmeier: *J. Biol. Chem.*, **90**, 619 (1931). Lindow, Peterson, and Steenbock: *J. Biol. Chem.*, **84**, 419 (1929).  
<sup>73</sup> In some laboratories a more highly restricted diet may be used with safety in vitamin A work. For this purpose skim milk powder may be substituted for whole milk powder.  
<sup>74</sup> Not irradiated or fortified with vitamin D.

is based on the analysis of their milk<sup>75</sup> or urine. The original Osborne-Mendel and McCollum-Davis salt mixtures, given below, have been modified to include readily available commercial forms of the chemicals employed (see p. 1262). The modification of the Osborne-Mendel mixture by Hawk and Oser includes salts which yield a similar stoichiometric mixture but, by avoiding acids and carbonates, eliminates the need for evaporation and dehydration.

OSBORNE-MENDEL SALT MIXTURE<sup>76</sup>

|                                       |       |                                      |       |                                          |        |
|---------------------------------------|-------|--------------------------------------|-------|------------------------------------------|--------|
| CaCO <sub>3</sub> .....               | 134.8 | H <sub>3</sub> PO <sub>4</sub> ..... | 103.2 | Fe citrate 1½ H <sub>2</sub> O           | 6.34   |
| K <sub>2</sub> CO <sub>3</sub> .....  | 141.3 | HCl.....                             | 53.4  | NaF.....                                 | 0.062  |
| MgCO <sub>3</sub> .....               | 24.2  | H <sub>2</sub> SO <sub>4</sub> ..... | 9.2   | KAl(SO <sub>4</sub> ) <sub>2</sub> ..... | 0.0245 |
| Na <sub>2</sub> CO <sub>3</sub> ..... | 34.2  | Citric acid + H <sub>2</sub> O..     | 111.1 | MnSO <sub>4</sub> .....                  | 0.079  |
|                                       |       |                                      |       | KI.....                                  | 0.020  |

All amounts are given in grams. The acids are added to the carbonates and ferric citrate, and stock solutions of the other salts are then added in proper amount. After effervescence is completed the mixture is dried at 90° to 100° C. and ground to a fine powder. These amounts of phosphoric, hydrochloric and sulfuric acids are equivalent to 71, 121, and 5.2 ml., respectively, of the concentrated acids. See also p. 1262.

**Guinea Pigs (Cavies).** The most suitable guinea pig for nutrition work is the English short smooth-haired variety, whose manifold coloring facilitates identification. Not all pure white guinea pigs are albinos since they may have dark-colored instead of pink eyes.

Guinea pigs must be housed away from drafts in dry cages, preferably with false bottoms although beds of sawdust or shavings are satisfactory. Dry hay should be provided at all times. They are herbivorous and may be fed clean hay and grain (oat meal, bran, wheat middlings, etc.) supplemented with fresh vegetables (carrots, beets, alfalfa, lettuce, celery, etc.). Moist vegetables must be sound and wholesome because guinea pigs will reject spoiled food. Diets containing fats (e.g., codliver oil) must not be fed when rancid. The addition of dried yeast to the grain mixture is frequently desirable. Specially prepared diet mixtures for guinea pigs are available commercially.<sup>81</sup> Water should be fed sparingly when fresh vegetables are supplied.

Most investigators purchase guinea pigs on the market, since their nutritional history is seldom of importance. However, they should be purchased from a reputable breeder<sup>82</sup> since they are prone to carry pulmonary and other infections when raised or shipped under adverse conditions. Guinea pigs breed about once every three or four months, the gestation period being from 65 to 70 days. Mating should commence not before the age of three months. The lactation period should last about two to three weeks.

**White Mice.** The white mouse has been employed with some success in studies in nutrition.<sup>83</sup> Advantages of the mouse include a smaller food requirement, more rapid growth, and frequency of reproduction. The dietary needs of the mouse are similar to those of the rat although a somewhat higher protein content is recommended.

Advantages of the rat over the mouse for nutritional work include the fact that the rat has been more extensively studied, thus affording

<sup>79</sup> McCollum and Davis: *J. Biol. Chem.*, **33**, 55 (1918).

<sup>80</sup> Steenbock and Nelson: *J. Biol. Chem.*, **56**, 355 (1923).

<sup>81</sup> See footnote 68, p. 1373.

<sup>82</sup> See footnote 63, p. 1366.

<sup>83</sup> Beard: *Am. J. Physiol.*, **75**, 645, 658, 668, 682 (1926). Bing and Mendel: *J. Nutrition*, **2**, 49 (1929). For ophthalmia studies see Pomerene and Beard: *Am. J. Physiol.*, **92**, 282 (1930). Woolley: *J. Biol. Chem.*, **139**, 29 (1941) used the mouse for inositol studies and Nielson and Black: *J. Nutrition*, **28**, 203 (1944) for the study of biotin and pteroylglutamic acid deficiencies.

more norms for comparison; also it is hardier than the mouse, and thus not so prone to contract minor illnesses or to be adversely influenced by changes in temperature, etc.

It has been claimed that mice require vitamin C for normal development.<sup>84</sup>

**Dogs.**<sup>85</sup> The feeding of a purely "synthetic" food mixture for long periods, in metabolism tests using dogs as experimental animals, is a procedure for the successful accomplishment of which investigators in metabolism have long striven. It remained for Cowgill to solve this important problem in dietary technique. His work was an extension of that initiated by Karr.<sup>86</sup>

The principles upon which the procedure is based are that the diet consist of a mixture of isolated food substances which supply the body with all factors necessary for proper nutrition, except a single dietary factor; and that the variable nutritive factor shall be administered apart from the diet mixture. In this discussion vitamin B (complex) is regarded as this variable nutrition factor.

In a test where vitamin B is the variable factor, the diet<sup>87</sup> should contain (1) *protein*, proper in kind and amount;<sup>88</sup> (2) *carbohydrate*,<sup>89</sup> and *fat*<sup>90</sup> to furnish satisfactory energy; (3) *mineral salts*,<sup>91</sup> proper in kind and

<sup>84</sup> Kleiner and Tauber: *Food Research*, 1, 399 (1936).

<sup>85</sup> Cowgill: *J. Biol. Chem.*, 56, 725 (1923). This procedure has been used at Yale University for periods of five months and over with excellent results.

<sup>86</sup> Karr: *J. Biol. Chem.*, 44, 255 (1920).

<sup>87</sup> *Calculation of the Diet.* Construct the diet on a kg. of body weight basis, or form what might be called a *kilo unit of food*. Dogs weighing 7 kg. and over require for the maintenance of body weight between 70 and 80 Calories per kg. per day. 80 Calories permits *maintenance* in adult animals and allows a slight increase of body weight in growing dogs. Dogs weighing considerably less than 7 kg. require slightly more energy intake in order to maintain their body weight; this fact, however, does not invalidate the choice of 80 Calories as the kilo unit quantity. Any variation in energy intake from this figure due to the size of the animal will not seriously affect the intake of nitrogen and salt mixture if liberal quantities such as 0.8 g. N and at least 0.2 g. salt mixture are furnished with every kilo unit of food. For further discussion of the basis for this diet consult the original paper.

<sup>88</sup> This may be *casein*, *extracted meat* (from the Valentine Meat Juice Co., Richmond, Va.) or *commercial coagulated egg albumin*. Casein is to be preferred.

<sup>89</sup> *Sucrose* is a desirable source of carbohydrate; pure starch or dextrin make the diet too pasty when moistened by saliva. Whole cereals, however, are suitable.

<sup>90</sup> See footnote 92, p. 1378.

<sup>91</sup> Cowgill suggests the use of one of the following salt mixtures:

| SALT MIXTURE (KARR, 1920)           |         | SALT MIXTURE (COWGILL)                     |      |

Karr's salt mixture, when fed with bone ash as a source of phosphate on the basis of 0.2 g. and 0.4 g., respectively, per kilo unit of food has given successful results during periods lasting over five months

Where 0.4 g. of agar-agar per kilo unit is used as a source of roughage, Cowgill's salt mixture may be used on the basis of 0.3 g. per kilo unit of food. It is supposed to furnish the dog the various essential inorganic substances equal to or slightly in excess of that eliminated through the kidney by a normal organism during 24 hours, these amounts being expressed in terms of g. eliminated per kilo of body weight per day; 0.3 g. of this mixture

amount; (4) sufficient *vitamin A*;<sup>92</sup> (5) *roughage*,<sup>93</sup> and (6) *water*.<sup>94</sup> The energy requirement as shown in the table of the “kilo unit” below is somewhat high for dogs whose activity is restricted, e.g., in metabolism cages. In such cases it is advisable to reduce the calories to 60–70 per kg. body weight by substituting sucrose for lard. The vitamin B (the variable

KILO UNIT OF CASEIN FOOD\*

|                                                        | Amount | Calories | Percentage |
|--------------------------------------------------------|--------|----------|------------|
|                                                        | g.     |          |            |
| Casein (81.9 per cent pure, 12.7 per cent N) . . . . . | 6.3    | 20.8     | 37.6       |
| Sucrose . . . . .                                      | 5.84   | 23.4     | 34.9       |
| Lard . . . . .                                         | 2.83   | 25.5     | 17.0       |

| Bone ash . . . . .                                     | 0.40   | ..       | 2.3        |
| Salt mixture† . . . . .                                | 0.20   | ..       | 1.2        |
| Totals . . . . .                                       | 16.74  | 80.2     | 100.0      |

\* This kilo unit contains 80 calories, 45 per cent of which are furnished by fat, and 0.8 g. of nitrogen.  
† See footnote 91, p. 1377.

factor) should be fed *separately from the rest of the diet*, in the form of dried yeast (about 0.4 g. per *kilo unit* of food) or preferably a synthetic vitamin mixture; or the various components of the vitamin B complex may be fed as separate supplements. *Excessive* amounts of sugar in the diet of dogs will cause diarrhea, hence cereals (but not pure starch) are better sources of carbohydrate. It has been claimed that meat is an indispensable article of diet in tests on dogs. As a matter of fact, meat in the feeding of dogs is not essential if the diet is adequate with respect to protein and other nutrients.

Cowgill’s work shows that “*monotony of diet* is not *per se* the cause of failure of appetite: loss of the desire to eat is rather an expression either (1) of the failure of the food being fed to nourish the animal properly, or (2) of an adjustment of the dog to its energy requirement when offered more than is necessary of a food mixture that is adequate in all respects.”

*per kilo unit* of food contains a liberal amount of the various inorganic substances desired in the synthetic diet. Karr’s salt mixture is particularly satisfactory when bone ash is used as roughage. These salt mixtures may be replaced by one of those given on p. 1375-6.

<sup>92</sup> Cowgill recommends the use of butterfat but lard or hydrogenated vegetable fat supplemented with codliver oil or some other source of fat-soluble vitamins may be used as the source of the bulk of the calories.

<sup>93</sup> Bone ash has proved very useful for this purpose.  
<sup>94</sup> Not mentioned by Cowgill in his procedure. However, a uniform water ingestion is very essential in certain types of metabolism work (see Hawk: *Biochem Bull.*, 3, 420 (1914) and *Endocrinology and Metabolism*, Vol. 3, p. 275, New York, D. Appleton, 1924). In certain nutrition experiments the animals are given a uniform volume of water daily.

VI. ANALYSIS OF VARIANCE<sup>95</sup>

Table 1

ANALYSIS OF VARIANCE (ASSAY NO. 34005)

Sample: Vitamin A Concentrate

Assay level: 217,200 U.S.P. u./g.

Number of groups: 4 (2 assay  
and 2 reference)

Number of rats per group (N): 9 males

|              | <i>S</i> <sub>1</sub>    | <i>S</i> <sub>2</sub> | <i>U</i> <sub>1</sub> | <i>U</i> <sub>2</sub>           |
|--------------|--------------------------|-----------------------|-----------------------|---------------------------------|
| Dose (mg.) . | 0.88 (1.5 u.)            | 1.47 (2.5 u.)         | 0.00691 ("1.5 u.")    | 0.01154 ("2.5 u.")              |
|              | 28 <i>Y</i> <sub>1</sub> | 20                    | 24                    | 45                              |
|              | 31 <i>Y</i> <sub>2</sub> | 49                    | 32                    | 68                              |
|              | 36                       | 65                    | 27                    | 38                              |
|              | 35                       | 37                    | 31                    | 27                              |
|              | 30                       | 30                    | 22                    | 50                              |
|              | 10                       | 37                    | 34                    | 45                              |
|              | 34                       | 36                    | 26                    | 58                              |
|              | 30                       | 35                    | 29                    | 32                              |
|              | 24                       | 41                    | 13                    | 26 <i>Y</i> <sub><i>n</i></sub> |
| Totals . . . | 258 ( <i>e</i> )         | 350 ( <i>f</i> )      | 238 ( <i>g</i> )      | 389 ( <i>h</i> )                |
| Means . . .  | 28.7                     | 38.9                  | 26.4                  | 43.2                            |

Calculation of sums of squares:

$$C = \frac{(e + f + g \cdots n)^2}{\text{Rows} \times \text{Columns}} = \frac{(258 + 350 + 238 + 389)^2}{9 \times 4} = \frac{(1235)^2}{36} = 42367.36$$

$$\begin{aligned} \text{Columns (between doses)} &= \frac{e^2 + f^2 + g^2 \cdots n^2}{\text{Rows}} - C \\ &= \frac{258^2 + 350^2 + 238^2 + 389^2}{9} - C \\ &= \frac{397,029}{9} - 42,367.36 = 1746.97 \end{aligned}$$

$$\begin{aligned} \text{Total} &= Y_1^2 + Y_2^2 \cdots Y_n^2 - C \\ &= 28^2 + 31^2 + 36^2 \cdots 26^2 - C \\ &= 47,791 - 42,367.36 \\ &= 5423.64 \end{aligned}$$

$$\text{Experimental error} = \text{total} - \text{columns} = 5423.64 - 1746.97 = 3676.67$$

<sup>95</sup> This is included to illustrate a useful experimental design for bioassays. For references to important text-books on biometrics, see footnote 42, p. 1130.

Table 4

## CALCULATION OF ESTIMATE OF POTENCY

$$M = \log \frac{\text{potency of } U}{\text{potency of } S} = \frac{KID}{B}$$

$K = 1$  (for two-dose assays; for three-dose assays  $K = 1.635$ )

$$I = \log \frac{\text{large dose}}{\text{small dose}} = \log 1.667 = 0.2219$$

$$\left. \begin{array}{l} D = 3.17 \\ B = 40.50 \end{array} \right\} \text{from factorial analysis (Table 2, on p. 1379)}$$

$$M = \frac{1 \times 0.2219 \times 3.17}{40.50} = 0.0174$$

Log estimated potency of sample ( $EP$ ) = log of assumed potency of sample ( $AP$ ) +  $M$

$$\text{Log } (AP) = \log 217,200 = 5.3369$$

$$M = 0.0174$$

$$\log (EP) = 5.3543$$

antilog 5.3543 = 226,100 = Estimated potency of sample in vitamin A units per gram

Table 5

## CALCULATION OF ERROR OF ESTIMATE

$$S_M = \log \text{ standard error} = \frac{sKI \sqrt{B^2 + D^2}}{B^2}$$

where

$s$  = standard deviation of assay = 10.72

$K = 1$

$I = 0.2219$

$\left. \begin{array}{l} B^2 = 1640.25 \\ D^2 = 10.03 \end{array} \right\} \text{from factorial analysis (Table 2, above)}$

$$S_M = \frac{10.72 \times 1 \times 0.2219 \times \sqrt{1650.28}}{1640.25} = 0.0589$$

$\log (EP) \pm S_M = \log (\text{limits of potency})$

$$5.3543 + 0.0589 = 5.4132$$

$$5.3543 - 0.0589 = 5.2954$$

$$\text{antilog } 5.4132 = 259,000$$

$$\text{antilog } 5.2954 = 197,400$$

$$\text{Difference} = 61,600$$

$$\frac{1}{2} \text{ difference} = 30,800$$

Estimated potency and standard error = 226,100  $\pm$  30,800 units of vitamin A per gram.

Standard error as per cent of estimate = 13.6 per cent

\* A value given in brackets denotes the mass number of the isotope of longest known half-life.

† Because of natural variations in the relative abundances of the isotopes of sulfur, the atomic weight of this element has a range of  $\pm 0.003$ .

# Index

## A

- absorbancy, in photometry, 513  
absorption, of carbohydrates, 429  
  of fats, 430  
  of inorganic salts, 432  
intestinal, experiments, 433  
mechanism, 428  
methods for studying, 433  
of proteins, 430  
spectra, 473, 492, 522  
of sterols, 432  
of sugars from intestinal tract, 434  
tube, Folin, 874  
accelerator globulin, liver disease, 424; (*see also* labile factor)  
acetal phospholipides, 293–294  
acetaldehyde, 68  
acetanilide, 442  
acetate buffer solutions, 35, 871  
  metabolism (*see* acetic acid)  
acetic acid, in cholesterol synthesis, 223  
  conjugation reactions, 439  
  in detoxication, 443  
  in fat formation, 223, 997–998  
  metabolism, 1009–1012, 1187–1188  
    cocarboxylase and, 992  
    coenzyme I and, 992  
    effect of fluoroacetate, 1299  
    thioctic acid, role of, 1214, 1215  
  in porphyrin synthesis, 475  
  from pyruvate, 992  
  in urine, 812  
acetoacetic acid, from acetate, 1009, 1011  
  acid-base balance and, 692  
  from amino acids, 1011, 1033, 1041, 1042  
  from fatty acids, 1005, 1006  
  metabolism, 1007  
  preparation, 841  
  tests, 841  
  urine, 837–838, 871, 931, 933  
    determination, 931  
acetoacetyl coenzyme A, 997, 1007, 1009  
acetone, 1007  
  bodies, 692, 1007–1008  
    tests, 839–842  
  in urine, 837–842, 933  
  tests, 840  
acetonuria (*see* ketonuria)  
acetyl, coenzyme A, 322, 1010, 1187, 1191  
  in carbohydrate metabolism, 991  
  and fat oxidation, 1005, 1006  
  in fat synthesis, 997  
acetyl groups, 1028  
  acetyl phosphate, 322, 997, 1011  
acetylamino acids, 1012, 1018, 1028  
2-acetylamino fluorene, 1157  
acetylation of amines, 1187  
  as detoxication reaction, 442  
acetylbenzoic acid, 442–443, 1009  
acetylcholine, 296–297, 1009–1011, 1220, 1222

- coenzyme I—(*Continued*)
  - in glycolysis, 274–275
  - vision and, 1113
- coenzyme II, 76, 1106, 1166, 1167, 1172
  - and carbon dioxide utilization, 995
  - citric acid cycle and, 993
  - cytochrome C reductase, 307, 318, 320
  - enzymes containing, 307, 1166–1167
  - riboflavin and, 1154
- coenzyme III, 322
- coenzymes, 311
- Cohen and Smith acid hematin method, for hemo-  
globin, 613
- Cohn's plasma protein fractions, 460
- colamine (*see* ethanolamine)
- Cole test, for lactose in urine, 846
- Coleman spectrophotometer, 531–532
- collagen, 183, 192, 244, 245, 247, 249
  - amino acid content, 122
  - ascorbic acid and, 244
  - disease, 245
    - and mineralocorticoids, 759
  - gelatin from, 244, 246
  - preparation and tests, 246
- Collip's method, for preparation of parathyroid  
extract, 772
- colloid mill, 3
- colloidal arsenious sulfide, 3, 10
  - behavior of proteins, 112
  - ferric hydroxide, 3, 10
  - gold, 3, 10
    - test, 482
  - osmotic pressure of plasma, 466
  - platinum, 10
  - solutions, 2–12
    - classification, 7
    - experiments, 10
    - osmotic pressure, 6
    - preparation, 2, 10
    - properties, 3, 10
    - viscosity, 12
  - state, 1, 3
- colloids, 1
  - electrophoresis, 12
  - mutual precipitation, 11
  - optical properties, 11
  - osmotic pressure, 20
  - precipitation by electrolytes, 11
  - protective, 3
  - proteins as, 164, 165
  - separation, by electrophoresis, 7
    - by ultracentrifuge, 4
    - by ultrafiltration, 4
- colorimeters, 503–512
  - Bausch and Lomb, 508, 509
  - calculations for, 505–506, 511
  - Duboseq, 508
  - Klett, 509
  - Myers test-tube, 504
  - photoelectric, 526–530
  - use, 503, 510–512
    - experiments on, 510–512
    - preparation for, 510
- colorimetry, 500–512
  - artificial standards, 502
  - balancing method, 205
  - colorimetry—(*Continued*)
    - calculations, 506, 511
    - comparison against series of standards, 503
    - dilution method, 504
    - duplication method, 503
    - experiments, 510–512
    - internal standards, 502
    - standards for, 501
    - use of light filters, 507
- colostrum, 219
- column chromatography, 14–16; (*see also* chroma-  
tography)
  - preparation of columns, 15
  - use for separation of adenosinepolyphosphates,  
287
    - of purines, 217
- combined hydrochloric acid, 362, 380
- combustion of foodstuffs, 1050
- comparator, use of, 41, 504, 702, 704, 873
- competitive inhibition, 1297–1298
- composition, of animal body, 1077, 1078
  - of foods, 1336–1356
  - of human blood in health and disease, 499
- compound B, 753, 758
- compound E (*see* cortisone)
- compound F (*see* hydrocortisone)
- compound S, 753
- concanavalin B, 162
- concentration cell, 45
- condensing enzyme, 992, 1188
- conductance, of biological fluids, 53
  - electrical, 53
- conjugate glucuronates, 825, 842
  - in urine, 918
    - determination, 918
- conjugated phenols, 941
  - proteins, 185, 192
- conjugation, 439
  - with glucuronic acid, experiment, 444
  - glycine, experiment, 444
- connective tissue, white fibrous, 244–246
  - yellow elastic, 246–247
- contractile fiber preparation, 286
- contractin, 279
- contraction, muscular (*see* muscular contraction)
- Conway diffusion cell, 668, 886
- Conway method, for determination of ammonia  
and urea, 886
- copper, amount in body, 1077
  - balance, 1094
  - in bile, 410
  - deficiency, 1094
    - experiment on, 1103
  - enzymes containing, 306, 320, 1094
  - hemoglobin formation and, 1092, 1094
    - experiment, 1103
  - isotopes, 971
  - metabolism, 1094
  - in milk, 227
  - in proteins, 186, 193, 461, 1094
  - requirement, 1094, 1109
  - soap test for lipase, 401
- copper sulfate—specific gravity method, for blood  
proteins, 607
- coprophagy, 1146

- coproporphyrins, 427, 782, 783, 852
  - in liver disease, 427
  - in urine, 852
- coprostanol, 295, 449
- coprostenol, 295
- coprosterol, 295, 449
- Coramine (*see* niacin diethylamide)
- Cori ester (*see* glucose-1-phosphate)
- Cori method, for studying absorption of sugars, 434
- Cornell test, for pasteurization of milk, 232
- corpus luteum hormone, 755
- cortical hormones and water balance, 1081
- corticoids, 758, 764
  - assay for, 764
- corticosteroids, in urine, 964
- corticosterone, 749, 753
  - action of, 758
- cortin, urine, determination, 764
- cortisone, 749, 753
  - action of, 758
- cosubstrates, 278
- cottage cheese, 224
- counter, Geiger-Müller, 974
  - proportional, 974
  - scintillation, 974
- countercurrent distribution, 25–28
  - experiments, 26–28
- Cowgill salt mixture, 1377
- cozymase (*see* coenzyme I)
- cramps, 1081
- cream, 222
- creatine, 266, 799, 1024, 1026, 1221
  - biological synthesis, 266, 279, 1025–1026, 1221
  - in blood (*see* blood, creatine)
  - diacetyl reaction, 280
  - in muscle, 266
    - determination, 287
  - origin from amino acids, 799, 1026
  - phosphate (*see* phosphocreatine)
  - preparation and tests, 279–280
    - from creatinine, 801
  - tolerance test, 799, 904
  - in urine, 797, 799–800, 871, 904
    - determination, 903–904
    - experiments, 800
- creatinine, 266, 788, 797–802, 825, 827, 899–902
  - in blood (*see* blood, creatinine)
  - coefficient, 798, 902
  - excretion, 798, 902
    - experiment on, 1054
  - formation from creatine, 266
    - experiment, 280
  - isolation from urine, 800
  - Jaffé reaction, 801
  - nitroprusside test, 801
  - properties, 798
  - in urine, 788, 797–802, 871, 902, 899–902
    - determination, 899–902
    - experiments on, 800
    - zinc chloride salt, 798, 801, 802
- creatinuria, 799, 904, 1276
  - and vitamin E, 1276
- cresol, 802, 815
- p*-cresol, from tyrosine, 436, 437
- p*-cresol sulfuric acid, 802, 815
- cretinism, 771
- Cross and Bevens' reagent, 91, 1325
- crotoxin, 162
- crude fiber, definition, 1051
- cryptoxanthin, 98, 1106, 1118, 1119
- crystalloids, 1
- Cullen-Hawkins correction for colorimetric blood pH, 703
- Cullen-Hawkins method, for blood pH, 699
- curd, of milk, 224, 365–366
- curie, unit, 974
- Cushing's syndrome, 759
- cyanide, detoxification of, 439
  - poisoning, treatment with methemoglobin, 475
    - with vitamin B<sub>12a</sub>, 1310
- cyanocobalamin (*see* vitamin B<sub>12</sub>)
- cyanosis, 691
- cyanuric acid, 790–791
- cyclopentanoperhydrophenanthrene nucleus, 295
- cyclotron, 972
- cystathionine, 149, 1030, 1031
- cysteic acid, 158, 1032
  - coenzyme III and, 322
- cysteine, 116, 139, 140–141, 1030
  - chemistry, 139
  - conjugation reactions, 439
  - and cystine sulfur, 168–169
  - in detoxication, 443
  - metabolism, 1030
  - oxidation, 139
  - preparation, 140
  - in proteins, test for, 168
  - relation to glutathione, 321
  - sulfinic acid, 322
  - tests, 141
    - Sullivan test, 141
- cystine, 116, 124, 140, 168, 807, 854, 897, 950
  - 1028, 1030, 1031
  - calculus, urinary, 862
  - chemistry, 140
  - determination, 124
  - metabolism, 1030
  - origin, from methionine, 1031
    - from serine, 1028
  - preparation, 140
  - in proteins, test, 168
  - tests, 141
    - Sullivan test, 141
  - in urine, 807, 854, 858, 863, 864, 897
- cystinuria, 807, 809, 950, 1030
  - arginine excretion in, 809
  - lysine excretion in, 809
- cytidine, 203
- cytidylic acid, 203, 206
- cytochrome, 186, 318–319
  - oxidase, 304, 306, 318, 319, 324, 1092
- cytochrome A, 318, 319
- cytochrome B, 318, 319
- cytochrome C, 162, 318, 319
  - reductase, 307, 318, 320, 323, 1154
- cytosine, 201, 202, 210
  - tests, 216
    - paper chromatography, 218
  - utilization, 209

## D

- Dalton's law, 725  
 Dann and Evelyn method, for vitamin A and carotene, 1127  
 Day and Taggard bromination method, for phenols, etc., 445  
 DCA (*see* deoxycorticosterone)  
 deamination (*see* oxidative deamination; amino acids)  
 decarboxylase, 1179, 1180  
 decarboxylation, 436  
 deficiency diseases (*see* vitamins)  
 dehydration, 466, 1080, 1081  
 dehydroascorbic acid, 321, 1107, 1229, 1231, 1234  
 dehydrobilirubin (*see* biliverdin)  
 7-dehydrocholesterol, 295, 1107, 1248, 1251, 1253  
   irradiation, 1253-1254  
 11-dehydrocorticosterone, 758  
 dehydrogenases, 304, 307, 317-319  
 dehydroisoandrosterone, 751, 759, 760  
 7-dehydrositosterol, 1107, 1254  
 Delsterol (*see* vitamin D)  
 denaturation of proteins, 178-180  
 Denis method, for blood magnesium, 648  
 Denis and Silverman method for gastric pH, 388  
 dental caries, 350, 351, 1096  
   fluorosis, 262  
 dentin, 255-260  
 dentition, human, chronology, 258, 259  
 6-deoxyascorbic acid, 1107, 1232  
 deoxycholic acid, 410, 411, 749  
 deoxycorticosterone, 749, 753, 758, 1081  
 deoxycytidine, 203  
 deoxypentose nucleic acids, 200, 201  
 deoxypyridoxine, 1306  
 deoxyribose, 55, 76, 201, 210  
   nucleoprotein, preparation, 212  
 deoxyribosenucleic acid, 185, 201, 203, 204  
   preparation and tests, 214  
 derived proteins, 186  
 desmolases, 304, 307  
 detergents, synthetic, 105  
 dethiobiotin, 1106, 1207, 1309  
 detoxication, 437-439  
   in liver disease, 424  
   *p*-aminobenzoic acid and, 1210  
 deuterium, 971, 979, 983  
   measurement, 984  
 dextran, 56, 92  
   clinical use, 92  
 dextrin, 56, 70, 84, 88-89, 94, 352  
   experiments on, 88-89  
 dextrose (*see* glucose)  
 DFP (*see* diisopropylfluophosphate)  
 diabetes, 499, 570, 768, 823, 920, 999  
   acetone bodies, 933  
   acidosis, 933  
   alloxan, 768  
   blood chemistry, 499  
   bronzed, 1044  
   glucose, in blood, 499, 570  
     in urine, 823, 920  
   hyperglycemia, 998  
   insipidus, 776, 781, 1081  
   insulin, role, 768  
   ketosis, 933  
   mellitus, 499, 570, 568, 781, 814, 823, 999  
   phlorizin, 781, 999  
   pituitary, 768  
   renal, 823, 999  
   sugar, in blood, 499, 570  
     in urine, 823, 920  
 diacetic acid (*see* acetoacetic acid)  
 diacetyl reaction for creatinine, 280  
 dialysis, 4, 10  
 dialyzing membranes, preparation, 10  
 diamine oxidase, 1303  
 diaminohydroxypimelic acid, 150  
 $\alpha$ - $\epsilon$ -diaminopimelic acid, 119, 125  
 2,6-diaminopurine, 209  
 diaphorase, 307, 320, 1155  
 diastase (*see* amylase)  
 diazo reagent, 1326  
 dicoumarol, 477, 1308  
 diet, adequate vs. optimal, 1074; (*see also* diets)  
   fat content, recommended levels, 1001  
   high caloric, nonnitrogenous, 1049  
   and hydrogen-ion concentration of urine, 1099  
   purine, high and low, 1051-1054  
   and urinary nitrogen and sulfur, 1054  
 dietary allowances, table, 1108  
 dietary efficiency of milk, 1074  
 diethenoid fatty acids, 100  
 diethyl stilbestrol, 753, 756  
 diets, acid- and base-forming, 1097  
   A.D.M.A. breeder, 1374  
   breeding and stock, for animals, 1373  
   calcium-deficient, 1101  
   caloric value, determination, 1051  
   carbohydrate-deficient, 1070  
   F.R.L. breeder, 1373  
   F.R.L. vitamin-restricted, 1374  
   iron-deficient, 1103  
   lysine-deficient, 1060  
   for nutrition experiments, 1288  
   purine-free and high-purine, 1051-1054  
   riboflavin-deficient, 1287  
   salt-free and salt-rich, 1048  
   stock, dogs, 1376  
     guinea pigs, 1376  
     rats, 1373  
   thiamine-deficient, 1286  
   vitamin-A deficient, 1286  
   vitamin-C deficient, 1287  
   vitamin-D deficient, 1286  
   vitamin-E deficient, 1287  
 diffusion, 5, 10  
 digestibility of proteins, determination, 1047-1049  
 digestion, effect of water, 1080  
   gastric, 359-374  
   intestinal, 404-407  
   pancreatic, 393  
   salivary, 349-358  
 digitalis, 77, 295  
 digitonin, 749  
 diglycerides, 101, 431  
 11-dihydrocortisone, 754  
 22-dihydroergosterol, 1107, 1254  
 dihydropenicillin-F, 1313  
 dihydrostreptomycin, 1315

dihydroxyacetone, urine, 964  
 dihydroxyacetonephosphate, 274  
 3,4-dihydroxyphenylalanine, 1042, 1044, 1180  
 3,4-dihydroxyphenylethylamine, 1180  
 2,5-dihydroxyphenylpyruvic acid, 1042, 1044  
 3,5-diiodotyrosine, 119, 138, 771, 1042, 1044  
 diisopropylfluophosphate, 298, 641  
 diketogulonic acid, 1231, 1234  
 diketopiperazine, 119, 130, 153  
 2,3-dimercaptopropanol, 1310  
 dimethylaminoazobenzene (*see* Töpfer's reagent)  
 1,7-dimethylxanthine (*see* paraxanthine)  
 diosgenin, 749  
 2,8-dioxyadenine, 211  
 dipeptidase, 306, 309, 404, 405  
     determination, 407  
 dipeptides, 130  
 diphosphoglyceric acid, 274, 634  
 diphosphoinositide, 292  
 diphosphopyridine nucleotide (*see* coenzyme I)  
 diphosphothiamine (*see* cocarboxylase)  
 disaccharide, 55, 77  
 dispensable amino acids (*see* amino acids)  
 dissociation constants, 30, 683  
     degree of, 682  
 distribution coefficient, 24  
     countercurrent, 25  
     experiments, 26-28  
 DNA (*see* deoxyribose nucleic acid)  
 D/N ratio, significance, 1022  
 dogs, use in experiments, 1376  
 Donnan equilibrium, 12-13, 428, 686  
 dopa (*see* 3,4-dihydroxyphenylalanine)  
 dopase, 1044  
 DPN (*see* coenzyme I)  
     nucleosidase, 1167  
 Drisdol (*see* vitamin D)  
 DRNA (*see* deoxyribose nucleic acid)  
 Du Bois standards of basal metabolism, 736  
 Duboseq colorimeter, 508  
 Dü Nouy surface tension apparatus, 24  
 Dutch cheese, 224  
 dwarfism (*see* anterior pituitary gland)

## E

E values of vitamins, 1125-1126  
 Eagle method, for preparation of thrombin, 491  
 edema, 467  
 edestan, 186, 193  
 edestin, 162, 167, 183, 189  
     tests, 189-190  
 egg albumin (*see* ovalbumin)  
 eggs, as acid-forming food, 1357  
     composition, 1344  
     digestion, 367-368  
     evacuation time from stomach, 367-368  
     proteins, amino acid composition, 122  
 Ehrlich aldehyde reagent, 1326  
     diazo reagent, 1326  
     test for indole and skatole, 444  
 Einhorn saccharimeter, 69  
 elaidic acid, 432, 978  
 elastin, 183, 192, 245, 246  
     amino acid composition, 122  
     in dentin, 258

elastin—(*Continued*)  
     experiments, 247  
     preparation and tests, 247  
 elastomucin, 183, 247  
 electrical conductance of solutions, 53  
 electrode, antimony, 48, 674  
     calomel, 45  
         standard values, 48  
     glass, 48  
     hydrogen, 45  
     quinhydrone, 48, 674  
 electro dialysis, 4  
 electrolyte, balance in liver disease, 426  
     distribution in plasma, 1084  
     and water balance, 1081, 1082  
 electrolytic separation of amino acids, 125  
 electrometric method, for hydrogen-ion concentration of blood, 704  
     of urine, 873  
 electrometric microtitration, 674  
 electrometric titration, of acids and bases, 50, 674  
     oxidation-reduction, 51  
 electrons, 970  
 electrophoresis, 6  
     experiments, 12  
     moving boundary method for, 6, 461-462  
     paper, 7  
         in protein fractionation, 464  
         of serum proteins, 184  
         in protein fractionation, 461-464  
 electrophoretic analysis, 6, 461  
     mobilities, 6  
     patterns of plasma proteins, 462  
     separation of serum proteins, 183-184  
 elements, atomic weights, 1384  
     in human body, 1077  
     inorganic, essential, 1078  
     isotopes occurring naturally, 971  
     trace, 1077, 1097  
 elution, 9  
 Elvehjem method for iron, in biological materials, 656  
     in urine, 963  
 Embden ester, 266  
 Emmerie-Engel test, for tocopherols, 1272  
 emulsification, 22  
     experiments, 107  
 emulsifying agents, 22, 105  
 emulsin, 77, 306  
 emulsions, 22, 105  
 emulsoids, 7, 8, 164-165  
     preparation, 10  
     properties, 7  
 enamel of teeth, 255-256, 260  
     crystal structure, 257  
 endergonic reactions, 316  
 endocrine glands, control of, 747  
     organs, 747-779  
     system, chart, 747  
 endopeptidase, 363, 395  
 energy metabolism, 723-746  
     requirements, basal, 732  
         for work, various, 732-733  
 energy-rich phosphates, 276-278  
 enolase, 275, 307  
 enol-phosphopyruvic acid, 275

- enriched foods, 1336–1356
- enterocrinin, 404
- enterogastrone, 360, 778
- enterokinase, 312, 396, 400, 406
  - preparation, 400
- enzymes, 303–333
  - action, kinetics, 312–315

         adenosinetriphosphatase activity, experiment, 285  
         enzymatic properties of, 267, 276, 277  
         experiments, 284  
         preparation, 284  
     Myrj, 105  
     myricyl alcohol, 98, 106

myristic acid, 99  
myxedema, 771

## N

Nadi reagent, 319, 323  
Najjar method for riboflavin in urine, 1162  
naphthol, 843  
 $\alpha$ -naphthol reaction, 63  
naphthoresorcinol test, for glucuronates, 843  
NDGA (*see* nordihydroguaiaretic acid)  
Nelson-Somogyi method, for blood glucose, 573  
neo- $\beta$ -carotene B, 1119  
neo- $\beta$ -carotene U, 1119  
neomycin, 1303, 1316  
neoretinene B, 1113, 1114  
neovitamin A, 1106, 1119, 1120  
nephelometry, 533-535  
nephritis, 499, 551, 884  
    blood chemistry of, 499  
    hyperglycemia, 570  
    urea output, 551, 884  
nephrosis, 499, 551, 884  
    blood chemistry of, 499  
    urea output, 551, 884  
nerve activity, chemical changes, 296  
nervone, 294  
nervous tissue, 290-302  
    acetal phospholipides, 293  
    acetylcholine, 297  
    carbohydrate metabolism, 296  
    cephalins, 290, 292  
    chemical changes during activity of, 296  
    cholesterol, 294  
    choline, 292  
    composition, 290, 1078  
    experiments, 299  
    fat, 290  
    gangliosides, 294  
    glycolipides, 294  
    inorganic components, 295-296  
    lecithins, 291  
    lipides, 290  
    nucleoprotein, 290  
    proteins 290  
    sphingomyelin, 293  
    sulfolipides, 294  
Nessler reaction with ammonia, spectrophotometric characteristics, 878-880  
    reagent, 1329  
Neuberg ester (*see* glucose-6-phosphate)  
Neumann's procedure for total phosphorus, 953  
neuraminic acid, 294  
neurine, 1220  
neurohormones, 296  
neurokeratin, 290  
*Neurospora*, use of, in microbiological assays, 1066-1068  
neutral sulfur, urine, 816  
neutrality regulation, 678-722  
    acid-base equilibrium, normal and abnormal variations, 691  
    role of ammonia in, 689  
    role of buffers, 681  
    role of hemoglobin, 679, 684

neutrality regulation—(*Continued*)  
    role of kidneys, 688  
    role of lungs, 688  
    role of oxygen, 678  
neutrons, 970, 976  
Newcomer method, for hemoglobin, 616  
Newton method, for blood uric acid, 562  
niacin, 1024, 1106, 1164-1178  
    analogs, 1170, 1307  
    chemistry, 1171-1172  
    deficiency, clinical aspects of, 1165  
        diagnosis of, 1073  
        stigmas, 1291  
        treatment, 1291  
    determination, 1131, 1172  
        colorimetric method of, 1173  
        U.S.P. method, 1175  
    dietary allowances, 1108  
    diethylamide, 1169  
    distribution in foods, 1171, 1335-1355  
    enzymes and, 1167  
    esters, 1106, 1169  
    in feces, 812  
    in milk, 228  
    physiological aspects, 1165  
    requirement, 1108, 1167  
    storage, 1170-1171  
    synthesis, 1171  
    tryptophan and, 1040, 1168, 1179  
    ureide, 1169  
    in urine, 812, 1168, 1170, 1173  
niacinamide, 1106, 1165  
    coenzymes, 1166-1167  
    determination (*see* niacin, determination)  
    excretion, 1168, 1170, 1175  
    methionine and, 1030  
Nicol prism, 69  
nicotinic acid (*see* niacin)  
    methylation of, 443  
    trigonelline from, 443  
nicotinic acid amide (*see* niacinamide)  
nicotinuric acid, 1173  
night blindness (nyctalopia) and vitamin A, 1114  
nikethamide (*see* niacin diethylamide)  
ninhydrin method, for amino acid nitrogen, 892  
    test, 172  
Nippe's method, for hemin test, 483  
nitranilic acid, 124  
nitrates, in urine, 822  
nitrites, in saliva, test, 356  
    in urine, 822  
nitrocellulose, 89  
nitrogen, balance, 1020, 1056  
    distribution, urine, 875  
    equilibrium, 1020  
    excretion, effect on, of purine, 1051-1052  
        of diet, 1054  
    factor for proteins, 239  
    isotopes, use, 971, 979, 980, 983  
    "lag," 1047  
    "metabolic product" in feces, 1055  
    metabolism, 1021-1022, 1047-1061  
        in liver disease, 422  
    organic, Lassaigne test, 168

## O

- nitrogen—(*Continued*)  
 partition, urine, 875, 1054–1055  
 trichloride, action on flour, 1301  
 in urine, determination of, 874  
     clinical interpretation, 875  
 nitroprusside test, for acetone, 840  
     for creatinine, 801  
     for glutathione, 326  
 nitrous acid reaction for amino acids, 129  
 N<sup>1</sup>-methylnicotinamide, 1141, 1168, 1169, 1170, 1173, 1175  
 nomogram, for calculation of plasma carbon dioxide capacity, 717  
     for specific gravity blood method, 609  
     for surface area, 737  
 nonblood proteins, 832  
 nonnitrogenous diet, 1049  
 nonprotein nitrogen in blood (*see* blood, nonprotein nitrogen)  
 nonprotein nitrogen, saliva, 350  
 noradrenaline, 296, 757, 766–767; (*see also* norepinephrine)  
 nordihydroguaiaretic acid, 104  
 norepinephrine, 1302; (*see also* noradrenaline)  
 normal solution, 866  
 normality of concentrated acids and bases, 1335  
 NPN (*see* blood nonprotein nitrogen)  
 nubecula, 810  
 nucleases, 306, 394  
 nucleic acid, 185, 200–218  
     amount in cells, 203  
     composition, 201–204  
     deoxypentose (*see* deoxyribose nucleic acids)  
     digestion, 405  
     enzymatic breakdown, 210  
     metabolism, 208–210  
     pentose (*see* ribose nucleic acids)  
     synthesis and vitamin B<sub>12</sub>, 1209  
 nucleohistone, molecular weight, 162  
 nucleoproteins, 185, 200–218, 825  
     characteristics, 200  
     composition, 213  
     deoxypentose, 200, 201; (*see also* deoxyribose nucleoprotein)  
     digestion, 405  
     effect of radiation on, 977  
     experiments, 212  
     pentose, 200, 201; (*see also* ribose nucleoprotein)  
     tests, 212  
     in urine, 782, 810, 828, 834  
     tests for, 834  
 nucleosidase, 210, 306, 404, 405  
 nucleosides, 202–203  
 nucleotidase, 210, 306, 404, 405  
 nucleotides, 202–206  
     isomers, 204–206  
 nutrition, adequate vs. optimal, 1074  
     water in, 1058  
 nutritional anemia, 1103  
 nutritional deficiencies, and gastric secretion, 306–307  
     student exercises, 1286–1288  
 nyctalopia and vitamin A, 1114  
 Nylander's reagent, 1330  
     test for reducing sugars, 66, 826  
 Obermayer's reagent, 1330  
     test for indican, 804  
 occult blood (*see* blood, occult)  
 Ochoa reactions for carbon dioxide fixation, 995  
 octamethylpyrophosphoramide, 299  
 octanoic acid oxidation, 1005  
 oils, 97  
     fish, vitamin A content of, 1115  
     vitamin D content of, 1115  
     hydrogenation (hardening), 103  
 oleic acid, 99, 100  
 olein (*see* triolein)  
 oligophrenia phenylpyruvica, 1043  
 oliguria, 781  
 olive oil, tests, 106  
 OMPA (*see* octamethylpyrophosphoramide)  
 oncotic pressure, 466  
 one-carbon intermediates, 209, 1027, 1032–1033, 1209  
 opsin, 1113–1114  
 optical activity, methods, 69  
 optical density, 513, 518  
     relation to transmittancy (table), 520  
 optical rotation, 69  
 optimal vs. adequate nutrition, 1074  
 orcinol-hydrochloric acid test, pentoses, 845  
 organic acids, urine, determination, 871  
 organized urinary sediments, 860  
 ornithine, 147, 148  
     conjugation reactions, 439, 440  
     cycle, in urea formation, 789, 1039  
     decarboxylation, 1180  
     metabolism, 1038–1039  
     and proline, 1033–1034  
     in tyrocidine, 1315  
 orosins, 163  
 orotic acid, 209  
 orthostatic albuminuria, 829  
 osazone reaction, 63  
     for sugars in urine, 824  
 osazones, *Plate II* (facing p. 64)  
 Osborne-Folin method, for sulfur in urine, 949  
 Osborne-Mendel salt mixture, 1374  
     Hawk-Oser modification of, 1374  
 Oser-Hawk salt mixture, 1374  
 Oser-Hochberg-Melnick method, for N<sup>1</sup>-methylnicotinamide in urine, 1174  
     for thiamine, 1144  
 Oser-Melnick-Pader method, for vitamin A, 1124  
 Osgood-Haskins test, for urinary protein, 830  
 osmolar, definition of, 1085  
 osmotic pressure, 19–21  
     of blood, 466, 1085, 1087  
     and electrode potentials, 43  
     experiments, 21  
     and intestinal absorption, 428  
     molecular weights by, 160  
 ossein (*see* collagen)  
 osseoalbuminoid, 249  
 osseomucoid, 192, 248, 249  
 osseous tissue, 249; (*see also* bone)  
     experiments, 254  
 ossification, chemistry, 252

osteomalacia, bone composition, 251  
 Ostwald-Folin pipet, 542  
 Ostwald-Folin viscosimeter, 12  
 Ott test, for nucleoprotein in urine, 834  
 ovalbumin, 122, 162, 167, 183  
   amino acid composition, 122  
 ovaries, 755, 773  
 "overproduction," 998  
 ovoflavin, 1106  
 ovomucoid, 119, 185  
 ovovitellin, 185, 193  
 oxalacetic acid, 991-992, 994, 996  
 oxalic acid, 788, 805-806, 867, 944  
   determination, 944  
   in diet, 806  
   metabolic origin, 806  
   standard (0.1 N) solution, 867  
 oxalosuccinic acid, 991-992  
   decarboxylase, 992  
 oxaluria, 945  
 oxaluric acid, 806, 944  
 oxamide, 171  
 oxidases, 304, 323-325, 1215  
   animal, 325  
   keto acid, and thioctic acid, (protogen), 1215  
   plant, 323-324  
 oxidation, by activation of oxygen, 319  
   of carbohydrates, 990  
   by dehydrogenation, 317-319  
   of fats, 1004  
   iron, role of, in, 322  
   and phosphorylation, 317  
   sulfhydryl group, role, 321  
   tissue, methods for study, 326  
 $\beta$ -oxidation, 438, 1004  
 $\omega$ -oxidation, 1007  
 oxidation-reduction systems, 316  
   titrations, 51  
 oxidative deamination, 1027, 1035  
 oxidizing enzymes, 304  
 oxoisomerase, 274  
 oxyacids, aromatic, in urine, 810  
 oxybiotin, 1206  
 oxygen, in blood (*see* blood)  
   caloric values for, 726  
   capacity (*see* blood)  
   combination with hemoglobin, 471, 679-680  
   consumption by tissues, average values, 340  
   measurement, 334-336  
   isotopes, 971, 979, 983  
   role of, in neutrality regulation, 678  
   tension, alveolar air, 680  
 oxyhemoglobin, 167, 471, 473, 487, 494, 679, 828, 835  
   in blood (*see* blood)  
   isoelectric point, 167  
   spectroscopic tests, 494  
   in urine, 828  
   tests for, 835  
 oxyproline (*see* hydroxyproline)  
 oxytetracycline, 1316, 1317  
 oxythiamine, 1138, 1305  
 oxytocin, action of, 775  
   amino acids in, 776

oxytocin—(*Continued*)  
   effect of, on mammary glands, 776  
   structure, 775

## P

PABA (*see* *p*-aminobenzoic acid)  
 PAH (*see* *p*-aminohippuric acid)  
 Palmer method, for hemoglobin, 616  
 palmitic acid, 99  
   aldehyde, 294  
   preparation and tests, 108-109  
 palmitin (*see* tripalmitin)  
 pancreas, 768, 1078  
   experiments on, 769  
   hyperglycemic factor, 769  
 pancreatic amylase, 396  
   experiments, 400  
 pancreatic digestion, 393

   clinical aspects, 1187  
   coenzyme A, relation to, 1187-1188  
   deficiency, 1187  
   symptoms, 1187  
   determination, 1191-1192  
   A.O.A.C. method, 1192  
   Skeggs and Wright method, 1192  
   distribution in foods, 1189, 1190  
   esters, 1106  
   in feces, 812  
   inositol and, 1225  
   in milk, 228  
   physiological aspects, 1186-1189  
   requirement, 1109, 1189  
   in saliva, 351  
   storage, 1189  
   in urine, 812  
   vitamers, 1106, 1188  
 pantothenyl alcohol, 1191  
 pantoyltauramine, 1189  
 pantoyltaurine, 1188, 1305  
 papain, 157, 306, 312  
 paper chromatography (*see* chromatography, paper)

- paper electrophoresis for protein fractionation, 7, 464  
 of blood serum, 184  
 paracasein, 224, 365  
 Para-oxon, 299  
 Parathion, 299, 641  
 parathyroids, 772, 1088, 1089  
 blood calcium and, 645, 772  
 deficiency and tooth formation, 261  
 experiments, 772  
 extract, preparation of, 772  
 effects of, 773  
 unit, 772  
 hormone, nature, 772  
 paraxanthine, 813  
 parenteral amino acid administration, 105  
 parenteral fat administration, 1013-1014  
 partial pressures, gases, 725  
 partition coefficient, 24  
 of nitrogen and sulfur in urine, 1054  
 theory of fat absorption, 431  
 Pasteur effect, 341  
 enzyme, 341  
 pasteurization of milk, 230  
 test for, 232  
 Pauling hypothesis for protein structure, 155  
 peanut-meal protein, amino acid content, 120  
 pectin, 56, 91, 92-93  
 experiments, 95  
 preparation, 95  
 pellagra, 1133, 1164, 1165; (*see also* niacin)  
 penicillin, 1312-1314, 1318-1320  
 chemistry, 1313  
 determination, Hiscox method, 1320  
 Rammelkamp method, 1320  
 Vincent and Vincent method, 1318  
 unit, 1319  
 penicillin-F, 1313; (*see also* dihydropenicillin-F)  
 penicillin-G, 1312, 1320

 penicillin-X, 1313  
 pentacosane, 98  
 pentamethylenediamine, 437  
 pentosan, 56, 76, 91, 94  
 experiments, 93  
 pentosazone, 76, 844  
 pentose nucleic acids, 200, 201  
 pentoses, 55, 75, 94, 287, 844  
 benzidine reaction (Tauber), 76, 845  
 dietary significance, 76  
 experiments, 76  
 in urine, 801, 844  
 tests for, 845  
 pentosuria, 76, 811, 828, 844  
 pepsin, 305, 306, 363-365  
 acetylated, 308  
 action, 157  
 experiments, 370-371  
 activity, determination of, 388-390  
 amino acid composition, 122  
 differentiation of, from pepsinogen, 371  
 milk, effect on, 365  
 preparation, 330  
 products of action, 364-365  
 substrate specificity, 157, 365  
 pepsin—(*Continued*)  
 in urine, 811  
 pepsinogen, 305, 364  
 differentiation of, from pepsin, 371  
 peptic activity, determination of, by Anson and Mirsky method, 389  
 by Riggs and Stadie method, 388  
 by Volhard and Löhlein method, 389  
 digestion, products, 370  
 peptidase, 306, 309, 363, 404-405  
 activation by metal ions, 311  
 activity, 406  
 experiments, 406  
 peptide linkage, 131  
 peptides, 152, 187, 199  
 in urine, 809  
 peptizing agents, 3  
 peptones, 113, 187, 195, 828  
 differentiation of, from proteoses, 197  
 experiments, 196  
 in urine, 828  
 periodide test, for choline (Rosenheim), 301  
 Perkin-Elmer flame photometer, 530  
 permanent waving, 243  
 Permutit method, for ammonia in urine, 890  
 peroxidase, 186, 306, 319, 324, 1092  
 determination, 325  
 experiments, 324  
 in milk, 225  
 preparation, 325  
 reaction with peroxide, 310  
 peroxides and radiation damage, 978  
 perspiration, 1081  
 Pettenkofer test, for bile acids, Mylius modification, 416, 837  
 Pfaltz and Bauer fluorophotometer, 536  
 pH (*see* hydrogen-ion concentration)  
 phenaceturic acid, 441, 1005  
 phenol, 802, 815, 825, 843

 pyridoxal, 1106, 1179, 1181, 1182  
   phosphate, 1106, 1179, 1180  
 pyridoxamine, 1106, 1179, 1181, 1186  
 pyridoxic acid, 1184  
 pyridoxine, 1106, 1178–1186  
   amino acid metabolism, relation to, 1179  
   antimetabolites, 1306–1307  
   chemistry, 1182  
   clinical aspects, 1179  
   cobalt, relation to, 1096  
   deficiency, 1179  
   determination, 1131, 1183–1186  
   excretion, 1181, 1184  
   in feces, 812  
   in foods, 1181  
   kynureninase and, 1040  
   in milk, 228  
   physiological aspects, 1179  
   requirement, 1109, 1181  
   stability, 1182  
   storage, 1181  
   synthesis, 1181  
   transaminase, relation to, 1034  
   tryptophan metabolism, relation to, 1040, 1041  
   in urine, 812  
   vitamers, 1106  
 pyrimidines, 201, 210, 211, 216, 217–218

pyrimidines—(*Continued*)

- in deoxyribose nucleic acids, 203
  - nucleosidase, 211
  - nucleosides, 210
  - nucleotides, 210
  - precursors, 209
  - separation by paper chromatography, 217–218
  - tests, 216
- pyrithiamine, 1138, 1304
- pyrocatecholsulfuric acid, 802, 815
- pyrroline carboxylic acid, 1034
- pyrophosphate and coenzyme A, 1011
- pyruvate (*see* pyruvic acid)
- pyruvic acid, 68, 275, 990–996, 1027, 1137; (*see also* phosphopyruvic acid)
- alanine as precursor of, 1027
  - in carbon dioxide utilization, 994–995
  - conversion of, to oxalacetate, 1137
  - to acetaldehyde by yeast, 68
  - glycolysis and, 275, 989
  - metabolism, 990–996
  - precursors, 989, 994, 996, 1027, 1028
  - relation, to citric acid cycle, 990–996
  - to coenzyme A, 992, 1137
  - to muscular contraction, 275
  - serine as precursor, 1028
  - thioctic acid relation, 992
  - in transamination reactions, 1024, 1034–1035
- pyuria, 836

## Q

- Q enzyme, 316, 332
- Quaife and Dju method, for tissue tocopherol, 1273
- Quaife and Harris method, for tocopherol in foods, 1273
- quercetin, 1243
- quercetrin, 1243
- Quick and Csonka methods for conjugated glucuronic acids, 918
- Quick's method, for hippuric acid, 914
- for preparation of glucuronic acid, 843
- Quick's test for liver function, 915
- quinhydrone electrode, 48, 674
- quinic acid, 784, 804, 1097
- quinoline, methylation, 443

## R

- $R_F$  value, in chromatography, 17
- rachitic rosary, 1244
- rachitogenic diets, 1261
- radiant energy, spectral distribution, 1249
- radiation, allowable exposure, 976
- ionizing, and sulfhydryl groups, 977, 978
  - effects of, 976–978
  - on water, 977
  - sickness, 977
- radioactive iodide, use in medicine, 772
- radioactive isotopes, 972–983
- experiments on, 980
  - in medicine, 982–983
- radioactive phosphorus, experiment, 980
- radioactive tracers, 978
- radioactivity, 972

radioactivity—(*Continued*)

- induced, 976
  - measurement, 973
- radioautograph, 975
- radioautography, 974
- raffinose, 56, 70, 81
- relative sweetness, 62
- Rammelkamp method, for penicillin, 1320
- rancidity, 104
- and antioxidants, 104
- rat anti-spectacled-eye factor (*see* inositol)
- rats, use in experiments, 1365–1376
- rayon, 89
- reagents and solutions, preparation, 1321–1334
- red blood cells, role in carbon dioxide transport, 684; (*see also* erythrocytes)
- reductinic acid, 1233
- reduction and oxidation, in biological systems, 317–320
- tests for sugars, 64–67
- reductones, 1233
- refection, 1146
- regurgitation, effect on gastric acidity, 361, 378
- Rehfuß method of fractional gastric analysis, 383
- stomach tube, 376
- Reichert method, for crystallization of hemoglobin, 487
- Reichert-Meissl number, 105
- Reinhold and Shiel's method, for blood cholesterol, 584
- Reinsch test, for arsenic in urine, 849
- for mercury in urine, 850
- rem, definition, 976
- renal albuminuria, 829
- renal diabetes, 823, 999
- renal function (*see* kidney function)
- renal threshold, for bilirubin, 595
- for glucose, 579, 999
- renin, 778
- rennet (*see* rennin)
- rennin, 223–224, 306, 365
- action on casein, 223–224, 365–366
  - determination, 372
  - effect of, on milk, 223–224, 365–366
  - experiments on, 234
  - occurrence, 365
- rep, definition, 976
- Research Corporation method, for niacin, 1173
- residual air, 731
- residuum, 359, 377, 384–385
- analysis, 384–385
  - composition, 377
- resins, ion-exchange, 15–16
- use in chromatography, experiments, 217, 287
- resorcinol-hydrochloric acid test for fructose, 73, 87, 848
- respiration, 333–348, 730
- calorimeters, 742–746
  - cell and tissue, 333–348
  - experiments, 341
  - chemistry, 678
  - external, 730–732
  - internal, 333–348
- respiratory center, 688
- respiratory enzyme, 319

- respiratory exchange and neutrality regulation, 678-722
- respiratory quotient, 337, 726, 730, 739  
     calculations and data sheet, 741  
     carbohydrate and fat oxidation, factors, 727  
     nonprotein, 728  
     of tissues, average values, 340
- retention meal in gastric analysis, 385
- reticulin, 192
- retinene, 319, 1113, 1114
- rhamnose, 55  
     relative sweetness, 62
- rhizopterin, 1198
- rhodanese, 316, 439
- rhodopsin, 1113, 1114
- riboflavin, 76, 1106, 1152-1164  
     antimetabolites, 1306  
     blood, 1153  
     cataracts, 1153  
     cheilosis, 1153  
     chemistry, 1158, 1159  
     clinical aspects of, 1153  
     coenzyme I and, 1155  
     coenzyme II and, 1154  
     content of foods, 1336-1356  
     deficiency, demonstration, 1286  
         diagnosis, 1153  
         stigmas, 1291  
         treatment, 1291  
     determination, biological assay, 1163-1164  
         general, 1159  
         method of Arnold, 1162  
         microbiological assay, 1131  
         Snell and Strong method, 1160  
     dietary allowances, 1108  
     dinucleotide, 1106  
     distribution in foods, 1158, 1336-1356  
     enzymes, 320, 1154  
     excretion, 1157  
     in feces, 812  
     in foods, 1158, 1336-1356  
     in milk, 227  
     mononucleotide, 1106, 1154  
     phosphate, 1154  
         in enzymes, 320  
     phosphorylation, 1156  
     physiological aspects, 1153  
     requirement, 1157  
     stability, 1158  
     storage, 1157  
     synthesis, 1157  
     tryptophan metabolism and, 1040  
     in urine, 812, 1153  
         determination of, by Najjar method, 1162  
     vision and, 1156, 1158  
     vitamers, 1106, 1157  
     yellow enzymes and, 320, 1154
- riboflavin-adenine-dinucleotide, 1155, 1158
- ribonuclease, action, 205-206
- ribose, 55, 58, 76, 201, 203, 210  
     in muscle, 267
- ribose nucleic acid, 185, 201  
     content in cells, 204  
     preparation and tests, 213  
     in protein synthesis, 204  
     structure (schematic) 207
- ribose phosphate from phosphogluconic acid, 996
- ricinoleic acid, 99
- rickets, 1244, 1246, 1258; (*see also* vitamin D, deficiency)
- ricin, 486
- Riggs-Stadie method, for peptic activity, 388
- rigor mortis, 266
- ring method, for determination of surface tension, 23-24
- Ringer's solution, 1086, 1332
- RNA (*see* ribose nucleic acid)
- Robert's reagent, 1332
- Robert's test, for albumin in urine, 830
- Robison ester (*see* glucose-6-phosphate) dehydrogenase, 307
- Roe and Kahn method, for serum calcium, 646
- Roe and Kuether method, for ascorbic acid, 1236, 1237
- roentgen equivalent man, 976
- roentgen equivalent physical, 976
- roentgen unit, 974
- Roese-Gottlieb method, for fat in milk and milk products, 237
- Röhrig tube, 237
- Roquefort cheese, 224
- Rose-György erythrocyte hemolysis method, for vitamin E, 1275
- Rosenbach modification of Gmelin test, for bile, 415, 837
- Rosenheim iodo-potassium iodide solution, 1332
- Rosenheim's test, for choline, 301
- Rothera's modification of nitroprusside test for acetone, 840
- R.Q. (*see* respiratory quotient)
- rutherford unit, definition, 974
- rutin, 1243
- Ryle gastric tube, 375-376

## S

- saccharase, 304
- saccharic acid, 60
- saccharimeter, 70
- saccharoid, 568
- saccharometer, 69, 827
- saccharose (*see* sucrose)
- Sage standards, 736
- Sahli hemoglobinometer, 612
- Sahli's reagent, 1332
- salicylic acid, 441  
     aldehyde test for acetone, 840
- salicin, 77
- salicyluric acid, 441
- saliva, 349  
     composition, 350-351  
     experiments, 355  
     microscopic constituents, 355  
     reaction, 351, 355
- salivary, amylase, 351  
     activity in stomach, 353  
     estimation, 357  
     experiments, 356-358  
     inhibition of activity, 353  
     nature of action, 352-353  
     products of action, 352, 357  
     digestion, 349

- salivary—(*Continued*)  
 digestion—(*Continued*)  
   separation of products, 357  
   of starch, 352–353  
   in stomach, 353  
 Salkowski test, for cholesterol, 300  
   for creatinine, 801  
 salmine, 185, 191  
   amino acid composition, 122  
 salt blocks, 1083  
 salt-free diet, metabolism on, 1098  
 salt licks, 1083  
 salt mixtures, 1374–1376, 1377  
   Cowgill, 1376  
   Hawk-Oser, 1374  
   Hubbell-Mendel-Wakeman, 1374  
   Karr, 1376  
   McCollum-Davis, 1375  
   Osborne-Mendel, 1374  
   Steenbock, 1375  
   U.S.P., 1262  
 salt-rich diet, metabolism on, 1098  
 salting out of plasma proteins, 459  
 sapogenins, 295, 748  
 saponification, 105  
   of bayberry tallow, 107  
   of butter, 236  
   of lard, 109  
   value (number), 105  
     determination, 109  
 sarcosine, 1030  
 Sauberlich method, for citrovorum factor, 1201  
 scaler for radioactivity measurement, 973  
 Schales and Schales method, for chloride in blood, 626  
 Schardinger enzyme (*see* xanthine oxidase)  
   reaction, demonstration, 325  
 Scherer test, for inositol, 851  
 Schiff reaction for uric acid, 797  
   test, for allantoin, 808  
 Schmidt diet, 452  
 Schoenheimer and Sperry method, for blood cholesterol, 580  
 Scholander microburet, 665–666  
 Schradan, 641  
 Schulte test, for nonblood proteins in urine, 833  
 Schweitzer reagent, action on cellulose, 90  
   preparation, 1332  
 scintillation counter, 974  
 scleroproteins, 183, 192  
 scombrine, 185  
 scombrone, 184  
 scotopsin, 1113  
 scurvy (*see* vitamin C deficiency)  
 scybala, 92, 448  
 secondary protein derivatives, 186  
 secretin, 393–394, 778  
 secretinase, 394  
 sedimentation, constant, 4  
   molecular weight and, 5  
   equilibrium, 5  
     and molecular weight, 5  
   method for molecular weight of proteins, 160–161  
   rate, erythrocyte, 467  
 sediments, urinary, organized, 860
- sediments—(*Continued*)  
 urinary—(*Continued*)  
   unorganized, 854–860  
 Segal method, for determining gastric acidity, 377  
 selenium, toxicity of, 1097  
 Selivanoff reagent, 1332  
   test, 73, 94, 848  
 Sendroy method, for chloride, 627, 956  
 separation of feces, 448, 1046  
 serine, 98, 115, 1025  
   chemistry, 133  
   as cystine precursor, 1031  
   determination, 121, 1063  
   metabolism, 1028  
   in phospholipides, 292, 1028  
   in phosphoproteins, 193  
   in pyrimidine synthesis, 209  
   in tryptophan synthesis, 1041  
 D-serine, 1018, 1028  
 seroglycoid, 119  
 seromucoid, 119  
 serotonin, 479  
 serum albumin; (*see also* blood, serum albumin)  
   blood, preparation of, 542  
 serum globulin; (*see also* blood, serum globulin)  
   in urine, 831  
 serum proteins (*see* blood, serum)  
 sex hormones (*see* hormones)  
 Shackell method, for total solids in urine, 874  
 Shaffer-Hartmann method, for sugar in blood  
   Somogyi modification, 571  
   in urine, 921  
 Shaffer-Marriott method, for acetone bodies in urine, 934  
 Shank-Hoagland unit, in thymol turbidity test, 596  
 Shankman method, for microbiological determination of amino acids, 1064  
 sherbet, 232  
 Sherman and Chase method, for thiamine, 1147  
 Sherman, La Mer, and Campbell method, for ascorbic acid, 1239  
 Shock-Hastings method, for blood pH, 703  
 Shohl and King method, for gastric juice pH, 388  
 Shohl and Pedley method, for calcium in urine, 959  
 sialolithiasis, 351  
 sickle-cell anemia, 470  
 silicate in urine, 822  
 silicon, 1077  
 silverskin, 1134  
 sinkalin (*see* choline)  
 Sisco, Cunningham, and Kirk micropipet, 665  
 sitosterol, 98  
 skatole, 437, 444, 447, 802, 815  
   test, 444  
 skatoxyl, 802  
 skatoxylsulfuric acid, 802, 815  
 Skeggs and Wright method, for pantothenic acid, 1192  
 skin, composition, 1078  
   dermatitis in vitamin deficiencies, 1153, 1179, 1292  
   factor (*see* biotin)  
   heat loss from, 742

- slide modification of benzidine test for blood in feces, 453
- snake venom phosphodiesterase, 206
- Snell and Strong method, for riboflavin, 1160
- soaps, 105
  - hard, 105
  - insoluble, experiment, 108
  - salting-out, experiment, 108
  - soft, 105
  - surface tension of solutions, 108
- sodium, amount in body, 1077, 1083
  - isotopes, 971, 979
  - metabolism 1083-1086
  - in serum (*see* blood, serum sodium)
  - in urine, 788, 819, 963, 1086
    - determination of, 962-963
- sodium alcoholate, preparation, 1332
- sodium chloride, dietary requirement, 1109
  - deficiency, 1083
  - effect of adrenal cortex on, 757
- sodium glutamate, as seasoning agent, 145
  - detection in foods, 19
- sodium hydroxide solution, concentrated, carbonate-free, 867, 1333
  - 0.1 N, 867
- sodium urate, in urine, 854, 857-858
- Solera reaction for thiocyanate in saliva, 356
- sols, 2
- solubility product and calcification, 252
- soluble starch, 82
  - preparation, 1333
- solutions and reagents, 1321-1335
- somatotropic hormone (*see* growth hormone)
- Somogyi-Nelson method, for blood glucose, 573
- Somogyi-Shaffer-Hartmann method, for blood glucose, 571
- sorbitol, 60, 1232
- Sørensen formol titration method, for amino acids, 130, 897
  - standards for determination of pH, 35, 702, 872
- Soxhlet method, for fat in milk, 238
  - extraction apparatus, 238
- soybean cephalin (*see* inositol)
- soybean-meal protein, amino acid content, 120
- Span, 105
- spatial configuration, of amino acids, 126
  - of sugars, 58
- specific activity, definition, 979
- specific conductance of biological fluids, 53
- specific dynamic action, 1023
- specific gravity, of blood, 457, 609
  - of concentrated acids and bases, 1335
  - method for plasma proteins, hemoglobin, hematocrit, 607
- specific ionization, 973
- specific rotation, definition, 69
  - of carbohydrates, 70
  - of various substances, 926
- specificity of enzyme action, 309
- "spectacled-eye" condition, 1187, 1204, 1224
- spectrophotometers, 524, 531-533
  - Beckman, 532
  - Coleman, 532
- spectroscope, angular vision, 493
  - direct vision, 492
- spectroscopic examination of blood, 492-495
- spectrum, absorption, 522
  - solar, 492
- Spencer "Hb-Meter," 611
- Spencer method, for trypsin, 390
- spermaceti, 106
- sphingomyelin, 98, 290, 293, 1222
- sphingosine, 98, 293, 294, 1222
- spinal fluid (*see* cerebrospinal fluid)
- spleen, 1078
- spongin, 192
- spreading factor (*see* hyaluronidase)
- squalene, 98
- stable isotopes, 983
- stalagmometer, Traube, 22
- standard acid and alkali solutions, 866-869
- standard buffer solutions, preparation, 35-37, 871-872
- standard conditions for gases, 724
- staphylokinase, 480
- starch, 56, 81-86, 94
  - digestion, 83, 352, 356, 397
  - distribution, 81
  - experiments, 84-86
  - in feces, detection, 453
  - hydrolysis, 82
    - by acid, 84
      - experiment, 86
    - by enzymes, 84, 352, 356, 397
  - ingestion, effect on metabolism, 1068
  - iodine test, 84
  - microscopic appearance, 84-85
  - potato, preparation, 84
  - soluble, 82, 352
    - preparation, 1333
  - structure, amylopectin, 83, 354
    - amylase, 83, 353
  - synthesis, 84
    - experiment, 333
- steam distillation for nitrogen determination, 881
- steapsin (*see* pancreatic lipase)
- stearic acid, 99
- stearic aldehyde, 294
- stearin (*see* tristearin)
- stearyl alcohol, 98
- steatorrhea, 398, 449
- Steenbock rachitogenic diet, 1261
- Steenbock salt mixture 40, 1376
- Steenbock stock diet, Bills' modification, 1374
- stellar phosphate, 855
- stercobilin, 412, 413, 447, 813
- stercobilinogen, 412, 413, 447, 813
- stereoisomerism, 59
  - among fats, 101
- sterility disease (*see* vitamin E)
- steroid hormones, 295, 749, 751-754, 760-766
  - chemistry, 749, 751-754
  - experiments, 760-766
  - isomerism, 749
  - metabolic relations, 751-754
- steroids, adrenal cortical, 749, 758
  - chemistry, 748-749
- sterols, 295, 432, 748
  - intestinal absorption, 432
- stigmas, symptoms and therapy, 1289

- stigmasterol, 98, 295  
stilbene derivatives, estrogenic action, 756  
stilbestrol, 753  
Stockholm and Koch method, for total sulfur, 643  
Stoddard and Drury method, for fatty acids, 587  
Stokes reagent, 1334  
Stokstad and associates' method, for thioctic acid, 1216  
stomach contents, examination, 386  
    glycerol extract, preparation, 369  
    removal, 386  
    tube, introduction, 384  
        Rehfuss, 375-376  
        Ryle, 375-376  
stomachs, fast and slow, 367-368  
stopcock grease, 713  
Strauss test, for lactic acid, 391  
strepogenin, 430, 1066  
streptidine, 1316  
streptobiosamine, 1316  
streptokinase, 480  
streptomycin, 1303, 1315  
streptose, 1316  
strontium, in bone, 249  
    rickets, 252, 1091  
sturine, 185

  - labile methyl groups, relation to, 1209
  - in milk, 228
  - in nucleic acid synthesis, 1209
  - pteroylglutamic acid, relation to, 1196
- vitamin B<sub>12a</sub>, 1107
- vitamin B<sub>12b</sub>, 1107
- vitamin B<sub>12c</sub>, 1107
- vitamin B<sub>c</sub> (*see* pteroylglutamic acid)
- conjugate, 1198
- vitamin B<sub>T</sub>, 1134
- vitamin B<sub>x</sub> (*see* *p*-aminobenzoic acid)
- vitamin C (*see* ascorbic acid)
- vitamin D, 98, 1107, 1243–1267
- activation of foods, 1248, 1251, 1256
  - calcification, relation to, 253, 1244
  - calcium utilization and, 1089
  - carbohydrate oxidation and, 1247
  - chemistry, 1251–1254
  - clinical aspects, 1244–1250
  - content of fish oils, 1115, 1255
  - deficiency (rickets), 1244–1246
    - demonstration, 1286
    - stigmas, 1292
    - treatment, 1292
  - determination, biological methods, 1257
  - chemical methods, general, 1257
  - U.S.P. method, 1261

vitamin D—(*Continued*)

- distribution in foods, 1255, 1256
  - esters, 97
  - fortification of foods, 1256
  - line test, 1260, 1266
  - milk, 229, 1256
  - phosphatase, relation to, 1246
  - physiological aspects, 1244–1250
  - precursors, 1253–1254
  - requirement, 1108, 1247
  - stability, 1254
  - storage, 1250
  - tooth formation, effect on, 259
  - toxicity, 1247
  - ultraviolet radiation and, 1247, 1248–1250
  - units, A.O.A.C. chick, 1260
  - U.S.P., 1267
  - vitamers, 1107
- vitamin D<sub>1</sub>, 1252
- vitamin D<sub>2</sub>, (*see* calciferol)
- vitamin D<sub>3</sub>, 1107, 1251, 1253
- vitamin D<sub>4</sub>, 1107
- vitamin D<sub>5</sub>, 1107
- vitamin-D-free diets, 1261
- vitamin E, 98, 266, 1267–1276; (*see also* tocopherol)
- antioxidant activity, 1270
  - biopotency, 1269–1270
  - chemistry, 1270
  - clinical aspects, 1267–1269
  - deficiency, 1268
    - erythrocyte rupture and, 1268
    - demonstration, 1287
  - determination, chemical, by Emmerie-Engel reaction, 1272
  - Evans' biological method, Mason-Harris modification, 1274
  - Quaife and Dju method, in tissues, 1273
  - Quaife and Harris method, in foods, 1273
  - Rose-György hemolysis method, 1275
  - distribution, in foods, 1272
  - International Standard, 1274
  - in milk, 229
  - oxidation, 1271
  - physiological aspects, 1267–1269
  - requirement, 1269
  - stability, 1271
- vitamin-E-deficient diet, 1274
- vitamin G (*see* riboflavin)
- vitamin H (*see* biotin)
- vitamin K, 98, 1107, 1276–1281
- absorption, role of bile in, 409
  - antimetabolites, 477, 1308
  - chemistry, 1278
  - clinical aspects, 1276
  - deficiency, 1277
    - stigmas, 1293
    - treatment, 1293
  - determination, 1279
    - biological method of Almquist, 1280
  - distribution, in foods, 1278
  - in milk, 229
  - physiological aspects, 1276
  - prothrombin, relation to, 577, 1276
  - requirement, 1109, 1277
  - storage, 1277

vitamin K—(*Continued*)

- tolerance test, 1276
  - unit, A.O.A.C., 1281
  - vitamers, 1279
  - vitamin K<sub>1</sub>, 1107, 1276, 1278
  - vitamin K<sub>2</sub>, 1107, 1276, 1278
  - vitamin P (*see* bioflavonoids)
  - vitamins, 1104–1296
    - analogs of, 1304–1310
    - clinical aspects, 1289–1293
    - content versus potency, 1110
    - deficiencies, American Medical Association syllabus, 1289–1293
    - symptoms, general, 1293
  - definition, 1104
  - dietary allowances recommended by the National Research Council, 1108
  - distribution of, in foods, 1336–1356
  - evaluation of sources (American Medical Association), 1111
  - in feces, 812
  - in hair, 243
  - human requirements, 1110
  - intestinal synthesis, 437, 1134, 1204
  - major and minor, 1110–1111
  - microbiological determination, 1131–1132
  - in milk, 227
  - minimum daily requirements, FDA, 1110
  - physiological availability, 1281–1284
  - relation between dosage and excretion, 1282
    - to enzymes, 1104
  - student exercises on, 1286–1288
  - table, 1106–1107
  - in urine, 811
- vitreous humor mucin, 185
  - Voisenet-Rhode test, for tryptophan, 143
  - Volhard-Arnold method, for chlorides, 955
  - Volhard-Harvey method, for chlorides, 956
  - Volhard-Löhlein method, for peptic activity, 389
  - Volterra's method, for phenols in urine, 939
  - Vulpian reaction for adrenaline, 768

## W

- W factor (*see* biotin)
- Wallace and Diamond method, for urobilinogen, 943
- Walpole acetate buffers, 871
- Warburg, method, for cell respiration, 334
  - for oxygen consumption 334–336, 343
  - old yellow enzyme, 307, 318, 320
  - vessels, 335
- Warburg and Christian yellow enzymes, 1156
- Warburg apparatus, 334, 336
  - calibration, 341
- water, amount in tissues, 1078
  - balance, 1080
    - in liver disease, 426
    - role of plasma proteins, 466
  - body, measurement, 980
    - sources, 1080
  - content of common foods, 1336–1356
  - deficiency, effect, 1058
  - dietary requirement, 1109
  - dissociation of, 30
  - distribution in body fluids, 1081–1082

water—(*Continued*)

- effect, on metabolism, 1057–1058
  - of radiation on, 977
- equilibrium, 1081
- extracellular, 1082
- fluoride content and tooth decay, 262, 1096
- heat of vaporization, 1080
- hormonal control of water-electrolyte balance, 1081
- intoxication, 1057, 1080
- intracellular, 1082
- loss (dehydration) channels, 1080
  - effects, 1080–1081
- at meals, influence, 360, 369, 1080, 1081
- reabsorption in kidneys, 780
- relation to urine volume and specific gravity, 1058
- significance in animal body, 1079–1083
- starvation vs. food starvation, 1058
- stimulation of gastric secretion, 360, 369
- test meal, 385
- vapor tension, table, 709
- Watson method, for urobilinogen, 943
- waxes, 97, 106; (*see also* lipides)
- Webster, Hill, and Eidinow method, for ultra-violet radiation, 1250
- Weinbach method, for blood sodium, 651
- Welker biuret reagent, 1323
- Welker, Hektoen, and Kretschmer protein, 833
- Welker method, for purines in urine, 912
- Werner hypothesis, 790–791
- Westphal balance, 785
- Weyl test, for creatinine, 801
- Wharton's jelly glycoprotein, 185
- white blood cells (*see* leukocytes)
- white fibrous tissue, 244–246
  - composition, 245
  - experiments, 245–246
- White-Green reaction for pentoses, 845
- Whitehorn method, for blood chloride, 626
- Wijs iodine solution, 1327
- Williams' and collaborators' microbiological method, for cobalamins, 1214
- Willstätter and collaborators' method, for amylase, 401
  - for lipase, 402
- Winkler's reagent, 1334
- Wong method, for hemoglobin and iron, 617
- Wood-Werkman reaction, 994
- wool, cystine in, 242–243

## X

- xanthine, 211, 214, 267, 795, 854, 859, 863, 864
  - in muscle, 267
  - oxidase, 186, 211, 307, 318, 320, 795, 1155
    - in milk, 225
  - molybdenum and, 1097
  - tests, 214
    - in urine, 854, 859, 863, 864
- xanthophyll, 102, 1118, 1119
- xanthoproteic reaction, 170
- xanthopterin, 1197
- xanthurenic acid, 1040, 1041, 1179

xanthidrol, in urea determination, 888  
xerophthalmia, 1111  
xerosis, 1111  
x-ray diffraction, proteins, 154, 161  
    effect on enzymes, 311  
    unit of measurement, 976  
xyloketose, 76, 845  
xylose, 55, 58, 70  
    relative sweetness, 62

## Y

Y factor (*see* pyridoxine)  
yeast adenylic acid, 204-205  
    fermentation, 67  
    Norit factor (*see* pteroylglutamic acid)  
    nucleic acid, preparation, 202  
        tests, 202  
    sucrase, preparation, 331  
yellow elastic tissue, 246-247  
    composition, 247  
yellow enzymes, 307, 318, 320, 1154  
Youngburg method, for blood lipide phosphorus,  
    589

## Z

zeaxanthin, 98  
zein, 118, 183, 191  
    amino acids in, 120  
    molecular weight, 162  
Zeller's test, for melanin, 852  
zero-order reaction, 312  
Zimmerman reaction, 765  
zinc, and carbonic anhydrase, 362, 1096  
    deficiency, 1096  
    determination, 677, 964  
    effect, on enzymes, 311  
        on hormones, 1097  
    in insulin, 1096  
    isotopes, 971  
    metabolism, 1096  
    in proteins, 186, 193  
zone electrophoresis, 464  
zwitterion, amino acids, 128  
    proteins, 166  
zymase, 304  
zymogen, 312  
zymohexase, 304, 307
